Full-term babies fed a skim-milk formula low in ALA are at risk of primary deficiency. In the past, patients fed long-term with fat-free total parenteral nutrition solutions were at risk, but fat emulsions are now in general use and prevent deficiency. Studies have demonstrated lower plasma levels of EPA and DHA in vegetarians and vegans, suggesting they may be at risk of deficiency; however, the findings of a cross-sectional study comparing the dietary intakes and plasma levels of 196 meat-eating, 231 vegetarian and 232 vegan men in the United Kingdom did not suggest that there is cause for alarm (Rosell et al 2005). Vegans and vegetarians had significantly lower levels of these fatty acids; however, they remained steady and there is evidence of some conversion of ALA into EPA and DHA.

There is much discussion regarding the inadequate intake of EPA and DHA generally in the Western diet. Australian data, based on dietary intake records from the 1995 National Nutrition Survey, have estimated the average daily intake of EPA and DHA to be 0.008 g and 0.015 g, respec-

tively. If correct, this indicates that the majority of Australians are failing to meet recommended amounts (Meyer et al 2003).

### Secondary deficiency

People with fat malabsorption syndromes, serious trauma or burns are at risk of reduced PUFA levels (Beers & Berkow 2003). A secondary deficiency may also manifest as a result of abnormal or compromised activity of the delta-6 and delta-5 desaturase enzymes, for example in diabetics, patients with a variety of metabolic disorders and individuals with increased dietary saturated fats and *trans* fatty acids, alcoholics and the elderly (Davis & Kris-Etherton 2003, Houston 2005).

### MAIN ACTIONS

As precursors of eicosanoids, PUFAs found in fish oils exert a wide influence over many important physiological processes.

#### Cardiovascular effects

Fish oils exert myriad different effects on the heart and vessels, demonstrated in both experimental models and human studies. It is speculated that the clinical effects attributed to  $\omega$ -3 PUFAs are due to the summation of many small pharmacological effects, adding up to a larger protective effect on mortality and/or cardiovascular events.

#### Prevent malignant cardiac arrhythmias

Dietary fish or fish oil intake has been shown to prevent cardiac arrhythmias and associated sudden death in numerous animal studies (Billman et al 1997, 1999, Kang & Leaf 1996, 2000, McLennan et al 1988, 1990), in vitro and more recently in human clinical trials (Jung et al 2008). This has been achieved using intakes below those required to alter plasma lipids or blood pressure. It appears that the myocardial membrane phospholipid content increases in DHA but not always EPA, with fish intake. The preferential accumulation of DHA affords protection against ventricular fibrillation induced under a variety of conditions, such as ischaemia and reperfusion (McLennan 2001).

Inadequate DHA in myocyte membranes has been reported to be associated with altered sodium, calcium and potassium ion channel functions, mitochondrial function and increased arrhythmia susceptibility with an increased prevalence of sudden cardiac death (Jung et al 2008, Siscovick et al 2003). One in vivo study suggests that fish oils electrically stabilise myocytes, increasing the electrical impulse required to produce an action potential by approximately 50% and prolonging the refractory time by 150% (Kang & Leaf 2000).

#### Triglyceride (TG)-lowering activity

Fish oil supplements effectively reduce TG levels, as demonstrated in human studies. This is of particular interest, given only moderate elevations in TG levels have been associated with a progressively increased risk of ischaemic heart disease, independently of other

major risk factors, including high-density lipoprotein (HDL) cholesterol (Jeppesen et al 1998). A significant plasma TG-lowering activity has also been demonstrated for a highly potent form of  $\omega$ -3 fatty acids, available as Lovaza in the United States (previously Omacor) (Kar 2014).

### Lipoprotein effects

Both  $\omega$ -6 and  $\omega$ -3 LCPUFAs can inhibit the expression of genes involved in fatty-acid and TG synthesis (Jung et al 2008). Dietary  $\omega$ -3 LCPUFAs, in particular, and their metabolites, through this mechanism are reported to increase beta-oxidation and inhibit adipogenesis. Ultimately, this may result in reduced substrate for TG synthesis and thus explain  $\omega$ -3 PUFAs' profound TG-lowering effects.

Concerns raised previously about increased LCPUFAs in lipoproteins increasing the susceptibility to oxidation of the low-density lipoproteins (LDLs) have recently been moderated, with a demonstrable difference between EPA and DHA. While increased levels of EPA (4.8 g/day) did increase the LDL susceptibility to damage, DHA supplementation (4.9 g/day) had no effect on the oxidation process (Mesa et al 2004). Concurrent supplementation with antioxidants however appears prudent with high doses of  $\omega$ -3 PUFAs.

### Improved endothelial function

Studies have indicated that fish oils can improve endothelial relaxation by enhancing nitric oxide (NO) and non-NO-induced vasodilation (Holub 2002).

A double-blind study conducted by Mori et al (2000) showed that, relative to placebo, DHA, but not EPA, enhances vasodilator mechanisms and attenuates constrictor responses in forearm microcirculation.

### Reducing resting heart rate

Regular  $\omega$ -3 LCPUFA intake can lower resting heart rate by up to 5 beats/min in patient and healthy populations, in healthy individuals during exercise without compromising maximum heart rate and during exercise recovery in post myocardial infarction (MI) patients (McLennan 2014).

### Reduce blood pressure

Three meta-analyses have concluded that fish oils exert a significant blood pressure-lowering effect in hypertensive people; however, the effects can only be described as modest, between 2 and 5 mmHg (Geleijnse et al 2002, Miller et al 2014, Morris et al 1993). Hypotensive activity appears to be dose-dependent and DHA may have greater effect than EPA. Alternatively, a 2006 Cochrane review found no significant changes to systolic or diastolic blood pressure with  $\omega$ -3 LCPUFA consumption (Hooper et al 2006). The review assessed studies that used both plant- and fish-based  $\omega$ -3 fatty acids, dietary sources and supplements.

While the mechanism is unknown, current theories include EPA stimulation of prostacyclin synthesis and increased NO production — both

vasodilators. An additional action may be improved autonomic nervous system function, and inhibition of adrenal activation (Din et al 2004, Ross 2005); however, these are inconsistent with the attribution of action to DHA. In addition to the actions improving endothelial function generally, other posited mechanisms for a hypotensive effect include: blunting of the renin-angiotensin-aldosterone system via reduced adrenal aldosterone synthesis, altered AA metabolism, modulation of calcium release and influx into vascular smooth-muscle cells and activation of vascular adenosine triphosphate-sensitive potassium channels (Jung et al 2008).

### Reduce and possibly reverse atherogenesis

$\Omega$ -3 fatty acids alter eicosanoid synthesis and inhibit smooth-muscle cell proliferation, suggesting a role in reducing atherosclerotic development (Holub 2002). One controlled study demonstrated that fish oil ingestion had a clinically significant influence on atherosclerosis (von Schacky et al 2001). This randomised, double-blind study of 223 patients found that a dose of 1.5 g  $\omega$ -3 fatty acids reduced progression and increased regression of established coronary artery disease as assessed by coronary angiography. The content of diets and relevant risk factors were examined through a health survey on the inhabitants in a fishing village ( $n = 261$ ) and in a farming village ( $n = 209$ ) in Japan (Yamada et al 2000). Pulse wave velocity of the aorta, intima media thickness (IMT) of the carotid artery and atherosclerotic plaques as obtained by ultrasonography were used as measures of atherosclerosis. The fish consumption of both males and females in the fishing village was about 1.8 and 1.6 times higher, respectively, than that reported in the farming village ( $P < 0.0001$ ). Dietary consumption of EPA and DHA was significantly higher in the fishing village versus the farming village ( $P < 0.001$ ). Pulse wave velocity and IMT were significantly lower in the fishing village than in the farming village in males ( $P < 0.01$  and  $P < 0.001$ , respectively). IMT was significantly lower in females ( $P < 0.001$ ). There was an eightfold difference in the average number of plaques in the common carotid arteries in males ( $P < 0.0001$ ) and a fivefold difference in females between the villages ( $P < 0.0001$ ).

### Antithrombotic and antiplatelet

Dietary  $\omega$ -3 PUFAs enhance antiaggregatory and antiadhesive platelet activity by inducing increased production of prostacyclin  $I_3$  and suppressing synthesis of the chemotactic platelet adhesion-promoting substances, leukotriene  $B_4$  and thromboxane  $A_2$  (Jung et al 2008, Kinsella 1987). A meta-analysis of randomised controlled trials (RCTs) ( $n = 15$ ) with 409 participants found daily supplementation with  $\omega$ -3 PUFA significantly reduced adenosine diphosphate (ADP)-induced platelet aggregation compared with placebo ( $P = 0.02$ ) (Gao et al 2013). Independently of this,  $\omega$ -3 LCPUFAs reduce levels of several coagulating factors (e.g. VII and X, and fibrinogen) (Jung et al 2008).

**Clinical interest — Do fish oil supplements pose a significant bleeding risk?**

A search through Medline reveals several case reports where bleeding episodes are attributed to fish oil ingestion (Buckley et al 2004, Jalili & Dehpour 2007, McClaskey & Michalets 2007). In each case, the person affected was elderly and also taking warfarin. One was a report of an elderly man taking high-dose  $\omega$ -3 fatty acids (6 g/day) with both aspirin and warfarin who developed a subdural haematoma after a minor fall (McClaskey & Michalets 2007). Another case is reported of a 67-year-old woman taking warfarin for 1.5 years who doubled the fish oil dose from 1000 to 2000 mg/day, causing an associated elevation in international normalised ratio (INR) from 2.8 to 4.3 within 1 month (Buckley et al 2004). A third case was of a 65-year-old male who had been taking warfarin for 6 months and then was recommended trazodone and fish oils, causing his INR to rise to 8.06 (Jalili & Dehpour 2007).

Although these case reports would lead us to believe that  $\omega$ -3 fatty acids interact with warfarin and increase the risk of bleeding, several intervention studies have come to a different conclusion. One randomised study of 511 patients taking either aspirin (300 mg/day) or warfarin (INR aimed at 2.5–4.2) found that a dose of 4 g/day of fish oils did not increase the number of bleeding episodes, bleeding time or any parameters of coagulation and fibrinolysis (Eritsland et al 1995). A smaller placebo-controlled study by Bender et al (1998) of patients receiving chronic warfarin therapy found that fish oil doses of 3–6 g/day produced no statistically significant difference in INR between the placebo lead-in and treatment period within each group. There was also no difference in INR between groups.

More recently, Harris (2007) examined 19 clinical studies which used doses of fish oils varying

from 1 g/day to 21 g/day in patients undergoing major vascular surgery (coronary artery bypass grafting, endarterectomy) or femoral artery puncture for either diagnostic cardiac catheterisation or percutaneous transluminal coronary angioplasty. Of note, in 16 studies patients were taking aspirin and in three studies patients were taking heparin. The review concluded that the risk for bleeding was virtually non-existent. Frequent comments accompanying the studies were 'no difference in clinically significant bleeding noted' or 'no patient suffered from bleeding complications'. The same conclusion was reached in a 2008 review which stated that no published studies have reported clinically significant bleeding episodes amongst patients treated with antiplatelet drugs and fish oils (3–7 g/day) (Harris et al 2008). In 2014, a clinical audit of over 900 cardiac surgery patients at the Alfred Hospital found that those taking 3 g of fish oils daily in the week before surgery did not have a significantly increased risk of major haemorrhage or re-admission due to bleeding, once again demonstrating the lack of risk for fish oil supplements in this population (Braun et al 2014).

Overall, when we consider the body of evidence available regarding  $\omega$ -3 fatty acid supplementation, it is clear that the benefits for cardioprotection far outweigh the risk of bleeding. This not only applies to patients taking aspirin but also those patients about to undergo coronary artery bypass surgery or percutaneous transluminal coronary angioplasty. While the evidence suggests that fish oils in low to moderate doses do not increase bleeding risk with warfarin, a general caution should still apply to patients taking high doses with antiplatelet or anticoagulant medication.

Platelet aggregation studies and flow cytometric analyses of platelet activation and platelet-leucocyte aggregates were determined at baseline and after 4 weeks of a moderate dose of  $\omega$ -3 (DHA 520 mg and EPA 120 mg) supplementation in 40 healthy subjects and 16 patients with a history of CVD. In healthy subjects,  $\omega$ -3 PUFA significantly reduced ADP-induced platelet aggregation, as measured by maximum amplitude of platelet aggregation ( $P = 0.036$ ) and velocity of aggregation ( $P = 0.014$ ), as well as adrenaline-induced platelet aggregation (maximum slope,  $P = 0.013$ ; lag time to platelet aggregation,  $P = 0.002$ ).  $\omega$ -3 PUFA also reduced P-selectin expression ( $P = 0.049$ ) on platelets and platelet-monocyte aggregates ( $P = 0.022$ ). There were fewer changes in platelet aggregation and activation found in subjects with CVD. Nevertheless, there was a reduction in the velocity of AA-induced platelet aggregation ( $P = 0.009$ ) and increased lag time to platelet aggregation for U46619-induced

platelet aggregation.  $\omega$ -3 PUFA had a greater effect on platelet aggregation and activation in healthy subjects and the findings of this study support the recommendation of a higher dose of  $\omega$ -3 PUFA in patients with CVD who are already receiving antiplatelet medication than in healthy people with CVD ( $P = 0.018$ ) (McEwen et al 2013).

In animal models of arterial thrombosis, fish oil-enriched diets have been shown to have an anti-thrombotic effect; however, there is evidence suggesting that this is most likely to occur when associated with reduced saturated fat intake (Hornstra 1989).

Clinical observations of Eskimos have found lowered platelet counts, inhibition of platelet aggregation and prolonged bleeding times compared with age- and sex-matched Danes. However, intervention studies using fish oil supplements have produced conflicting results (Hellsten et al 1993, Kristensen et al 1989, Radack et al 1990) and, more

recently, a review of clinical studies concluded that there was no clinically significant effect on bleeding with usual therapeutic doses (Harris 2007).

### Anti-inflammatory

Fish oils induce a series of chemical changes in the body that ultimately exert an anti-inflammatory action. They partially replace AA in inflammatory cell membranes, and compete with it for the enzymes cyclo-oxygenase and lipoxygenase, leading to reduced production of proinflammatory metabolites such as 2-series prostaglandins and 4-series leukotrienes (Calder 2002, 2003, Cleland et al 2003). Resolvins are compounds that reduce cellular inflammation by inhibiting the production and transportation of inflammatory cells and chemicals. EPA-derived lipid mediator resolvin E1 has potent anti-inflammatory and pro-resolution actions both in vitro and in vivo. In addition, EPA-derived and DHA-derived products such as resolvin D1 and protectin D1 have potent anti-inflammatory and pro-resolution properties (Seki et al 2009).

Besides this,  $\omega$ -3 PUFAs suppress the production of proinflammatory cytokines, and reduce the expression of cell adhesion molecules, critical in recruiting circulating leucocytes to the vascular endothelium (Calder 2002, Din et al 2004). According to new research, it appears that anti-inflammatory activity may vary among different sources of fish oils due to variations in EPA/DHA content (Bhattacharya et al 2007).

### Neurological effects

Fatty acids are major components of the brain and are found in high concentrations in two structural components: the neuronal membrane and the myelin sheath. About 50% of the neuronal membrane is composed of fatty acids (one-third from  $\omega$ -3 LCPUFAs), while in the myelin sheath lipids constitute about 70% (Yehuda et al 2005). The lipid component has a relatively high turnover, in contrast to the protein component, which is fundamentally stable. The de novo synthesis of PUFA is very low within the brain (Chen & Bazinet 2014). The supply of PUFA to the brain is via the blood, either from exogenous PUFA obtained through diet or from endogenous liver synthesis of PUFA from dietary precursors. Brain DHA levels are 250–300-fold higher than EPA compared to about four-, five-, 14- and 86-fold higher levels of DHA versus EPA in plasma, erythrocyte, liver and heart, respectively. EPA enters the brain at a broadly similar rate to DHA and is rapidly and extensively  $\beta$ -oxidised upon entry into the brain (Chen & Bazinet 2014).

$\omega$ -3 fatty acids play an active role in neuronal membrane function, fluidity and control of neuronal growth factors. They also potentially influence each step in biogenic amine function, including neurotransmitter synthesis, degradation, release, reuptake and binding (Bruinsma & Taren 2000). Studies indicate that dietary PUFAs may influence noradrenergic and serotonergic neurotransmission and receptor

function in the nervous system and, thereby, have a direct effect on function, mood and behaviour. Other actions at the neuronal cell membrane include suppression of the phosphatidyl-associated signal transduction pathways, blocking of the calcium ion influx through L-calcium channels and direct inhibition of protein kinase C, which are similar actions to those exhibited by some pharmaceutical mood stabilisers.

### Prenatal and postnatal neurological development

DHA plays an important, if not critical, role in the growth and functional development of the brain during the third trimester and the early postnatal period when maximal growth occurs (Horrocks & Yeo 1999). Given that 15% of brain growth occurs during infancy, much attention has been paid to the consequences of variable  $\omega$ -3 levels during late pregnancy and early infancy. It also plays an important role in retinal development, where DHA constitutes 60% of total PUFAs.

### Chemopreventive effects

Marine fatty acids, particularly EPA and DHA, have been consistently shown to inhibit the proliferation of breast and prostate cancer cell lines in vitro and to reduce the risk and progression of these tumours in animal experiments (Bagga et al 2002, Terry et al 2003). Similar effects have also been observed for colorectal and prostate cancers (Calder et al 1998, Llor et al 2003, Stoll 2002).

Chemopreventive actions demonstrated by  $\omega$ -3 LCPUFAs include suppression of neoplastic transformation, cell growth inhibition and enhanced apoptosis and antiangiogenicity (Rose & Connolly 1999). The proposed mechanisms for these are extensive, including the suppression of  $\omega$ -6 eicosanoid synthesis; influences on transcription factor activity, gene expression and signal transduction pathways; effects on oestrogen metabolism; increased or decreased production of free radicals and reactive oxygen species, and influences on both insulin sensitivity and membrane fluidity (Larsson et al 2004). Ongoing research is attempting to elucidate the specific chemopreventive mechanisms of fish oils with the individual cancer cell lines.

### CLINICAL USE

Thousands of studies have been conducted in various populations to determine the clinical consequences of regular fish consumption and fish oil supplementation. Initially, interest was focused on CVD but in recent years this has extended to other areas such as neurological conditions, neonatal and childhood health and development and mental health. While the plethora of studies published have begun to clarify the potential benefits of increasing intakes of  $\omega$ -3 EFAs and fish on a regular basis, some are inconsistent with the general body of evidence, an issue which needs to be resolved.

There are multiple factors which could account for the sometimes inconsistent results that are seen.

Some studies have focused on  $\omega$ -3 fatty acids intake as a whole and included both vegetable and marine-based sources; however, in light of the lack of bioequivalence and clinical efficacy between the  $\omega$ -3 precursors (e.g. ALA) and their long-chain derivatives (e.g. EPA/DHA), the results of these studies are likely to be confounded. Similarly, prospective studies investigating the effects of  $\omega$ -3 PUFAs may be producing inconsistent results due to improper placebo selection (e.g. olive oil) (Pizzorno & Murray 2006). This was most recently seen in a large RCT comparing  $\omega$ -3 EFAs to olive oil (placebo) and both groups experiencing a reduction in cardiovascular risk factors (Roncaglioni et al 2013). It is also important to note that few studies or reviews have considered the effect of variations in  $\omega$ -3: $\omega$ -6 ratio, which may be important, and the ratio of EPA:DHA being administered. McLennan (2014) suggests that dietary fish tends to have a greater amount of DHA than EPA whereas many studies use supplements containing EPA > DHA, which means they don't replicate the usual dietary sources which tend to show multiple health benefits. In regard to cardiovascular benefits, this could be important, as the human myocardium selectively incorporates DHA over EPA. De (2011) further suggests that the great variation in dietary fish intakes between populations could be another influence, as people with low baseline levels of  $\omega$ -3 EFAs are more likely to experience a range of benefits with supplementation compared to those who already have high dietary intakes. Finally, the role of mercury in fish needs to be taken into account as research suggests it counteracts the benefits of  $\omega$ -3 PUFAs on sudden cardiac death and MI and possibly other outcomes. Unfortunately, few studies consider participants' mercury levels when analysing results (see Clinical note p. 330).

### Prevention of morbidity and mortality of cardiovascular disease

Consuming fatty fish at least twice per week reduces the risk of developing cardiovascular disease. In addition, a reduced risk of all-cause mortality, cardiovascular death, sudden death, and myocardial infarction is often reported in population studies. This is largely based on research conducted over the last three decades, which has linked fish and fish oils to CV health. Benefits have also been reported in people with pre-existing CV disease. This association was first recognised when significantly lower death rates from acute MI were found among Greenland's Inuit population, despite only moderate differences between the Inuits' blood cholesterol levels and those of other populations (Holub 2002). A high dietary  $\omega$ -3 LCPUFA intake in the form of marine mammals (seal, whale) and various fish was thought to be responsible for the protective effect (Bang et al 1980).

In 1989, results from the first large, randomised, clinical trial investigating the effects of fatty fish consumption on survival and risk of secondary MI confirmed a link to cardiovascular health (Burr et al

1989). The Diet and Reinfarction Trial (DART) found that a modest intake of two to three portions weekly of fatty fish reduced mortality in men who had previously experienced an MI and produced a relative reduction in total mortality of 29% during the 2-year follow-up, attributed mainly to a reduction in deaths from coronary heart disease (CHD). Increased consumption of fish (relative risk [RR] = 0.66 for five or more times per week) was further confirmed in the Nurses Study as significantly reducing risk in both CHD and CHD-related mortality independent of the cardiovascular status (Hu et al 2002).

Since then, 25 studies involving a total of 280,000 participants have identified an inverse association between fish consumption and morbidity or mortality from CHD. Blood levels of  $\omega$ -3 fatty acids also appear to correlate inversely with death from cardiovascular causes and total mortality (De 2011). Similar findings were reached in another 2011 review which concluded that prospective observational studies and adequately powered RCTs provide strong concordant evidence of the benefits of  $\omega$ -3 PUFA, most consistently for CHD mortality and sudden cardiac death (Mozaffarian & Wu 2011). More specifically, both epidemiological and interventional approaches have clearly demonstrated that individuals with a diet rich in fish (30–35 g/day) or supplemented with EPA and DHA (up to 665 mg/day) show a 30–50% reduction in CHD and CHD-related mortality compared to individuals who did not eat fish (Russo 2009). It appears that, while some level of primary CVD prevention occurs, secondary prevention effects are more notable.

These protective effects are achieved via multiple mechanisms which include lowering plasma TGs, resting heart rate and blood pressure and possibly also improvements to myocardial filling and efficiency and lowering inflammation. There is also evidence that  $\omega$ -3-PUFAs have the ability to protect vascular endothelial cells by decreasing oxidative stress, halting atherosclerotic events and preventing vascular inflammatory and adhesion cascades (Balakumar & Taneja 2012). The effects have been succinctly described as both intrinsic and extrinsic. Intrinsic effects refer to effects on cardiac function dependent upon membrane incorporation at <1 g/day; extrinsic effects are indirect cardiac effects through vascular disease which require EPA + DHA doses >3 g/day (McLennan 2014).

Not surprisingly, in 2004, the US Food and Drug Administration (FDA) reported that it would allow products containing  $\omega$ -3 fatty acids to claim that eating the product may reduce the risk of heart disease. The FDA based its decision on the wealth of scientific evidence that suggests a correlation between  $\omega$ -3 fatty acids such as EPA and DHA and a reduced risk of coronary artery disease. The FDA subsequently approved  $\omega$ -3 fatty acids as a treatment to reduce plasma TGs (Frishman et al 2009).

The largest study is known as the GISSI trial, which involved 11,324 survivors of MI, demonstrating that a low-dose fish oil supplement (1 g/

day) significantly reduced the risk of all-cause death, non-fatal MI and non-fatal stroke compared to vitamin E (300 mg/day) (Stone 2000). The group receiving  $\omega$ -3 EFAs experienced a 15% reduction in the composite primary end point of death, non-fatal MI or non-fatal stroke ( $P < 0.02$ ), with a 20% reduction in the rate of death from any cause ( $P < 0.01$ ) and a 45% reduction in the rate of sudden death, an end point adjudicated by a committee whose members were unaware of the group assignments ( $P < 0.001$ ), whereas the incidence of MI was not significantly reduced. Vitamin E provided no additional benefit. The effect on significantly reducing total mortality was evident early on, within 3 months (RR 0.59), and the rate of sudden death after only 4 months (RR 0.47) (De 2011). The effect was highly significant at 3.5 years, the end of the study, when it accounted for 59% of the  $\omega$ -3 PUFA advantage in mortality. The reduction observed in all-cause mortality and in cardiovascular mortality resulted mainly from the prevention of sudden cardiac death by the  $\omega$ -3 LCPUFAs. (Marchioli et al 2002).

The Japan Eicosapentaenoic Acid Lipid Intervention (JELIS) study followed afterwards and was a very large open-label study testing the long-term use of isolated EPA (1800 mg/day) in addition to statin therapy for the prevention of major coronary events in Japanese patients with hypercholesterolaemia. At a mean follow-up of 4.6 years a 19% relative reduction in major coronary events ( $P = 0.01$ ) was observed with the combination therapy compared to statins alone and there was also a significant reduction in stroke (Tanaka et al 2008, Yokoyama 2009). Non-fatal coronary events were also significantly reduced in the EPA group, but sudden death from cardiac causes and death from coronary causes were not. Importantly, the reduction in events associated with EPA was similar in patients with and those without a history of coronary artery disease, but it was significant only in the former group, with a very low number needed to treat (De 2011). The JELIS study involved a total of 18,645 patients with total cholesterol levels  $\geq 6.5$  mmol/L who were randomly assigned to 1800 mg of EPA per day with statins or statins alone. A later analysis comparing people with good adherence (>80% of dose) to others found that, in good adherers with previous coronary artery disease, EPA substantially reduced the risk compared with statin alone (hazard ratio 0.55,  $P < 0.014$ ). Furthermore, the clinical benefit of EPA + statin was significantly larger in patients with good adherence than in those with poor adherence ( $P = 0.041$ ) (Origasa et al 2010). De Caterina (2011) suggests that the high dietary intake of fish amongst the Japanese population may account for the lack of effect on death from cardiac causes in this trial as a result of high baseline levels.

More recently, a 2013 double-blind study which compared fish oils (1 g/day) to placebo (olive oil) in people with multiple cardiovascular risk factors or atherosclerotic vascular disease but not MI found no change to the end points of cumulative rate of

death, non-fatal MI and non-fatal stroke. Interestingly, at 1 year the event rate was found to be lower than anticipated so the researchers revised the primary end point to death from cardiovascular causes or admission to hospital for cardiovascular causes. They concluded that daily treatment with  $\omega$ -3 fatty acids did not reduce cardiovascular mortality and morbidity as compared to the placebo group (Roncaglioni et al 2013). Unlike the GISSI trial, which used vitamin E as a comparator, this study used olive oil, a choice which must be questioned as it was obviously active because both groups experienced lower event rates than expected and, by the end of the trial, the overall cardiovascular risk profile had improved in both groups.

Unfortunately, the authors of these three studies did not report on the ratio of EPA:DHA used in their  $\omega$ -3 EFA capsules or baseline EPA + DHA measures, thereby limiting further comparisons and interpretation.

### Meta-analyses

In 2002, a high-quality systematic review of 11 RCTs on the effect of fish-based dietary or supplemental  $\omega$ -3 fatty acids on cardiovascular morbidity and mortality in people with CHD found a strongly significant benefit (Bucher et al 2002); however, a 2006 Cochrane review came to a different conclusion (Hooper et al 2006). The review assessed 48 studies that compared at least 6 months of  $\omega$ -3 fats (vegetable- and fish-based) with placebo or control and used data involving 36,913 participants. Meta-analysis of the studies assessing the effects of increased  $\omega$ -3 fats on total mortality or combined cardiovascular events found strongly significant statistical heterogeneity. When randomised studies considered to be at medium or high risk of bias were removed, there was no significant effect of  $\omega$ -3 fats on total mortality (RR 0.87; 95% confidence interval [CI] 0.73–1.03, with significant heterogeneity), whereas the cohort studies suggested significant protection (RR 0.65; 95% CI 0.48–0.88, no significant heterogeneity).

It is important to note that, until the publication of the DART-2 trial in 2003 (Burr et al 2003), the evidence showed that  $\omega$ -3 from oily fish or supplements reduced the risks of fatal MI, sudden death and overall mortality among people with existing disease. Inclusion of the DART-2 trial in the Cochrane review had a major influence on the conclusion, as removing it produced RRs similar to those in the Bucher review (fatal MI: RR 0.70, 95% CI 0.54–0.91; sudden death: RR 0.68, 95% CI 0.42–1.10; overall mortality: RR 0.83, 95% CI 0.75–0.91). The DART-2 trial included 3114 men with stable angina and tested the hypothesis that the main benefit of  $\omega$ -3 fat is derived from its antiarrhythmic action in the presence of chronic disease. Surprisingly, it did not confirm this, showing an excess of sudden and total cardiac deaths most clearly in participants taking fish oil capsules rather than eating oily fish. Authors of the Cochrane review report that something about the DART-2

study is different from the other included studies; however, further investigation has failed to clarify the issue. It is possible that, based on this latest review, the effect of  $\omega$ -3 fats on CVD is smaller than previously thought or that effects in people who have had an MI are protective, but the effects in men with angina and no MI are not.

More recently, a 2013 meta-analysis of 11 double-blind RCTs for investigating the cardiovascular-preventive effects of  $\omega$ -3 EFA supplementation (at least 1 g/day) for at least 1 year in patients with existing CVD concluded that there were significant protective effects observed for cardiac death (RR 0.68; 95% CI 0.56–0.83), sudden death (RR 0.67; 95% CI 0.52–0.87) and MI (RR 0.75; 95% CI 0.63–0.88) (Casula et al 2013). The review, involving 15,348 patients with a history of CVD, also found no statistically significant association for all-cause mortality (RR 0.89; 95% CI 0.78–1.02) and stroke (RR 1.31; 95% CI 0.90–1.90).

### Congestive heart failure

The current body of evidence indicates modest benefits for fish oils in patients with chronic heart failure. One of the first major studies was published in 2005: this was a large epidemiology study of 4738 adults aged over 65 years that showed 20% reduced incidence of heart failure associated with the consumption of tuna or other broiled or baked fish (but not fried), delivering estimated intakes of  $\omega$ -3 LC-PUFA as low as 260 mg/day (Mozaffarian et al 2005). In 2008, a large, double-blind, placebo-controlled trial involving 6975 patients with CHF New York Heart Association class II–IV (GISSI-HF) demonstrated that the use of 1 g of  $\omega$ -3 EFAs was associated with a statistically significant 9% reduction in all-cause mortality and cardiac-cause hospitalisations, with specific improvement in the proportion of subjects with low (<40%) ejection fraction (Tavazzi et al 2008).

More recently, a large cohort trial which recruited 12,500 patients with multiple CVD risk factors reported a 35% reduction in hospitalisations from heart failure as the only physiologically and clinically meaningful outcome from treatment with 850 mg/day EPA + DHA over 5 years (Risk and Prevention Study Collaborative Group 2013). These outcomes reflect improved myocardial function in clinical populations.

EPA levels appear to be more important than DHA levels in patients with CHF, according to a 2013 study which tested baseline levels of  $\omega$ -3 EFAs in patients with CHF enrolled in the GISSI-HF study. An average difference of 43% was seen between patients with the lowest and highest consumptions of dietary fish ( $P < 0.0001$ ). Baseline EPA but not DHA was inversely related to C-reactive protein, pentraxin-3, adiponectin, natriuretic peptide and troponin levels and 3 months of supplementation raised their levels of PUFA by 43%, independently of dietary fish consumption. Additionally, increases in EPA levels were associated with

decreased pentraxin-3. Importantly, low EPA levels were inversely related to total mortality in patients with chronic heart failure (Masson et al 2013).

### Patients with implantable cardioverter defibrillators (ICDs)

At least three double-blind RCTs have been conducted in patients with ICDs exploring whether  $\omega$ -3 EFAs can reduce ventricular tachycardia. In one study, a dose of 2.6 g/day of combined EPA and DHA demonstrated significantly increased 'time to first ICD event' for ventricular tachycardia, fibrillation or death (Jung et al 2008). However, not all studies have produced such positive results, with some suggesting that the  $\omega$ -3 LCPUFAs are ineffective in this patient group (Jenkins et al 2008, Nair & Connolly 2008).

#### **Clinical note — The $\omega$ -3 : $\omega$ -6 balance: implications in cardiovascular disease and cancer**

In recent years, attention has been drawn to the importance of not only  $\omega$ -3 fatty acid intake but also its relation to concurrent  $\omega$ -6 fatty acid intake (Simopoulos 2008). When there is increased  $\omega$ -3 LCPUFAs in the diet and in our bodies, a shift in AA metabolism occurs, which results in the production of metabolites that have beneficial effects on cardiovascular physiology and cancer incidence and promotion (Leaf 2002). For example, when EPA is available to compete with AA, production of thromboxane A<sub>2</sub> (a potent vasoconstrictor and platelet activator) is reduced and production of thromboxane B<sub>3</sub> results, which is only weakly active. Additionally, several forms of research implicate  $\omega$ -6 PUFAs as stimulating processes that promote human cancer development and progression, whereas  $\omega$ -3 LCPUFAs have the opposite effect (Weisburger 1997). Once again, competition with AA is thought to be involved, although several other protective mechanisms have also been identified. Overall, it seems that, in order to obtain maximal cardiovascular and chemopreventive benefits, intake of  $\omega$ -3 LCPUFAs should be increased and intake of  $\omega$ -6 PUFAs must be reduced.

It has been estimated that the ratio of  $\omega$ -6 to  $\omega$ -3 EFAs in the Western diet is some 15:1 to 20:1 or higher, whereas the optimal ratio appears to be closer to 2:1 or 1:1 (Leaf 2002, Simopoulos 1999, 2008).

### Elevated triglyceride levels

DHA and EPA supplementation significantly reduces TG levels in both normo- and hyperlipidaemic individuals and is used as sole therapy in cases of elevation or as adjunctive therapy with cholesterol-lowering medication when indicated.  $\omega$ -3 LCPUFAs reduce TG concentrations in a dose-dependent manner, with intakes approximating 4 g/day lowering serum TGs by 25–30% in hyperlipidaemic patients at

baseline (Balk et al 2006, Din et al 2004, Jung et al 2008). Studies have emerged using  $\omega$ -3 LCPUFA in combination with statins for the treatment of hyperlipidaemia (Barter & Ginsberg 2008). While LDL reduction is the primary target of statins, fish oil co-supplementation both enhances this action and produces additional beneficial changes in other lipid parameters (e.g. HDL, TGs and lipoprotein particle size).

Overall, it appears that the smallest amount of  $\omega$ -3 LCPUFAs required to lower serum TG levels significantly is approximately 1 g/day, as provided by a fish diet (Weber & Raederstorff 2000).

In the United States in 2004, the FDA approved Omacor as an  $\omega$ -3 fatty acid prescription for adults with severe hypertriglyceridaemia (>5.65 mmol/L). Each 1 g capsule contains 465 mg (46%) EPA ethyl esters, 375 mg (38%) DHA ethyl esters and approximately 60 mg (6%) other  $\omega$ -3 fatty acid ethyl esters. The remaining part is mainly composed of  $\omega$ -6 fatty acids along with 4 mg  $\alpha$ -tocopherol (Nicholson et al 2013). In 2007 the name was changed to Lovaza. Evidence to support its use as an effective therapy for elevated TGs is derived from clinical trials involving patients suffering from dyslipidaemia, familial combined hyperlipidaemia and CHD and studies examining its effects in combination with statin therapy (atorvastatin, simvastatin). A dose of 4 g daily was used in all studies, taken as a single dose or as two capsules twice daily. The reduction in TGs ranged from 19.1% to 45%; however, changes in LDL and HDL cholesterol were inconsistent and often insignificant (Nicholson et al 2013).

### Hypertension

According to three meta-analyses, fish oils have a significant but modest dose-dependent effect on blood pressure in hypertension (Geleijnse et al 2002, Miller et al 2014, Morris et al 1993). The DHA component is likely to have stronger effects than EPA.

The most recent meta-analysis analysed results from 70 RCTs and confirmed that fish oils significantly reduce blood pressure, most notably amongst hypertensive patients but also to a modest extent amongst normotensive people (Miller et al 2014). More specifically, compared with placebo, EPA + DHA reduced systolic blood pressure (-1.52 mmHg; 95% CI -2.25 to -0.79) and diastolic blood pressure (-0.99 mmHg; 95% CI -1.54 to -0.44). The strongest effects of EPA + DHA were observed amongst untreated hypertensive subjects (systolic blood pressure = -4.51 mmHg, 95% CI -6.12 to -2.83; diastolic blood pressure = -3.05 mmHg, 95% CI -4.35 to -1.74), although blood pressure also was lowered among normotensive subjects but to a very modest extent only (systolic blood pressure = -1.25 mmHg, 95% CI -2.05 to -0.46; diastolic blood pressure = -0.62 mmHg, 95% CI -1.22 to -0.02). Doses of at least 2 g/day are required to achieve the effect.

### Prior to cardiac surgery

While many secondary CHD prevention trials require months of treatment before the benefits of  $\omega$ -3 fatty acid supplementation are detected, a clinical study with cardiothoracic surgical patients suggests acute benefits within weeks. Calo et al (2005) conducted a randomised, placebo-controlled study which found that patients taking 2 g/day of fish oils for at least 5 days prior to coronary artery bypass grafting and until discharge had a significantly reduced incidence of postoperative atrial fibrillation. Specifically, 15.2% of patients receiving fish oils experienced postoperative atrial fibrillation compared with 33.3% of patients who were not taking the supplement. In addition, hospital length of stay was significantly reduced by 1 day. Except for a single case of allergy, no adverse effects were observed.

A meta-analysis of 21 high-quality RCTs and subgroup analysis of trials using intravenously administered fish oil-enhanced lipid emulsions found that active treatment was associated with a significant reduction in the length of hospital stay (mean = -2.14 days, 95% CI = -3.02 to -1.27), infections (odds ratio [OR] = 0.53, 95% CI = 0.35-0.81), alanine aminotransferase (mean = -6.35 U/L, 95% CI = -11.75 to -0.94), gamma-glutamyl transferase (mean = -11.01 U/L, 95% CI = -20.77 to -1.25) and total bilirubin (mean = -2.06 micromol/L, 95% CI = -3.6 to -0.52), as well as a non-significant change in mortality and postoperative medical cost (Li et al 2014).

### Intermittent claudication

A 2007 Cochrane review of six studies involving 313 subjects suffering from intermittent claudication and treated with  $\omega$ -3 LCPUFAs (typical dose 1.8 g EPA and 1.2 g DHA per day) over weeks to years found that, in spite of some haematological improvements (e.g. reduced viscosity), there were no demonstrable improvements in clinical outcomes (Sommerfield et al 2007). A more recent 2013 Cochrane systematic review came to a similar conclusion, stating that  $\omega$ -3 fatty acids appear to have little benefit in this condition (Campbell et al 2013). A closer look at the studies reveals there is relatively little research looking at long-term use of fish oils as a stand-alone treatment for this indication and further research is required to better explore this potential treatment option.

### Neurological effects

There is evidence that alterations to  $\omega$ -3 fatty acid metabolism and the composition of the phospholipids in serum and membranes are involved in the pathogenesis of some neurological disorders (Ulbricht & Basch 2005). Also, several epidemiological studies have reported low-plasma DHA status in individuals with schizophrenia, ADHD, dyslexia, personality disorder, depression and bipolar disorder

**Clinical note — Would you like methylmercury (MeHg) or organohalogen pollutants (OHPs) with that?**

In aquatic environments, inorganic mercury, either naturally occurring or as an industrial byproduct (e.g. coal-fired power plants, waste incinerators), is converted into MeHg by microorganisms present in sediment or within the intestine of fish themselves (Dórea 2006). The MeHg, which is the most hazardous dietary form, then accumulates in the aquatic food chain, making fish the primary source of exposure for most individuals (FSANZ 2004). There has been increasing public awareness and concern regarding MeHg exposure secondary to fish consumption. This has been partly in response to the health warnings issued by Food Standards Australia and New Zealand (FSANZ) in March 2004 regarding maximal intake of selected fish species during pregnancy and childhood (Bambrick & Kjellstrom 2004). Interestingly, while the main public concern relates to neurodevelopmental toxicity, some data show a relationship between increasing MeHg exposure and CVD, in particular MI (Stern 2005). Postulated mechanisms include the oxidative stress and reactive oxygen species observed with *in vitro* exposures to MeHg, as well as impaired calcium homeostasis and kidney function.

MeHg concentrations in fish and shellfish species, which represent 80–90% of the mercury present, range from <0.1 ppm for shellfish, such as oysters and mussels, to multiple parts per million in large predatory fish such as tuna, marlin, swordfish and shark. Consequently, MeHg intake depends on the species and age of fish consumed, as well as the quantity eaten. Previous American data determined that adults consumed an average of 18 mcg MeHg/day, with 80–90% coming from fish and shellfish (Mahaffey et al 2004).

Inorganic mercury is readily excreted in the urine, whereas MeHg accumulates in erythrocytes across a wide range of exposures (Mahaffey et al 2004). Multiple international studies assessing MeHg exposure levels have revealed that approximately 10% of blood samples were high. American studies have identified populations at greater risk, among them a subpopulation consuming a substantial amount of fish in pursuit of health benefits. Blood MeHg analysis revealed blood mercury levels up to 90 mcg/L (Hightower & Moore 2003). This is concerning, given levels >5 mcg/L have been reported as potentially detrimental in women of child-bearing age.

Some researchers propose that the potentially cardiotoxic effects of MeHg are countered by the presence of the  $\omega$ -3 oils also found within fish, and interestingly, there is some overlap between those species with the highest concentrations of

both (Bambrick & Kjellstrom 2004). However, there is also concern that the converse is true and MeHg could counteract the health-giving benefits of fish.

While fish oil supplements are not a major source of mercury and as such there is no need to restrict their intake (Bays 2007, FSANZ 2004, Levine et al 2005, Schaller 2001), OHPs such as polychlorinated biphenyls, dioxins and organochlorine pesticides, widely used in flame retardants, pesticides, paints and electrical equipment prior to their ban in the 1980s in most countries (Bays 2007), may be present in these products. OHPs also accumulate in the aquatic food chain and are lipophilic carcinogens as well as being associated with other health risks (Dórea 2006). Data across the board confirm significantly higher OHPs in farmed fish and the supplements produced from these (Jacobs et al 1998, 2004) compared with wild harvested samples. These higher levels are attributed most consistently with use of contaminated feed (Domingo & Bocio 2007, Dórea 2006, Easton et al 2002, Jacobs et al 2002, Melanson et al 2005).

A UK study analysing the OHP content of 21 commercially available fish (both whole-body fish and cod liver oil) and vegetable oil dietary supplements in 2004 found that levels in all fish oil products had increased dramatically in brands tested 8 years previously (Jacobs et al 1998, 2004). For example, OHP levels in cod liver oils, which originally ranged from 0 to 13 ng/g, were found to contain 15–34 ng/g in the most recent analysis. The findings of an American study contrast with this, however, with OHP levels below the level of detection in five over-the-counter fish oil products (Melanson et al 2005). There are no published data on Australian products.

There remains little doubt that the discriminating inclusion of fish is an important part of a healthy diet. Recent research suggests that high exposure to mercury may reduce the benefits of long-chain  $\omega$ -3 PUFA on sudden cardiac death (Virtanen et al 2012). It also reduces the benefits of fish oils on preventing MI, according to a Scandinavian study involving over 500 volunteers. It was identified that a small increase in fish consumption (increasing serum PUFA by 1%) would prevent 7% of MI, despite a small increase in mercury (Wennberg et al 2012). However, the higher the hair-mercury, the more the benefits on preventing MI were counteracted. Thus, MI risk may be reduced by the consumption of fish high in PUFAs and low in methylmercury.

(BD) (Riediger et al 2009). As a result, there has been much interest in understanding the effects of supplemental  $\omega$ -3 fatty acids in neurological development, cognitive function, behavioural problems and other neurological conditions.

**Cognitive function**

Low-serum DHA level is considered a significant risk factor for the development of Alzheimer's dementia (Conquer et al 2000). Additionally, both DHA and total  $\omega$ -3 LCPUFAs are significantly

lower in cognitively impaired but non-demented people and people with other dementias. One of the first interventional studies was a small RCT of 4.3 g/day DHA in 20 elderly nursing-home residents, assessing the efficacy of fish oil in the treatment of vascular dementia. DHA supplementation resulted in a small improvement in dementia-rating scores within 3 months of treatment (Terano et al 1994).

Dietary factors influence the association between physical activity and cognitive performance. Executive and memory functions were investigated in 344 participants. High levels of DHA relative to AA mitigated the effects of lower levels of physical activity on cognitive performance. The combination of higher AA:DHA ratios with lower physical activity was associated with markedly decreased performance. In contrast, there were no significant associations between serum AA:DHA ratio levels and cognitive function (Leckie et al 2014).

The results from numerous animal studies, demonstrating neuroprotection and slowing of neurodegeneration from the  $\omega$ -3 LCPUFAs, appear promising (Hashimoto et al 2005, Mucke & Pitas 2004); however, more clinical trials are required to determine the clinical implications of these positive findings.

#### Alzheimer's dementia

Epidemiological studies have shown that dementia and CVD may share several common risk factors, including high intakes of dietary total fat, high saturated fat, high  $\omega$ -6: $\omega$ -3 fatty acid ratio and low fish intake (Riediger et al 2009). Considering  $\omega$ -3 fatty acids possess anti-inflammatory properties and inflammatory markers have been located in the brain of patients with Alzheimer's disease, it seems reasonable to suggest that  $\omega$ -3 fatty acids may delay the onset of Alzheimer's disease by reducing brain inflammatory state. This may be one of the reasons behind prevention of Alzheimer's disease/dementia by adequate DHA/EPA intake suggested by the Framingham heart study (Kalmijn 2000, Kalmijn et al 2004), the Rotterdam study (Kalmijn et al 1997) and the 2003 prospective study by Morris et al (2003), although later follow-up of the Rotterdam study found no association (Engelhart et al 2002).

In 2005, a review of the evidence prepared for the US Department of Health and Human Services concluded that there is a significant correlation between fish consumption and reduced incidence of Alzheimer's disease. Total  $\omega$ -3 LCPUFA and DHA consumption correlated with this risk reduction; however, ALA and EPA did not (MacLean et al 2004). A Cochrane review came to a similar conclusion, reporting that there is a growing body of evidence from biological, observational and epidemiological studies to suggest a protective effect of  $\omega$ -3 LCPUFAs against dementia; however, further research is required before firm conclusions can be made (Lim et al 2006). A study investigating supplementation with 1.8 g/day of fish oils over 24 weeks

in subjects with either mild to moderate Alzheimer's disease or mild cognitive impairment yielded greatest benefits in individuals suffering only mild cognitive impairment (Chiu et al 2008). Further studies using higher doses, larger sample sizes and only subjects mildly affected by the condition are recommended.

#### Brain trauma injury

Brain trauma injury is characterised by significant neuroinflammation. Acute administration of  $\omega$ -3 PUFA after injury and dietary exposure before or after injury have the potential to improve neurological outcomes in traumatic brain injury and spinal cord injury. The mechanisms include decreased neuroinflammation and oxidative stress, neurotrophic support and activation of cell survival pathways (Michael-Titus & Priestley 2014). A paper by Sears et al (2013) reported a case where  $\omega$ -3 supplementation was given (10.8 g of EPA and 5.4 g of DHA) in two divided doses on a daily basis. The patient was a 26-year-old male exposed to a carbon monoxide and methane gas atmosphere for 41 hours following an explosion at a coal mine. When rescued, his breathing was laboured, and he had significant neurological, cardiovascular and renal dysfunction (being the classic symptoms of carbon monoxide poisoning), dehydration and rhabdomyolysis. Magnetic resonance imaging scans indicated significant cytotoxic cell injury and demyelination. He emerged from the coma after 3 weeks. He spent the next 2 months in a rehabilitation facility, at which time the  $\omega$ -3 fatty acid supplementation was continued for another 2 months. He steadily improved over time. He was released into home care nearly 3 months after the explosion. Six years after the explosion he was functionally normal and had fathered two young children (Sears et al 2013). Although this is a single case report,  $\omega$ -3 PUFAs show potential in brain trauma injury and are worthy of further investigation.

#### Autism spectrum disorder (ASD)

Two studies have found evidence of low levels of EPA and DHA in autistic patients (Curtis & Patel 2008). A moderately sized epidemiological study of women with children with ASD ( $n = 317$ ) revealed that pregnant mothers with the lowest  $\omega$ -3 intake had a significant increase in offspring ASD risk as compared with the remaining distribution ( $n = 17,728$ ; RR = 1.53). The data obtained from online survey research from 861 parents of autistic children also suggest that consumption of a formula devoid in DHA and AA during infancy is associated with an OR of 4.41 for autism generally and 12.96 for regressive autism, compared with breastfed infants (Schultz et al 2006). However, the heavy reliance upon self-reporting in addition to the non-random sample leaves these results open to scrutiny. Given all this epidemiological evidence, surprisingly few studies have investigated the effects of  $\omega$ -3 LCPUFAs in autistic individuals. One study conducted in a sample of 12 children, employing 5 g/day of  $\omega$ -3

LCPUFAs over 6 weeks, produced significant remission of hyperactivity (Amminger et al 2007); however another using comparable doses in adults failed to demonstrate efficacy on any behavioural parameter (Politi et al 2008). The paucity of  $\omega$ -3 studies in ASD is striking and has been commented on by reviewers (Frye et al 2013), including the Cochrane review which failed to find a single study that met their inclusion criteria in this area (Tan et al 2012).

While theories abound about the potential role of aberrant LCPUFA metabolism in ASD (Das 2013) as an explanation for the higher incidence in boys, secondary to hormonal differences in fat metabolism (Field 2014), other reviewers argue there isn't a plausible biological mechanism by which  $\omega$ -3 could be implicated (Prior & Galduroz 2012).

### Pregnancy, breastfeeding and infants

The three big focus points in  $\omega$ -3 research for improved offspring health are in the areas of reduced adulthood obesity, prevention of atopy in at-risk individuals ( $\geq 1$  atopic primary family member) and improved cognitive outcomes.

Animal studies suggest that changes in peri- and early postnatal  $\omega$ -3 intake can affect the development of adulthood obesity (Bagley et al 2013); however, attempts to replicate these findings in humans have so far produced negative findings in both early infancy and even adolescence (Hauner et al 2013, Rytter et al 2011).

### Prevention of atopy in at-risk infants

Cross-sectional studies measuring breast milk  $\omega$ -3 content in new mothers found an inverse relationship between LCPUFA levels and positive skin prick test responses in infants at 12 months (Soto-Ramirez et al 2012), while maternal and infant phospholipid  $\omega$ -3 were inversely correlated with non-atopic persistent infant wheezing and positive skin prick test at 6 years old (Pike et al 2012). These later cross-sectional studies suggest  $\leq 50\%$  reduced incidence.

Pregnancy  $\omega$ -3 interventions in high-risk mothers for allergic offspring have demonstrated a protective effect against immunoglobulin E (IgE) sensitisation; however, an absolute reduction in atopic incidence is less certain (Dunstan et al 2008, Furuhejm et al 2011, Noakes et al 2012, Storro et al 2010). There have been several RCTs with positive findings, such as a significantly reduced incidence of food allergy (2% vs 15%) and atopic eczema (8% vs 24%) in 1-year-old infants whose mothers consumed high-dose  $\omega$ -3 (1.6 g/day EPA and 1.1 g/day DHA) from week 25 to 3–4 months postpartum compared with those receiving placebo (Furuhejm et al 2008). A follow-up study of this original cohort found the decreased incidence was sustained at 2-years-old and higher maternal and infant  $\omega$ -3 levels were associated with less IgE-associated disease and reduced severity of the allergic phenotype (Furuhejm et al

2011). One of the strengths of this study was the comprehensive diagnosis of food allergy — a combination of clinical picture assessment, IgE antibody assays and skin prick test.

A large Mexican RCT of 869 pregnant women administered 400 mg/day DHA from the third trimester to delivery observed a significant protective effect of DHA treatment on respiratory symptoms (phlegm and nasal discharge) following adjustment for potential confounders, among infants of atopic mothers (Escamilla-Nunez et al 2014). Interestingly, however, there was no significant difference in cord blood IgE levels between the treatment and placebo groups (Hernandez et al 2013). A large Norwegian study adopted a multipronged approach to reducing asthma in offspring, advising pregnant women in the treatment group to increase their  $\omega$ -3 intake, stop parental smoking and reduce exposure to damp environments during the first 2 years of life (Dotterud et al 2013). The combined effect was a significantly reduced incidence of asthma compared with controls but only in girls (OR 0.41).

One of the longest longitudinal studies in this area to date is a 16-year follow-up investigation of offspring born to women supplemented with 2.7 g/day fish oils from week 30 until delivery as part of an RCT (Olsen et al 2008). Children born to mothers in the fish oil group demonstrated a 63% reduction in asthma diagnoses and 87% reduction in the prevalence of allergic asthma. In line with these findings, it has been suggested that longer follow-up may be necessary to accurately ascertain the impact of  $\omega$ -3 interventions on offspring allergy incidence (Almqvist et al 2007, Marks et al 2006).

In regard to infants' diets, the results of a prospective, longitudinal study from Sweden of 4921 infants' diets, exposure patterns and eczema diagnoses have found a protective effect for early introduction of fish (Alm et al 2009). Infants introduced to fish prior to 9 months of age demonstrated reduced rates of eczema at 1 year (OR 0.76). This finding flies in the face of previous primary prevention strategies whereby many child health authorities have encouraged delaying the introduction of fish in order to reduce allergy.

### Cognitive development

Although numerous studies of mothers and infants have demonstrated that consuming greater amounts of EFAs had a positive effect on the subsequent cognitive development and IQ of their young offspring (Cohen et al 2005, Helland et al 2003, Williams et al 2001), the Evidence Report/Technology Assessment prepared for the Agency of Healthcare Research and Quality of the US Department of Health and Human Services concludes that, based on the small number of current well-designed studies, there is no conclusive evidence of any benefit (Moher 2005). The report observes that studies demonstrating a positive relationship between  $\omega$ -3 LCPUFAs and cognition are those that assessed children under 1 year of age, whereas in studies of

older children a significant statistical relationship is not sustained. Despite the conclusions of this report, several studies with longer follow-up periods have demonstrated both improved eye and hand coordination (Dunstan et al 2008) and IQ at 4 years old (Helland et al 2003), but not at 7 years old (Helland et al 2008). The latter is an Australian study, following up on 98 women who were supplemented with 2.2 g DHA and 0.1 g EPA per day or placebo from 20 weeks' gestation. Children's eye and hand coordination scores correlated with  $\omega$ -3 LCPUFA levels in cord blood red blood cells (RBC) and inversely correlated with  $\omega$ -6 LCPUFA at 2½ years of age.

Other studies investigating fish oil supplementation during lactation have produced mixed findings, including possible negative outcomes only in male offspring (impaired working memory and inhibitory control, increased diastolic blood pressure at 7 years old). However, these figures all come from the same small study ( $n = 122$ ) of Danish mothers administered either 1.5 g/day of fish or olive oil for 4 months during lactation and these conclusions were based on only 36 children in the treatment group who were assessed at 7 years old (Asserhoj et al 2009, Cheatham et al 2011). Therefore, additional research is necessary before any firm conclusions can be drawn.

According to the WHO and Food and Agriculture Organization (FAO), pregnant women should take at least 2.6 g of  $\omega$ -3 EFAs, incorporating 100–300 mg of DHA, daily to look after the needs of the fetus (Bambrick & Kjellstrom 2004). Postnatal deficiencies have been associated with reduced visual acuity, poor neurodevelopment and ill effects on behaviour. Breastfed infants generally receive sufficient DHA if the maternal diet is adequate, but it is not known whether formula-fed infants receive adequate amounts if their formula does not contain PUFAs.

#### Prevention and treatment of postpartum depression (PPD)

The rationale for considering  $\omega$ -3 EFAs as potential risk reducers in PPD relates to consistent evidence of maternal DHA depletion and increasing inflammation throughout pregnancy. However, in spite of evidence of decreased DHA in the frontal cortex correlated with lower serotonin in pregnant animals (Chen et al 2012) and several international cross-sectional epidemiological studies suggesting that higher seafood intake (reflected especially in higher breast milk DHA content) is protective against PPD (Jans et al 2010, Kendall-Tackett 2010), interventional studies in humans have not produced consistently positive findings.

A large Australian study of 2399 pregnant women randomised to DHA-rich fish oil (800 mg DHA and 100 mg EPA/day) or placebo found a non-significant reduction in the percentage of women with high levels of depressive symptoms overall and in the subgroup of women with previously

#### **Clinical note — What determines infants' $\omega$ -3 inheritance?**

Many expectant mothers are aware that one 'breast is best' argument relates to an improved fatty-acid profile in breast milk compared with formula milk. Adding to this is a study by Meldrum et al (2012), investigating the efficacy of direct high-dose fish oil supplementation of infants from birth to 6 months, which found that even in supplemented infants, the  $\omega$ -3 content of the breast milk was the stronger determinant of infant RBC DHA, in spite of total daily exposure being approximately a third of that provided by the supplement. While this result may be the consequence of methodological error, there is speculation that this underscores the superior bioavailability of LCPUFAs in breast milk.

Consistent evidence points to a correlation between  $\omega$ -3 intake during pregnancy (dietary or supplements) and breast milk  $\omega$ -3 concentrations (Urwin et al 2012), but what else influences the infant's  $\omega$ -3 inheritance? Breast milk DHA levels are at their highest in the early postpartum period and progressively decline over the first month of lactation (Weiss et al 2013). However, other variables that dictate how much is available to begin with include birth order (levels decline with each subsequent pregnancy) and multiple versus single pregnancies (Al et al 2000). Additionally, there is growing interest in genetic variations with the FADS1/2 gene clusters which code for the desaturases and how this impacts on  $\omega$ -3 status of mother and infant. Molto Puignt (2010) found that, while plasma DHA levels rose in mothers regardless of genotype, their breast milk DHA changed. Women homozygous for a mutation, with reduced efficacy of these enzymes, demonstrated limited incorporation into breast milk. The results of another interesting but very small study suggest that women with atopic eczema had lower  $\omega$ -3 breast milk levels compared with non-atopic mothers and even atopic mothers who were free from eczema, in spite of comparable intake (Johansson et al 2011). The key take-home message currently seems to be that, while good  $\omega$ -3 intake during pregnancy and lactation is sensible, intake and breast milk concentrations will not perfectly correlate due to a range of other variables we are just starting to identify.

diagnosed depression (Makrides et al 2010). Criticisms of this study include the lack of dietary  $\omega$ -3 assessment, the inclusion of individuals with depression at baseline, the use of self-rated depression scales only and the reliance on high-dose DHA with nominal EPA. A systematic review published the same year, which didn't include the trial by Makrides, examined seven studies of EPA/DHA administration in pregnancy for the prevention of

PPD (four studies sampled healthy individuals and in three studies individuals were depressed at baseline) and found the pooled mean effect size was non-significant and indicated no or a small pre- to posttreatment decrease in perinatal depression.

More recently, 126 women in early pregnancy at high risk of depression were randomised in a trial to receive EPA-rich or DHA-rich fish oil or placebo throughout pregnancy. While fatty-acid analyses revealed increased  $\omega$ -3 levels in the DHA-rich group particularly, demonstrating an inverse relationship between DHA levels and depression-rating scores evident at 34–36 weeks, overall there were no statistically significant differences in the mean depression scores among the groups at entry or at any of the study visits and no statistically significant differences among the groups in the proportion of women who started antidepressant medications (Mozurkewich et al 2013). In summary, these findings have led researchers, and the latest Cochrane review on nutritional prevention of PPD, to currently conclude that fish oil is not effective (Miller et al 2013). In spite of these findings, Goren and Tewksbury (2011) reiterate the numerous benefits of adequate DHA during pregnancy (e.g. fetal neurocognitive development, reduced cardiovascular risks) and encourage pregnant women to continue supplementing high-dose DHA during the third trimester.

### Preventing depression

After adjusting for several confounding factors, Kamphuis et al (2006) reported that every 50 mg/day increase in  $\omega$ -3 fatty acid intake was correlated with a 7% risk reduction of depressive symptoms in elderly men. It has been suggested that the balance between  $\omega$ -6 and  $\omega$ -3 EFA influences the metabolism of biogenic amines, an interaction that may be relevant to changes in mood and behaviour (Bruinisma & Taren 2000). In several observational studies, low concentrations of  $\omega$ -3 LCPUFAs predicted impulsive behaviours and greater severity of depression. Additionally, early research by Horrobin and Bennett (1999) revealed that almost all studies on depression have found increased prostaglandin G<sub>2</sub> series or related thromboxanes and there is evidence that the older antidepressants (monoamine oxidase inhibitors and tricyclic antidepressants) either inhibit prostaglandin synthesis or are powerful antagonists of their actions. The findings of a number of studies showing a correlation between low erythrocyte  $\omega$ -3 EFAs and suicide attempts go one step further. One demonstrated an eightfold difference in suicide attempt risk between the lowest and highest RBC EPA quartiles (Huan et al 2004). Belgian researchers have also speculated about seasonal variations in EFA status that correlate with seasonal patterns of suicide (De Vriese et al 2004); however, studies on larger populations of depressed people are required to confirm this link.

Several international cross-sectional studies have found a correlation between  $\omega$ -3 intake and rates of depression, including that depression rates are

10 times higher in countries with limited seafood intake and PPD 10–50 times higher (Kendall-Tackett 2010). In countries with traditionally high seafood consumption, such as Finland, individuals who consume smaller amounts were found to have a 31% higher chance of developing depression, even when other risk factors were controlled for. Noaghiul and Hibbeln (2003) postulated that countries where individuals consumed less than  $\approx$  450–680 g of seafood per person per week demonstrated the highest rates of affective disorders.

Superior epidemiological evidence comes from longitudinal rather than cross-sectional studies of  $\omega$ -3 intake in healthy individuals and subsequent depression diagnoses. Four such trials were included in a recent review (Sanhueza et al 2013). While two of these did not find any association between fish consumption and depression incidence, the other two found that an inverse relationship was only seen with intermediate intake which equated to  $\approx$ 0.16% of the total energy intake or 1.17 g/day (energy-adjusted) and produced a significant risk reduction of 35–40% in depression. The loss of apparent protection with the highest fish intake remains unexplained, possibly an issue of excess exposure to the contaminants found in certain fish (see *Would you like methylmercury (MeHg) or organohalogen pollutants (OHPs) with that?*). However, it is noteworthy that a similar phenomenon was evident with  $\omega$ -3 supplementation (Peet & Horrobin 2002).

### Treating depression

In spite of widespread epidemiological data correlating  $\omega$ -3 status with a range of depressive disorders, including major depression, PPD and seasonal affective disorder, and extensive evidence of the role of inflammation in depression (Kendall-Tackett 2010), there are relatively few interventional studies and those published are typically compromised by small sample size and possess heterogeneous designs, particularly with regard to the composition and dose of the intervention itself (Grenyer et al 2007). More recent reviews have focused on eliminating the confounding issue of variable  $\omega$ -3 forms and dose. These reviews (Martins 2009, Ross et al 2007, Sublette et al 2011) appear to have reached a consensus regarding the superiority of EPA over DHA in depressed individuals. Sublette et al (2011) in particular postulate that interventions providing  $>$ 60% EPA and a minimum of 200–2200 mg EPA in excess of DHA were significantly more effective. Although DHA is more prevalent in the brain and possesses actions that would suggest it would be helpful in depression, several theories are proposed why this doesn't translate into clinical findings, including that oral DHA supplementation has not conclusively been shown to increase brain DHA levels. Secondly, it is EPA that directly competes with AA for conversion to eicosanoids and therefore may have the most relevant anti-inflammatory action.

Trials published since these reviews include a small, double-blind randomised study ( $n = 66$ ) of

mildly depressed elderly individuals (mean age 80 years) administered low-dose EPA and DHA (180 mg and 120 mg/day, respectively) over 6 months to Iranian nursing-home patients with extremely low dietary  $\omega$ -3, e.g. three fish meals over 6 months. Using self-assessment via the Geriatric Depression Scale-15, 40.7% of subjects in the treatment group demonstrated improved mood compared with only 27.6% of placebo, which was a significant difference (Tajalizadekhoob et al 2011). In young healthy adults (aged 18–35 years) also with low baseline  $\omega$ -3 intake, EPA-rich (EPA 300 mg and DHA 200 mg/day) and DHA-rich (450 mg and EPA 90 mg/day) supplements were compared with placebo for improving cognition and, as a secondary assessment, mood, via the Depression Anxiety Stress Scale and Bond-Lager visual analogue (Jackson et al 2012). Treatment with fish oils at these doses failed to produce any mood or cognitive benefits, which the authors argue may be illustrative that baseline  $\omega$ -3 levels need to be lower and functional impairment evident in order to benefit from fish oil supplementation. However, the results could also be explained by inadequate unopposed EPA according to the work of Sublette et al (2011). Most recently, a randomised double-blind placebo-controlled study of 152 patients preparing for interferon treatment revealed that those treated with EPA 2 weeks before interferon treatment started reported significantly lower rates of depression (10%) compared with both DHA-supplemented individuals (28%) and subjects taking placebo (30%) (Su et al 2014).

### Bipolar disorder

Interest in the role and therapeutic potential of  $\omega$ -3 in BD is substantial and has moved beyond the epidemiological associations to more sophisticated investigations, i.e. fatty-acid levels present in specific brain regions of BD sufferers, genetic variations in expression of LCPUFA metabolic enzymes (Igarashi et al 2010). Proposed mechanisms of action include their capacity to increase cell membrane fluidity (altering receptor numbers and dampening signal transduction pathways), reduce brain inflammation, antagonise phosphoinositide protein kinase C and, to a small extent, inhibit reuptake of serotonin and dopamine, which would all be beneficial in BD depression (Sarris et al 2011). Additionally, some researchers have found a correlation between individuals' LCPUFA levels and BD severity (DHA and depression; EPA and mania) (Clayton et al 2009). It is also noteworthy that many of the medications prescribed in BD (e.g. lithium, valproate) reduce turnover of AA and therefore are postulated to be anti-inflammatory (Goren & Tewksbury 2011).

Poor methodological quality as well as heterogeneous design have plagued  $\omega$ -3 interventional studies, however, as illustrated by the Cochrane review which based their negative conclusion on the results of one study (Frangou et al 2006), while >23 others failed to meet their inclusion criteria (Montgomery & Richardson 2008).

A broader review by Sarris et al (2011) notes that, of nine adjunctive  $\omega$ -3 trials in BD, seven were randomised, double-blind and placebo-controlled and four of these demonstrated a statistically significant positive effect on reducing depression. While generally  $\omega$ -3 oils have not demonstrated significantly superior results to placebo in the management of mania, Sarris et al comment that all studies are in favour of fish oils over placebo in this respect; however, small sample sizes could explain the lack of statistically significant findings. Again, particular note is made of the differences in  $\omega$ -3 preparations, which range from high-dose EPA alone, EPA:DHA blends, to flaxseed oil and with dosage variations, e.g. up to 3400 mg DHA and 6000 mg ethyl-EPA. One of the open-label studies also included by Sarris is a small Australian study ( $n = 18$ ) of juvenile BD, in which subjects stable on pharmaceutical medications then took  $\omega$ -3 (360 mg/day EPA 1560 mg/day DHA) for 6 weeks, producing a 50% reduction in depression ratings, and again a non-significant improvement in mania (Clayton et al 2009).

### Addiction/abstinence

A study in polysubstance abusers (Buydens-Branchey et al 2008), using 2.25 g EPA and 500 mg DHA administered over 3 months to 24 individuals, resulted in decreased anger and anxiety scores, corresponding with plasma increases in both EPA and DHA. A randomised double-blind placebo-controlled study of abstinent alcoholics revealed that 3 weeks of supplementation with fish oil (60 mg/day EPA and 252 mg/day DHA) produced lower basal salivary cortisol levels compared with placebo, accompanied by lower depression and anxiety ratings. At the end of intervention, amplitude and duration of stress-evoked cortisol response did not differ between groups; however, the peak of cortisol response was temporally anticipated in supplemented subjects (Barbadoro et al 2013).

An animal study which injected rats with amphetamine and fed subgroups different dietary fats (soybean, hydrogenated vegetable fats or fish oil) found that fish oils largely attenuated the detrimental effects on brain structure, mitochondrial activity and vitamin C levels typically seen with chronic amphetamine exposure. The researchers hypothesise that this action could be similar to the protective effects of  $\omega$ -3 oils in other forms of mania (Trevizol et al 2001).

### Aggressive and impulsive behaviour

Animal studies demonstrate increased aggression test scores in rats and other species deprived of  $\omega$ -3 LCPUFAs during either gestation or early life. This has been linked to deficits in neuronal arborisation and multiple indices of synaptic pathology, including deficits in serotonin and mesocorticolimbic dopamine neurotransmission (Hibbeln et al 2006, Liu & Raine 2006). Human data also support this proposition, whereby preterm delivery is associated with deficits in fetal cortical DHA accrual, and children/adolescents born preterm exhibit deficits in

cortical grey-matter maturation, neurocognitive deficits, particularly in the realm of attention, impulsivity and increased risk of ADHD and schizophrenia (Hibbeln et al 2006, McNamara & Carlson 2006). While there is strong support for the biological basis for a relationship between  $\omega$ -3 LCPUFAs and aggressive and impulsive behaviour (Garland & Hallahan 2006), the results of interventional studies have been somewhat mixed.

DHA has been used to reduce aggressive behaviour in children and adolescents. One placebo-controlled study of 42 college students showed that DHA supplementation (1.5–1.8 g/day) prevented an increase in aggression towards others at times of mental stress (Hamazaki et al 1996); however, there was no effect on aggressive behaviour under non-stressful conditions (Hamazaki et al 1998). A 2005 randomised, placebo-controlled clinical trial looked at 166 Japanese children aged 9–12 years administered 3.6 g DHA and 840 mg per week via both supplements and fortified foods over a period of 3 months (Ito-mura et al 2005). While reducing aggression in girls, concomitant with improved EPA:AA RBC ratios, the same effect was not evident in boys. Impulsivity amongst female subjects was also significantly reduced in the treatment group.

Other small successful studies for anger reduction have been conducted in abstaining polysubstance abusers (2.25 g EPA, 500 mg DHA administered over 3 months) (Buydens-Branchey et al 2008), borderline personality disorder (1 g/day ethyl EPA over 8 weeks) (Zanarini et al 2003) and borderline personality disorder in adolescents at high risk of psychosis (1.2 g/day  $\omega$ -3 over 12 weeks) (Amminger et al 2013). In a separate study, however, individuals exhibiting recurrent self-harm, scores for impulsivity, aggression and hostility remained unchanged, in spite of decreased depression and suicidality scores, when treated with 1.2 g EPA and 900 mg DHA per day over 12 weeks (Hallahan et al 2007). New research has found a relationship between AA/EPA + DHA RBC ratios and individuals' vulnerability to anger with interferon treatment. Marked anger and irritability are common adverse effects of interferon that can compromise compliance and success of the treatment, therefore co-administration of  $\omega$ -3 LCPUFA may represent an effective way to reduce the likelihood of this occurrence (Lotrich et al 2013).

### Anxiety

In spite of consistent animal evidence that decreased  $\omega$ -3 LCPUFA leads to chronic mild stress-induced anxiety (Vinot et al 2011), limited well-designed studies have been conducted in patients with anxiety disorders as a stand-alone diagnosis rather than a comorbidity, e.g. BD, substance abuse (Goren & Tewksbury 2011).

Animal studies of both supplemental  $\omega$ -3 during the perinatal period and, more recently, adulthood confirm a moderate anxiolytic action (Vinot et al 2011) and new mechanisms such as improved

neural plasticity and endocannabinoid activity have been elucidated (Larrieu et al 2011). A placebo-controlled, double-blind 12-week RCT compared  $\omega$ -3 (2085 mg EPA and 348 mg DHA) supplementation with placebo on proinflammatory cytokine production and anxiety symptoms in medical students ( $n = 68$ ) for 12 weeks.  $\omega$ -3 supplementation produced a 20% reduction in anxiety symptoms ( $P = 0.04$ ), as measured by the Beck Anxiety Inventory, and a 14% decrease in stimulated interleukin-6 production ( $P = 0.04$ ).  $\omega$ -3 PUFA also had a borderline effect on serum tumour necrosis factor-alpha (TNF- $\alpha$ ) (7% decrease,  $P = 0.06$ ). At the completion of the study, plasma levels of EPA and DHA were approximately sixfold and  $\frac{1}{2}$ -fold higher compared to levels prior to supplementation. The levels of EPA and DHA in peripheral blood mononucleated cells (PBMCs) also increased but were not as dramatic in increase: threefold and  $\frac{1}{3}$ -fold, respectively, for EPA and DHA. Supplementation with the placebo oil resulted in no changes of either plasma or PBMC EPA and DHA. There was no significant change in depressive symptoms (Kiecolt-Glaser et al 2011). Further human studies of anxiety disorders are needed to confirm these findings.

### Attention-deficit hyperactivity disorder

It has been reported that many children with ADHD have EFA deficiency (mainly  $\omega$ -3 fatty acid), with a high correlation between severity of symptoms and severity of deficiency (Yehuda et al 2005). Deficiency may be due to insufficient dietary intake or inefficient conversion of EFA to LCPUFAs. Several studies have investigated the effects of supplemental fatty acids in ADHD with mixed results; however, interpretation of findings is difficult because of the use of different treatments, measurements and subject selection (Richardson & Puri 2000). Although the evidence is hampered by small samples and other methodological issues, at this time  $\omega$ -3 LCPUFAs do not appear to be effective in ADHD (Goren & Tewksbury 2011).

### Schizophrenia

Schizophrenic patients have been frequently found to have low LCPUFAs (Peet 2003, 2006). Some studies have found higher saturated and monounsaturated fat in red cells at the expense of LCPUFAs of both the  $\omega$ -3 and  $\omega$ -6 families (Kemperman et al 2006). The evidence linking LCPUFAs with this condition was so persuasive it generated the 'membrane phospholipid theory of schizophrenia'; however, while most evidence points to increased LCPUFA turnover, a consensus on the exact nature of this disturbance is still pending (Atker et al 2012). Interestingly, an in vitro study of cells exposed to  $H_2O_2$  as a model of the high oxidative stress seen in schizophrenia found that resperidone and fish oils together reduced lipid peroxidation and free  $Ca^{2+}$  while simultaneously increasing glutathione, glutathione peroxidase and vitamin C levels (Altinkilic 2010).

A key researcher in the area of EFAs and psychiatry also points to the significant overlap between core features of the metabolic syndrome and established physiological aberrations evident in schizophrenia, including visceral adiposity, insulin resistance, dyslipidaemias, increased inflammatory markers and reduced  $\omega$ -3 LCPUFAs in cell membranes (Peet 2006). Importantly, these similarities predate the introduction of the novel antipsychotics, which are known to be diabetogenic. Schizophrenic patients demonstrate a two- to fourfold increased risk of type 2 diabetes mellitus (T2DM) and two to three times greater risk of coronary artery disease mortality, which cannot be entirely related to secondary lifestyle behaviours.

In a 2003 review, four out of five placebo-controlled, double-blind trials of EPA in the adjunctive treatment of schizophrenia have produced positive results with a typical effective dose of 2 g/day of EPA for a minimum of 3 months (Peet 2003). An updated Cochrane review of six studies, involving 353 subjects, has similarly concluded that ethyl-EPA may exert positive effects when added to standard medication; however, more large well-designed, conducted and reported studies are needed (Joy et al 2006). Since this time another systematic review has reached similar conclusions (Akter et al 2012), with small sample sizes ( $n = 16$ –122), short intervention duration (6–16 weeks) and heterogeneous LCPUFA interventions hampering more robust findings. The authors note, however, with suggestive positive effects in this cohort and an excellent safety profile, many clinicians may opt to add  $\omega$ -3 into their schizophrenic patient management.

A new area of research opening up is psychosis prevention in high-risk individuals. One randomised double-blind placebo-controlled study of 81 adolescents classified as being at ultra-high risk of psychosis, treated with either fish oils (480 mg/day DHA, 700 mg/day EPA, 7.6 mg vitamin E) or placebo over 12 weeks, found that, while 27.5% of the control group transitioned to their first psychotic episode, only 4.9% of those taking fish oil did (Amminger et al 2010). Impressively, these benefits were sustained following cessation of the intervention throughout the year of follow-up. Early treatment of psychosis is considered to be a major determinant of overall outcomes and, compared to the risks associated with long-term antipsychotic medications,  $\omega$ -3 supplements are an appealing alternative.

## Cancer

It is well established that dietary fat has an influence on human cancer development and progression. Several forms of research implicate  $\omega$ -6 PUFAs as catalysts, whereas  $\omega$ -3 LCPUFAs have the opposite effect and have been shown to inhibit development and progression (Leitzmann et al 2004, Weisburger 1997). Therefore, it is the ratio of  $\omega$ -3 to  $\omega$ -6 PUFAs intake that appears to be an important factor influencing cancer incidence and progression.

This observation is supported by both animal and epidemiological studies. The largest to date involved 24 European countries and identified a significant inverse correlation with fish and fish oil consumption, when expressed as a proportion of total or animal fat, for both male and female colorectal cancer and for female breast cancer (Caygill et al 1996). Importantly, the protective effects were only detected in countries with a high animal fat intake, suggesting that fish oil protects against the promotional effects of animal fat in carcinogenesis.

## Breast and prostate cancers

Increased intake of  $\omega$ -3 fatty acids associated with decreased  $\omega$ -6, resulting in a higher  $\omega$ -3/ $\omega$ -6 ratio compared with the western diet, are inversely associated with breast cancer risk, as shown by Yang et al in their meta-analysis (de and Salen 2014). A 2003 review found that overall it remains unclear as to whether dietary fish or fish oil consumption exerts a protective effect against the development of breast and prostate cancers (Terry et al 2003). The assessment of EPA and DHA intake and their relation to  $\omega$ -6 fatty acid intake and cancer incidence still requires further examination before conclusions can be confidently made. An updated review conducted by the same researchers in 2004 (Terry et al 2004) reached a similar conclusion; however, they also observed that those studies that assess  $\omega$ -3 intake concomitant with the  $\omega$ -6 consumption were most likely to yield a statistically significant inverse relationship between fish oils and breast and prostate cancers. Once again this reinforces the understanding that due to interrelated metabolism and actions the fats should not be viewed independently.

A prospective cohort study in the United States of 47,866 men aged 40–75 years with no cancer history were assessed using a 131-item semiquantitative food frequency questionnaire administered annually over 14 years, as part of the Health Professionals Follow-Up study. Nutrient intake data from this trial suggest an association between ALA and advanced prostate cancer, but an inverse relationship with the ALA metabolites, EPA and DHA. Earlier studies investigating the relationship between ALA and prostate cancer have had mixed results while the inverse relationship with EPA/DHA appears to be largely supported. Again the authors demonstrate that ratios of  $\omega$ -3: $\omega$ -6 appear to be highly influential in conveyed risk (Leitzmann et al 2004).

More recently, an association was confirmed between consuming salted or smoked fish and an increased risk of advanced prostate cancer, whereas fish oil consumption may be protective against progression of prostate cancer in elderly men (Torfadottir et al 2013). Interestingly, serum PSA concentrations from 6018 men (from the 2003–2010 National Health and Nutrition Examination Survey), matched with dietary intake of fish, found little evidence for  $\omega$ -3PUFA consumption in influencing PSA levels (Patel et al 2014). Emerging data further suggest  $\omega$ -3 PUFAs may slow the growth of

many tumours, including prostate (Masko et al 2013).

### Colorectal cancer

Epidemiological evidence investigating associations between fish intake and colorectal cancer have produced mixed findings (Caygill et al 1996, Daniel et al 2009), with the most recent prospective cohort study (Cancer Prevention Study-II Nutrition Cohort) involving over 99,000 individuals failing to demonstrate a protective effect of increased  $\omega$ -3 intake. In fact, increased consumption of ALA was associated with increased risk in women. Contrastingly, higher marine  $\omega$ -3 intake did appear protective. The latter finding is consistent with the results of other large prospective studies on this issue (Hall et al 2008).

Other sources of evidence attribute both EPA and DHA and their main dietary source, fish oil, with antineoplastic effects in colorectal cancer (Llor et al 2003). Fish oil supplementation, in one study, providing 4.1 g EPA and 3.6 g DHA per day in patients with sporadic adenomatous colorectal polyps, was reported to reduce the percentage of cells in the S-phase in the upper crypt of the rectal mucosa (Anti et al 1992). The evidence to date, as reviewed in 2004 by Roynette et al, suggests a primary preventive effect with some residual ambiguity over the safety of  $\omega$ -3 LCPUFA with respect to secondary tumour formation.

One study has investigated the effects of  $\omega$ -3 LCPUFA parenteral supplementation postoperatively on clinical outcomes and immunomodulation in colorectal cancer patients using a randomised, double-blind design (Liang et al 2008). Treatment effect comparisons revealed that those treated with  $\omega$ -3 LCPUFAs had significantly lower serum interleukin, TNF-alpha and increased ratios of CD4<sup>+</sup>/CD8<sup>+</sup>. These patients also tended towards shorter postoperative hospital stays. Consequently, the authors conclude that such a treatment regimen may have beneficial effects on lowering the magnitude of inflammatory responses and modulating the immune response in this patient group.

The results of an *in vitro* study have demonstrated synergistic inhibition of proliferating colon cancer cells using a combination of lycopene and EPA (Tang et al 2009). The results of other *in vitro* studies attribute the protective effects of  $\omega$ -3 LCPUFAs with DHA rather than EPA (Kato et al 2007). Both animal studies and RCTs are now required to clarify the 'active' fatty acid and confirm these findings.

### Diabetes

Increasing the intake of  $\omega$ -3 LCPUFA has been shown to be both preventive in a healthy population and beneficial in people with diabetes (Montori et al 2000, Nettleton et al 2005, Sirtori & Galli 2002, Sirtori et al 1997). A recent systematic review and meta-analysis revising results from 24 studies, including 24,509 type 2 diabetes patients and 545,275 participants overall, found marine  $\omega$ -3

PUFA to have beneficial effects on the prevention of type 2 diabetes in Asian populations (Zheng et al 2012). Alternately, no clear association was found between  $\omega$ -3 EFAS and type 2 diabetes in a review of 16 studies comprising 540,184 individuals (Wu et al 2012). In addition, no major harms or benefits of fish/seafood or EPA+DHA on development of DM were observed, but there was suggestion of modestly lower risk with ALA.

While the preventative effect of  $\omega$ -3 EFAS on diabetes is still being investigated,  $\omega$ -3EFAs do provide other benefits for people with established diabetes. Diets higher in fish and  $\omega$ -3 PUFA may reduce cardiovascular risk in diabetes by inhibiting platelet aggregation, improving lipid profiles and reducing cardiovascular mortality (McEwen et al 2010). Two meta-analyses found that fish oil supplementation lowers plasma TG levels in type 2 diabetic subjects; however, a possible rise in plasma LDL cholesterol may occur (Balk et al 2006, Montori et al 2000). Although an increase in LDL cholesterol was noted after  $\omega$ -3 supplementation, the levels of LDL were not significantly increased in subgroup analyses of hypertriglyceridaemic patients, high (greater than 2 g of EPA and DHA daily) or low  $\omega$ -3 PUFA doses and in trials lasting longer than 2 months (Hartweg et al 2008). The rise in plasma LDL cholesterol has been speculated to be the result of enhanced conversion of very LDLs and studies in primates suggest that  $\omega$ -3 LCPUFA-enriched LDLs do not convey the same atherogenic potential (Jung et al 2008). Additionally, no significant effect occurs on glycaemic control, total cholesterol or HDL cholesterol. In addition, studies reveal an average of 7.4% increase in HDL levels concomitant with a 25% reduction in TGs in response to 1020 mg EPA and 700 mg DHA supplementation over 6 months (Sirtori et al 1998). Such findings are supported by the results of other trials in patients with diabetes (Nettleton et al 2005).

In a randomised study, serum phospholipid  $\omega$ -3 PUFA levels were found to be significantly decreased in patients with type 2 diabetes and non-alcoholic fatty liver disease ( $n = 51$ ;  $P < 0.05$ ). In addition, serum  $\omega$ -3 levels were negatively related with insulin resistance. Homeostasis model assessment method (HOMA-IR) levels were higher in patients with type 2 diabetes and non-alcoholic fatty liver disease than in the type 2 diabetes ( $n = 50$ ), non-alcoholic fatty liver disease ( $n = 45$ ) and healthy control groups ( $n = 42$ ;  $P < 0.05$ ). Furthermore, Pearson analysis showed that the  $\omega$ -3 PUFA level was negatively correlated with HOMA-IR ( $r = -0.491$ ), total cholesterol ( $r = -0.376$ ), TGs ( $r = -0.462$ ) and LDL cholesterol ( $r = -0.408$ ), all  $P < 0.05$  (Lou et al 2014).

The effect of fish on endothelial function was investigated in 23 postmenopausal women with type 2 diabetes. Participants were assigned to two 4-week periods of either a fish-based diet ( $\omega$ -3 PUFAs  $\geq 3.0$  g/day) or a control diet in a randomised cross-over design. Endothelial function was measured

with reactive hyperaemia using strain-gauge plethysmography and peak forearm blood flow, duration of reactive hyperaemia and flow debt repayment (FDR). This was then compared with the serum levels of fatty acids and their metabolites. In the fish-first group, the peak forearm blood flow response and FDR increased markedly after the fish-based diet period (4 weeks), and these effects were sustained after the control diet period (8 weeks). In addition, the durations of reactive hyperaemia and FDR increased significantly, and the peak forearm blood flow showed improvement. Conversely, in the control diet-first group, the peak forearm blood flow response, duration of reactive hyperaemia and FDR were unchanged after the control diet period (4 weeks) (Kondo 2014).

Furthermore, the anti-inflammatory properties of  $\omega$ -3 PUFA, such as the reduction of prostaglandin E<sub>2</sub>, leukotrienes (B<sub>4</sub> and E<sub>4</sub>), thromboxane B<sub>2</sub> and C-reactive protein, may be of beneficial use in patients with diabetes and CVD. Large trials are suggested to assess the therapeutic potential of  $\omega$ -3 PUFA as an anti-inflammatory agent in patients with diabetes and CVD (McEwen et al 2010). Despite the potential benefits associated with  $\omega$ -3 LCPUFAs, a 2008 Cochrane review of 23 RCTs involving 1075 individuals concluded there is currently insufficient evidence to recommend high-dose fish oils to T2DM patients for cardiovascular benefits (Hartweg et al 2008).

### Weight reduction

Animal studies illustrate the potential for  $\omega$ -3 as disease modifiers in obesity via anti-inflammatory mechanisms such as activation of peroxisome proliferator-activated receptors, lowering levels of TNF- $\alpha$  produced by adipocytes and therefore attenuating secondary insulin resistance (Pedersen et al 2011), and that  $\omega$ -3 interventions consistently reduce body weight and fat mass (Munro & Garg 2013). The results of  $\omega$ -3 interventions in humans, however, are very mixed. Some positive findings include attenuating negative PUFA changes associated with weight loss regimes (Hlavatý et al 2008) and improving insulin resistance in overweight subjects (Ramel et al 2008), and possible reduced incidence of obesity, increased ease of weight loss and maintenance of body weight in this population (Nettleton et al 2005). One study found that overweight and obese subjects consuming >1300 mg/day  $\omega$ -3 LCPUFAs compared with those consuming <240 mg/day demonstrated significantly increased satiety 2 hours postprandially, which correlated with increased  $\omega$ -3: $\omega$ -6 (Parra et al 2008). In contrast there are numerous interventional studies which have failed to produce these anticipated outcomes, including a recent small Australian trial ( $n = 33$ ) conducted over 12 weeks (Munro & Garg 2013). Speculation regarding such inconsistent results includes the heterogeneous nature of the supplements, with highly variable DHA and EPA ratios and dose, the possible need for longer treatment periods and the perennial issue

of human dietary compliance. A new finding in animal research may shed some light on this, with evidence that background diet exerts a crucial influence on the ability of fish oil to protect against obesity development and adipose tissue inflammation (Hao et al 2012). In fact, in this study of mice the beneficial effects of  $\omega$ -3 intake in mice were significantly diminished or completely abrogated by a simultaneous intake of high-glycaemic index carbohydrates. Another Australian study posits the question of whether other nutrients in fish beyond LCPUFAs contribute to positive weight- and insulin-lowering effects, with a small human trial showing statistically greater adiponectin increases with high dietary  $\omega$ -3 versus comparable EPA/DHA from supplements (Neale et al 2012). Finally, preliminary research investigating  $\omega$ -3's effect on lowering endocannabinoid levels in obese rats and humans suggests that krill oil may be superior for this application (Banni et al 2011). Further human studies investigating these issues are necessary.

### Polycystic ovarian syndrome (PCOS)

Evidence of fish oil's ability to improve insulin sensitivity has led to several small investigations in PCOS populations. One study of 45 non-obese PCOS sufferers administered 1.5 g of  $\omega$ -3 for 6 months found that body mass index, insulin and HOMA levels decreased significantly, in addition to hormonal improvements e.g. lower serum LH, testosterone and higher SHBG. Glucose levels themselves however didn't change and TNF- $\alpha$  levels showed a significant increase (Oner & Muderris 2013). Similar results were obtained in another study of 61 PCOS patients administered 720 mg/day EPA and 480 mg/DHA or placebo over 8 weeks. Again statistically significant improvements were evident on multiple parameters (TGs, HDLs, HOMA) but the inflammatory marker, this time CRP, was unchanged (Mohammadi et al 2012). Interestingly, in a study of PCOS patients which included those with healthy body mass index, favourable lipid changes were lessened. Several of these studies illustrate the androgen-lowering effect of high-dose  $\omega$ -3 (Oner & Muderris 2013, Phelan et al 2011) which is hypothesised to be the result of reduced  $\omega$ -6: $\omega$ -3 rather than a direct effect of  $\omega$ -3 (Phelan et al 2011).

### Inflammatory diseases

Numerous clinical trials have investigated the effects of fish oil supplementation in several inflammatory and autoimmune diseases, such as RA, Crohn's disease, ulcerative colitis, lupus erythematosus and migraine headaches (Belluzzi 2002, Belluzzi et al 1996, Miura et al 1998, Simopoulos 2002). Although not all trials have produced positive results, many of the placebo-controlled trials reveal significant benefit in chronic disease, including decreased disease activity and sometimes reduced requirement for anti-inflammatory medicines (Adam et al 2003).

## Rheumatoid arthritis

Of the inflammatory diseases, the use of fish oil supplementation is most widely seen and supported in RA. RCTs, meta- and mega-analysis of RCTs indicate reduction in tender joint counts, pain intensity, morning stiffness and decreased use of non-steroidal anti-inflammatory drugs with fish oil supplementation in long-standing RA (Adam et al 2003, Cleland et al 2003, Goldberg & Katz 2007, James et al 2010, Kremer 2000, Miles & Calder 2012, Ulbricht & Basch 2005, Volker et al 2000). Since non-steroidal anti-inflammatory drugs confer cardiovascular risk and there is increased cardiovascular mortality in RA, an additional benefit of fish oil in RA may be reduced cardiovascular risk via direct mechanisms and decreased non-steroidal anti-inflammatory drug use. Interestingly, fish oil has been shown to slow the development of RA in animal models and to reduce disease severity (Miles & Calder 2012).

Generally, supplements are taken daily as adjuncts to standard therapy, with clinical effects appearing after 12 weeks. A dose ranging from 30 mg to 40 mg/kg of EPA and DHA daily has been used successfully, although some studies have found a minimum of 3 g/day is required. Results from a double-blind, crossover study suggest that the beneficial effects obtained from fish oil capsules are further enhanced when combined with an anti-inflammatory diet providing less than 90 mg/day of AA (Adam et al 2003).

Symptomatic relief with  $\omega$ -3 LCPUFAs in RA was more recently confirmed in a meta-analysis of 17 RCTs assessing the pain-relieving effects in RA patients or joint pain secondary to inflammatory bowel disease and dysmenorrhoea (Goldberg & Katz 2007). Supplementation for 3–4 months significantly reduced patient-reported joint pain intensity, minutes of morning stiffness, number of painful and/or tender joints and non-steroidal anti-inflammatory drug consumption. Significant effects were not detected, however, for doctor-assessed pain or Ritchie articular index. These papers, together with other authoritative reviews, conclude that, based on high-level evidence,  $\omega$ -3 LCPUFAs are an attractive adjunctive treatment for joint pain associated with RA and have a beneficial follow-on effect on cardiovascular morbidity and mortality pertinent to this population (Proudman et al 2008).

Although the anti-inflammatory activity of fish oil supplementation is thought to be chiefly responsible for symptom-relieving effects, there is also evidence that  $\omega$ -3 LCPUFAs can modulate expression and activity of degradative factors that cause cartilage destruction (Curtis et al 2000). A 2005 randomised study found that fish oil supplements (3 g/day), whether taken alone or in combination with olive oil (9.6 mL), produced a statistically significant improvement ( $P < 0.05$ ) compared to placebo on several clinical parameters (Berbert et al 2005). Significant improvements were observed for joint pain intensity, right and left handgrip strength after 12

and 24 weeks, duration of morning stiffness, onset of fatigue, Ritchie's articular index for pain joints after 24 weeks, ability to bend down to pick up clothing from the floor and getting in and out of a car after 24 weeks. The group using a combination of oils showed additional improvements with respect to duration of morning stiffness after 12 weeks, patient global assessment after 12 and 24 weeks, ability to turn taps on and off after 24 weeks and rheumatoid factor after 24 weeks. In addition, this group showed a significant improvement in patient global assessment compared with fish oils alone after 12 weeks.

Based on these results, it appears that, while fish oils will not improve all parameters of RA, overall they have demonstrated symptomatic relief in the majority and result in significantly reduced use of anti-inflammatory and corticosteroid use, a fact that MacLean et al (2004) acknowledge and which is confirmed by a 2005 review by Stamp et al and meta-analysis by Goldberg and Katz (2007). There appears to be little evidence of sustained improvements following cessation of the supplements.

A 2008 paper from the Joint Nutrition Society notes that, in addition to modifying the lipid mediator profile,  $\omega$ -3 LCPUFAs exert effects on other aspects of immunity relevant to RA, such as antigen presentation, T-cell reactivity and inflammatory cytokine production (Calder 2008).

## Reducing incidence of RA

A large prospective cohort study ( $n = 57,053$ ) investigating the association between dietary factors and risk of RA found that each increase in intake of 30 g fatty fish ( $\geq 8$  g fat/100 g fish) per day was associated with 49% reduction in the risk of RA ( $P = 0.06$ ); however, a medium intake of fatty fish (3–7 g fat/100 g fish) was associated with significantly increased risk of RA (Pedersen et al 2005). No associations were found between risk of RA and intake of a range of other dietary factors, including long-chain fatty acids, olive oil, vitamins A, C, D and E, zinc, selenium, iron and meat. The authors caution that, due to the limited number of patients who developed RA during follow-up, it is not yet possible to make firm conclusions.

## Asthma

$\Omega$ -3 LCPUFAs exhibit anti-inflammatory activity and epidemiological evidence has demonstrated an inverse relationship between fish intake, asthma risk and improved lung function (Wong 2005). Evidence suggests this protective effect may extend back as far as adequate fetal  $\omega$ -3 LCPUFA exposure (Salam et al 2005).

A 2002 Cochrane review of nine RCTs conducted between 1986 and 2001 concluded that  $\omega$ -3 LCPUFA supplementation demonstrated no consistent effect on any of the analysable outcomes: forced expiratory volume in 1 s, peak flow rate, asthma symptoms, asthma medication use or bronchial hyperreactivity (Woods et al 2002). However, one

of the RCTs involving children showed that, when fish oil supplementation was combined with dietary changes, positive results were obtained, as evidenced by improved peak flow and reduced asthma medication use.

An interesting crossover study of 72 asthmatic children aged 7–10 years involved five randomised phases of treatment each lasting 6 weeks: placebo;  $\omega$ -3 (300 mg/day combined EPA and DHA); zinc (15 mg/day); vitamin C (200 mg/day); combination of all nutrients (Biltagi et al 2009). While the  $\omega$ -3 LCPUFA supplementation was associated with improved lung function and a reduction in both sputum production and markers of airway inflammation, these positive effects were significantly augmented when combined with zinc and vitamin C, suggesting that a broader nutritional approach to inflammation and oxidation control results in greatest clinical outcomes.

The equivocal nature of  $\omega$ -3 LCPUFAs interventions, as documented by a 2005 review (Wong 2005), may be clarified in future with the identification of a subtype of asthma more likely to respond to EFA manipulation.

Another interesting paper reports on three patients with disabling salicylate intolerance producing urticaria, asthma and anaphylactic reactions who, following administration of 10 g/day fish oils for 6–8 weeks, experienced complete or virtually complete resolution of symptoms (Healy et al 2008). Treatment response was so effective corticosteroids could be discontinued; however, symptoms reappeared following fish oil dose reduction.

The focus for fish oils in asthma has broadened to include other populations such as athletes. One randomised, double-blind, crossover study of 16 non-atopic asthmatic patients with documented exercise-induced bronchoconstriction compared the effects of 3.2 g of EPA and 2.0 g DHA per day and placebo capsules for 3 weeks. During treatment with fish oils, subjects demonstrated improved pulmonary function to below the diagnostic exercise-induced bronchoconstriction threshold, which was

#### **Clinical note — Oils ain't oils**

Arguably the biggest ongoing methodological sticking point in  $\omega$ -3 research is the heterogeneous nature of the interventions used, which has hindered comparisons, meta-analyses and consensus about their therapeutic actions. While the inferiority of plant-based  $\omega$ -3 EFAs has now been established (see [Are ALA-rich oils a worthy substitute for fish oils?](#)), new questions over different forms — e.g. fish versus supplements, supplemental forms, e.g. TGs, ethyl esters, ratios of EPA to DHA and sources, e.g. krill, algal — have arisen and there is a focused effort to clarify differences in the behaviour and bioavailability of each, such that researchers can better understand disparate outcomes of RCTs and, most importantly, identify superior ways of improving  $\omega$ -3.

#### **Fish versus fish oil supplements**

Underpinning interest and excitement about  $\omega$ -3s, particularly in the context of CVD prevention, stemmed from epidemiological studies of high fish-consuming populations. Early on an assumption was made that these benefits were entirely attributable to the  $\omega$ -3 fatty acids. More recently, however, this has been questioned, with increasing speculation that EPA/DHA may interact with other nutrients, e.g. taurine, selenium, astaxanthin, within fish and/or that dietary fish may displace other unhealthy food choices and therefore may be superior to supplementation with fish oils (Brazionis et al 2012, Deckelbaum & Torrejon 2012, Harvard Heart Letter 2011, He 2009). Some researchers reason that this explains the disparate and somewhat disappointing results of fish oil interventions in some RCTs compared with studies of increasing fish intake in the prevention of CVD, especially fatal CHD (He 2009). An interesting small crossover Australian study found that fish consumption (150 g of Atlantic salmon twice a week) significantly reduced blood pressure and waist circumference when compared with fish oil (1.2 g/day 6 days/week) in spite of comparable changes in  $\omega$ -3 index (Brazionis et al 2012). The current consensus is: eat low mercury-containing fish where possible and if not possible, take supplements; however, more research in other conditions is necessary.

#### **Triglycerides versus ethyl esters**

Several studies presented improved bioavailability from fish oils presented as TGs (either natural or re-esterified) over ethyl esters, including a long-term study (6 months) of moderate intake (1.01 g EPA and 0.67 g DHA) and its effects on RBC levels in healthy individuals (Neubronner et al 2011). Another debate is the impact of the position of the LCPUFAs along the glycerol backbone in these TGs; this differs between natural TGs and chemically re-esterified TGs. However, a small study found that EPA bioavailability at least was significantly greater from the re-esterified TGs than the NTGs (Wakil et al 2010). Other similar studies reviewing DHA uptake, however, are inconsistent.

associated with a concurrent  $\omega$  reduction in bronchodilator use. Measurement of leukotriene B<sub>4</sub> and B<sub>5</sub> levels also confirmed a significant reversal of the inflammatory picture (Mickleborough et al 2006).

#### **Atopic dermatitis and eczema**

In a sample of adult patients ( $n = 53$ ), randomised to 5.4 g/day DHA or isoenergetic saturated fats for 20 weeks, active fish oil treatment produced significant clinical improvements which correlated with increases in plasma DHA (Koch et al 2008);

**Comparing krill, algal and fish oil**

Pressing issues of non-sustainability of both wild harvesting and aquaculture together with increasing contaminants in fish and their products have motivated researchers to search for alternative sources to meet our increasing  $\omega$ -3 demand (Racine & Deckelbaum 2007, Robert 2006). Two key emerging areas are algal and krill oil (*Euphausia superba*). Microalgae, such as *Cryptothecodinium cohnii* and *Schizochytrium* spp., represent part of the coastal food chain as a primary food source for shellfish, contain no contaminants (Arterburn et al 2000, Doughman et al 2007) and are currently commercially developed as sustainable crops (Doughman et al 2007, Whelan & Rust 2006). Krill is by far the most dominant member of the Antarctic zooplankton in terms of biomass, which also makes it attractive as a more sustainable crop (Ulven et al 2011); however, both algal and krill oil are produced at significantly higher production costs (Deckelbaum & Torrejon 2012) and differ chemically and behaviourally from fish oil, e.g. both algal and krill oil contain the astaxanthin not found in fish oil. Also, algal oil predominates in DHA and initial human studies have confirmed both bio-equivalence and comparable clinical efficacy with other DHA sources such as salmon (Arterburn et al 2000, Doughman et al 2007). However, some conditions respond preferentially to higher EPA levels (see Depression), which would limit the application of these products. Attempts to produce high EPA forms have been unsuccessful to date (Deckelbaum & Torrejon 2012).

In contrast, krill oil has a lower yield per gram of LCPUFAs compared with fish oil but its ratio of EPA:DHA is greater. Additionally, LCPUFAs in fish oils are presented as either TGs or ethyl esters; however, 30–65% found in krill oil are incorporated into phospholipids. This phospholipid form appears to favour increased bioavailability and several studies have found that krill oil can produce comparable or superior improvements in  $\omega$ -3 levels in spite of lower actual EPA and DHA content (approximately 68% of that used in fish oil comparator studies) (Banni et al 2011, Ramprasath et al 2013, Schuchardt et al 2011, Ulven et al 2011). Preliminary evidence suggests that krill oil may offer a therapeutic advantage over fish oil in the treatment of metabolic syndrome and weight loss (Banni et al 2011, Vigerust et al 2013); however the vast majority of RCTs performed to date with PUFAs have used fish oils.

however, due to the small sample size, larger studies are required to confirm these preliminary results.

Previously, a double-blind multicentre study involving 145 patients with moderate to severe atopic dermatitis showed that  $\omega$ -3 LCPUFAs (6 g/day) improved clinical symptom scores by 30% after 4 months' treatment (Soyland et al 1994). The results were confirmed by patients' subjective

scoring. An earlier, 12-week, prospective, double-blind study produced similar results, with a dose of 10 g/day (fish oil) improving overall severity of atopic dermatitis and reducing scaling (Bjorneboe et al 1989). A 2012 Cochrane review that included all four studies concluded that two trials suggest a moderate effect on reducing severity in adults; however, further research is needed (Bath-Hextall et al 2012).

**OTHER USES**

Fish oil supplements are also used in the management of acute respiratory distress syndrome, psoriasis, multiple sclerosis, osteoporosis and dysmenorrhoea and in children with dyslexia.

**DOSAGE RANGE**

- Fish should be considered part of a healthy diet for everybody and be consumed at least twice a week. Care should be taken to avoid intake of fish known or suspected to contain higher levels of mercury.
- Additional administration of  $\omega$ -3 LCPUFA supplements should be considered in specific groups.
- Fish meals should consist of deep-sea oily fish, whereas fried or processed fish containing partially hydrogenated fats and salted or pickled fish should be avoided.

**Cardiovascular disease**

Secondary prevention trials after MI indicate that consumption of 0.5–1.8 g/day of EPA and DHA from fish or fish oil supplements may be beneficial. Intake of marine-derived  $\omega$ -3 fatty acids can be increased through diet or with fish oil supplements.

- An expert US panel of nutrition scientists has recommended an intake of 0.65 g/day, whereas the British Nutrition Foundation's recommendation is 1.2 g/day (Din et al 2004).
- National Heart Foundation/Cardiac Society of Australia and New Zealand: >2 servings/week.
- Patients who have experienced coronary artery bypass surgery with venous grafts: 4 g/day of  $\omega$ -3 LCPUFAs.
- Moderate hypertension: 4 g/day of fish oils.
- Elevated TG levels: 1–4.6 g/day of fish oils; Lovaza 4 g/day.

**Other conditions**

- Aggression induced by mental stress: DHA supplementation, 1.5–1.8 g/day.
- Anger and anxiety reduction in polysubstance abuse withdrawers: 2.25 g EPA, 500 mg DHA and 250 mg other  $\omega$ -3 per day.
- Asthma prevention in pregnancy: 2.7 g/day from week 20 gestation until delivery.
- Asthma treatment in children: 300 mg combined EPA and DHA with 15 mg zinc and 200 mg vitamin C per day.
- Atopic dermatitis: 6 g/day fish oils or 5.4 g/day DHA.
- Autism: 5 g/day (limited evidence to support).
- BD: 1 g/day EPA.

- Colorectal cancer: 4.1 g EPA + 3.6 g DHA daily.
- Dementia: DHA supplementation, 4.32 g/day.
- Depression: 1 g/day EPA or a combined supplement with  $\geq 60\%$  EPA.
- Exercise-induced asthma in non-atopic individuals: 3.2 g EPA + 2.0 g DHA daily.
- High blood pressure: 3–5.6 g/day.
- Intermittent claudication: 1.8 g EPA and 1.2 g DHA per day (limited evidence to support).
- Pregnancy: According to the WHO and FAO, the pregnant woman should take at least 2.6 g of  $\omega$ -3 EFAs, incorporating 100–300 mg of DHA daily to look after the needs of the fetus.
- Psychosis prevention in high-risk individuals: 480 mg/day DHA, 700 mg/day EPA for 12 weeks.
- RA: 30–40 mg/kg body weight of EPA and DHA daily.
- Schizophrenia: 2 g/day EPA for a minimum of 3 months.
- Weight reduction and improved insulin sensitivity: 660 mg EPA and 440 mg DHA/day.

### ADVERSE REACTIONS

Fish oil supplementation is generally safe and well tolerated. The few side effects reported are usually mild and can include gastrointestinal discomfort and loose bowels, halitosis and a fishy odour of the skin and urine.

Studies using Lovaza (previously Omacor) report the main side effects as belching, indigestion, taste aversions, fishy taste, infection and flu-like symptoms. Reports have also shown that it may increase levels of alanine aminotransferase; in addition ratio of LDL:apolipoprotein B may increase after pharmacological doses of  $\omega$ -3 (Nicholson et al 2013).

### SIGNIFICANT INTERACTIONS

#### Antiplatelet agents

Theoretically, concomitant use with antiplatelet agents may increase the risk of bleeding; however, multiple clinical studies have found no clinically significant effect on bleeding and one study has suggested that the combined effects may be beneficial (Engstrom et al 2001) — no clinically significant interaction expected at therapeutic doses.

#### Anticoagulants

Clinical studies of surgical patients taking warfarin have not found a clinically significant increase in bleeding. According to one clinical study, bleeding time is increased at very high doses of 12 g/day. Usual therapeutic doses, which tend to fall below this dosage, appear safe in this population, although care should still be taken. Very high doses  $>12$  g should be used only under professional supervision to ensure no adverse outcomes.

#### Non-steroidal anti-inflammatory drugs

Additional anti-inflammatory effects are theoretically possible with concurrent use of fish oil supplements, suggesting a beneficial interaction. Drug dosage may require modification.

### CONTRAINDICATIONS AND PRECAUTIONS

One area of concern is the growing problem of heavy-metal contamination found in fish, specifically mercury. In areas where contamination is possible, fish oil supplements may represent a safer option. According to the *Australia New Zealand Food Standards Code*, fish with higher levels of mercury include: marlin, swordfish, southern bluefin tuna, barramundi, ling, orange roughy, rays and shark. Fish considered to have lower levels of mercury include: mackerel, silver wahoo, Atlantic salmon, canned salmon and canned tuna in oil, herrings and sardines.

People with bleeding disorders should take fish oil supplements under medical supervision.

### PREGNANCY USE

Fish oils appear to be safe during pregnancy at dietary doses and are likely to have benefits.

#### Practice points/Patient counselling

- As precursors of eicosanoids, PUFAs found in fish oils exert a wide influence over many important physiological processes.
- They have demonstrated anti-inflammatory, immunological, neurological, antiplatelet and chemopreventive effects, and a range of beneficial actions within the cardiovascular system.
- Daily ingestion of at least 1 g EPA and DHA (equivalent to fish eaten at least twice weekly) may result in a reduction in total mortality, cardiovascular mortality and morbidity and incidence of dementia and depression.
- Trials generally support the use of supplements in a range of inflammatory and autoimmune diseases such as RA and atopic dermatitis, elevated TGs, hypertension and other cardiovascular conditions, poor cognitive function and diabetes. Preliminary research suggests a possible role in depression.
- People with bleeding disorders should take fish oil supplements under medical supervision.

#### Pravastatin

Low-dose pravastatin combined with fish oil supplementation is more effective than pravastatin alone for changing the lipid profile after renal transplantation, according to one clinical study — potential beneficial interaction.

### PATIENTS' FAQs

#### What will this supplement do for me?

Regular consumption of fish oils may reduce total mortality, cardiovascular mortality and morbidity, dementia, depression and possibly diabetes and various cancers. Additionally, beneficial effects have been demonstrated in a wide variety of conditions.

**When will it start to work?**

This will depend on the dosage taken and indication for use.

**Are there any safety issues?**

People with bleeding disorders should take fish oil supplements under medical supervision.

# Flaxseed oil

**HISTORICAL NOTE** For over 5000 years, flaxseed in its various forms has been a part of the diet of people in Asia, Africa and Europe. It has a long history of use as both a food and a medicine, with the seed being most commonly used. The oil was also popular and has been a traditional food of the Egyptians from the time of the Pharaohs to the present day. The oil is also consumed by the Chinese, who documented its medicinal properties in the Pen-T's AO, the Great Chinese Pharmacopeia (Judd 1995). Its Latin name *usitatissimum* means 'most useful', suggesting its various uses have been recognised for centuries (Kolodziejczyk & Fedec 1995). Interestingly, research into its nutritional properties and effects on human health were not studied in earnest until the 1980s (Cunnane & Thompson 1995). In Australia in 1981, cultivation of a low alpha-linolenic acid (ALA) variety, now known as Linola, was pioneered in an attempt to improve the stability of the oil and increase its commercial viability as a cooking oil. Such modifications were successful and resulted in ALA content <3.0% and a higher concentration of linoleic acid than the naturally occurring form (Bhatty 1995, Hall et al 2006). These modified oils are not used for medicinal purposes.

## OTHER NAMES

Flax oil and linseed oil.

Internationally, it is accepted that 'flaxseed' refers to products for human consumption, whereas 'linseed oil' refers to products that have been denatured, made unfit for human consumption and used in commercial products, such as paints and varnishes.

## BOTANICAL NAME/FAMILY

*Linium usitatissimum* (family Linaceae)

## PLANT PART USED

Fixed oil is derived from the seeds of the plant. Due to the highly polyunsaturated nature of the oil ( $\approx 73\%$ ), extracts are obtained by cold-pressing rather than heat extraction. Flaxseed oil (FSO) is highly susceptible to photo-oxygenation, so it is packaged in opaque bottles. It is also susceptible to auto-oxidation, resulting in the production of hydroperoxides and aldehydes that can give a rancid flavour. Encapsulated FSO is considered more stable, particularly when antioxidants are added (Kolodziejczyk & Fedec 1995).

## Eating the seeds versus defatted flour or taking the oil

With the growth of flaxseed-based bakery goods that have arrived on the market in recent years, it is valuable to review the bioavailability and therapeutic potential of such products. A study compared the effect of consuming flaxseeds (30 g/day) versus both milled flaxseed (30 g/day) and FSO (6 g/day) over a 3-month period on corresponding blood lipid profiles (Austria et al 2008). These results revealed that while the milled preparation and oil extract produced significant physiological increases in ALA levels (with the FSO producing the largest effect), consumption of the whole seeds did not (Austria et al 2008). Effects in individuals consuming the whole seeds also demonstrated the greatest

inter-individual variability, probably related to the degree of chewing each subject performed. Consequently, while the consumption of whole flaxseeds can boost dietary fibre and phyto-oestrogen content, they do not appear to be a reliable means to supplying ALA. In a study comparing the energy and macronutrient balance between flaxseed (FS), defatted flaxseed flour (FF) and flaxseed oil (FO), investigators found a higher energy excretion in the FF and FS groups, and higher total lipid and PUFA (ALA) excretion in the FS group, with a maintenance of body weight despite a higher energy intake (Gonçalves de Oliveira et al 2012). Further, in a study of flaxseed oil bioavailability, emulsified versus non-emulsified FO was examined in rats. ALA bioavailability was improved in rats who ingested FO in the emulsified state.

## CHEMICAL COMPONENTS

Flaxseed oil contains several types of fatty acids (FAs). It contains a high concentration of ALA, ranging from 40% to 60%, and is the most concentrated plant source of omega-3 FA identified to date.

FSO also contains unsaturated FAs, such as linolenic acid, linoleic acid and oleic acid. Linoleic acid (LA or C18:2  $\omega$ -6) and oleic acid each contribute 15% to the total FA content of the oil. Due to the range of FA present, it contains precursors for the omega-3, -6 and -9 families. Environmental factors can profoundly influence the unsaturated FA composition and ratios (Hall et al 2006). FSO may also contain varying amounts of the lignan, secoisolariciresinol diglycoside (SDG), which is a precursor to enterodiol and enterolactone.

Flax seeds contain 41% fat, 28% dietary fibre, 21% protein and significantly higher amounts of lignans, which behave as phyto-oestrogens (Morris 2001). This review, however, focuses on FSO.

**Clinical note — Is FSO equivalent to the fish oils?**

FSO has been commercially promoted as the vegetarian or vegan alternative to fish oils, with many of the health benefits ascribed to fish oils also being attributed to FSO. A review of the literature suggests that FSO is unlikely to be equipotent with fish oils in the treatment of a variety of conditions.

The ALA present in FSO can theoretically undergo desaturation and elongation to synthesise eicosapentaenoic acid (EPA) and docosahexaenoic (DHA), which are found in fish oil; however, most studies using oral FSO intake demonstrate only moderate increases in EPA and DHA remains unchanged (Allman et al 1995, Arterburn et al 2006, Barcelo-Coblijn et al 2008, Kelley et al 1993, Mantzioris et al 1994, Nestel et al 1997). Although results from one early study suggest that increases in DHA levels may be achieved with long-term supplementation (Cunnane et al 1993), more recent studies fail to confirm this result (Barcelo-Coblijn et al 2008, Harper et al 2006a, Hussein et al 2005).

Conversion rates of ALA to EPA and docosapentaenoic acid (DPA) are reported to be <10% and approximately 8%, respectively, whereas the DHA yield ranges from 0% to 0.5%. One explanation for this is that DHA synthesis is under separate regulatory control, a hypothesis supported by enzymatic studies (Burdge 2004). Theoretically, therefore, a 20 mL serve of FSO, providing 11.1 g of ALA, would result in a maximum of 880 mg DPA and 5 mg of DHA. A recent study investigating optimal minimal dosing of FSO, however, reported that increased red blood cell omega-3 concentrations are evident at a minimum of 2.4 g/day taken over 2 weeks, with the largest effect seen at the 6–8-week timeframe (Barcelo-Coblijn et al 2008). These authors also report that 1.2 g/day of fish oil produced comparable changes, concluding that FSO or other plant-based ALA sources represent a realistic alternative source of omega-3s, and at doses much lower than previously studied.

However, there is marked inter-individual variation in conversion efficacy, even in the face of comparable background diets and some notable gender differences, with resultant DHA typically undetectable in males consuming high-dose ALA (Arterburn et al 2006). Adding to this puzzle is a

wide range of other variables that can inhibit the conversion of ALA into its metabolites. For instance, high dietary intake of linoleic acid (LA), common in Western cultures (Arterburn et al 2006, Breslow 2006, Faintuch et al 2011), inhibits both the uptake of ALA and its conversion to long-chain metabolites due to competition for shared enzymes. An interesting study conducted in 1998, which used radioactively labelled ALA, showed that a diet high in omega-6 fats reduced conversion by 40–50% (Gerster 1998), resulting in 70% net reduction of long chain omega-3 end products (Arterburn et al 2006). This adds weight to the argument that the ratios of FAs may have the primary influence on their resultant health benefits. The authors of this study suggest that the ratio of omega-6:omega-3 should not exceed 4. In contrast, the typical American diet demonstrates an LA:ALA ratio of  $\geq 11.5$  (Arterburn et al 2006, Breslow 2006). However, there are authors who refute that the ratios are a major determinant (Goyens et al 2006).

Other studies have reported abnormal or compromised activity of the delta-6 and delta-5 desaturase enzymes in the elderly, diabetics and patients with a variety of metabolic disorders, as well as those individuals with increased dietary intake of saturated fats, *trans*-fatty acids and alcohol (David & Kris-Etherton 2003). Studies using radioisotopes of ALA have revealed significant gender differences in conversion capability, with women demonstrating higher levels of FA metabolites. It is believed that this is due to their higher oestrogen levels, a theory supported by the increased conversion capacity evident in women taking synthetic oestrogens and speculated as representing a physiological adaptation that ensures adequate essential fatty acid (EFA) delivery to the fetus in pregnancy (Burdge 2004).

Finally, it appears that ALA conversion to long chain omega-3 FA is also self-limiting, with high intakes producing significantly increased oxidation and impairing conversion into EPA and DHA (Arterburn et al 2006, Schwab et al 2006). Based on the available evidence, it appears that ALA conversion is relatively inefficient in humans, making ALA a poor means of increasing omega-3 levels (Arterburn et al 2006).

F

**MAIN ACTIONS**

The main actions of FSO have been attributed to its high ALA content. ALA is subject to three different metabolic fates: (a) incorporation into structural, transport or storage pools, (b) beta-oxidation as an energy source, and (c) elongation and further desaturation to form EPA, DPA and DHA. It appears that all three contribute to the biological effects of this oil.

ALA's direct role in cell membrane structure is likely to be minor, with ALA representing less than 0.5% of the total FA in cell membranes and blood lipids in healthy adults and possessing a limited distribution (e.g. adipose, rectal epithelium, cheek, heart) (Arterburn et al 2006). However, its limited propensity to generate the  $\omega$ -3 metabolites, EPA and DHA, the major FAs in cell membranes, could represent an indirect effect via this mechanism

(Burdge 2004). Studies exploring the metabolism of ALA have revealed that 22% of ALA undergoes beta-oxidation in women and 33% in men. Once broken down, the carbon chain can be used as fuel or in the synthesis of cholesterol and other fatty acids such as palmitic, palmitoleic, stearic and oleic acids de novo (Burdge 2004). FSO also influences the eicosanoid production cascade via conversion of the  $\omega$ -3 and  $\omega$ -6 parent FAs in FSO to their respective metabolites.

It is also thought that some of the actions of FSO may be independent of its FA content and can be attributed to the lignan SDG. This has been supported by research conducted by Prasad et al in 1998 and again in 1999. The SDG has been confirmed as the main lignin present in flaxseed, and that this lignin is converted to the mammalian lignans enterodiol (ED) and enterolactone (EL) by gastrointestinal microbiota (Bassett et al 2009, Dukes et al 2012, Gagnon et al 2009, Park & Velasquez 2012, Rhee and Brunt 2008). In a study of ruminal metabolism of flaxseed in dairy cows, researchers identified that concentrations of SDG were higher in urine, plasma and milk when placed in the rumen of the cows and that ruminal microbiota are important in the metabolism of flaxseed lignans.

### Anti-inflammatory

Metabolites of ALA and LA act as substrates for the formation of the anti-inflammatory eicosanoids, comprising prostaglandins, thromboxanes and leukotrienes (Gerster 1998). ALA suppresses AA production by interfering with the conversion of LA to AA, and reduces the biosynthesis of inflammatory eicosanoids, although not to the same extent as EPA and DHA (Morris 2001). Cytokines, another important group of inflammatory mediators, are generated in response to these eicosanoids and are influenced by changes in the  $\omega$ -3: $\omega$ -6 ratios in cell membranes (James et al 2000). In one study, ingestion of FSO (equivalent to 13.7 g/day ALA) for 4 weeks by healthy male subjects resulted in a 30% reduction in TNF-alpha, 31% reduction in IL-1-beta, 29% reduction in eicosanoids thromboxane B(2) and 30% reduction in PGE<sub>2</sub> (Caughey et al 1996). In contrast, more recent studies have failed to demonstrate anti-inflammatory effects (Barcelo-Coblijn et al 2008, Paschos et al 2007, Sturgeon et al 2011, Zong et al 2013).

In animal models, ALA has consistently demonstrated eicosanoid-mediated anti-inflammatory effects; however, the magnitude of the effect has been dependent on the levels of both ALA and LA in the diet, duration of use and type of tissue studied (Cunnane & Thompson 1995).

### Immune effects

Evidence of ALA deficiency has been reported in patients on prolonged total parenteral nutrition (TPN), which resulted in reduced T-helper cells to below the normal range and impaired proliferation of peripheral blood mononuclear cells. Although

supplementation with small doses of ALA corrected these abnormalities, the effect of ALA on human immune cells appears to be paradoxical, with evidence of immune function inhibition at higher doses ( $\geq 40$  mL/day FSO) (Kelley 1992).

More recently, animal models have suggested some beneficial effects of chronic flaxseed intake on haematological and immunological function in the development of Wistar rats. Female rats were fed 25% flaxseed during gestation, and continuing in the male newborn pups through to adult life (250 days old). A significant increase in haemoglobin and albumin, and a smaller percentage of segmented lymphocytes was observed, as well as a significant reduction in body mass (Ferreira Medeiros de Franca Cardozo et al 2011). In human studies, researchers have not found convincing evidence of increased immune function as a result of effects of flaxseed lignan, secoisolariciresinol diglucoside (SDG) (Rhee & Brunt 2008). More research is required.

### Cardiovascular effects

Because ALA can be converted to long-chain ( $\omega$ -3) PUFA in humans and may potentially reproduce the beneficial effects of fish oils, FSO and ALA have been studied as possible preventive or treatment agents for cardiovascular disease. Epidemiological evidence of secondary coronary event prevention from ALA, in the context of a modified Mediterranean diet, support this premise (Schwab et al 2006). While numerous studies have suggested that FSO and ALA exert a myriad of different mechanisms in the body, which can be beneficial in cardiovascular disease, inconsistent results have been reported. In secondary prevention trials, such as the Lyon Diet Heart Study (1999), reporting on the effects of the Mediterranean Diet, it was shown that dietary ALA has a significant cardioprotective effect, with a decreased risk of recurrent fatal and nonfatal myocardial infarction and a significant reduction in risk (73%) in primary end points of cardiac mortality and morbidity (Rodriguez-Leyva et al 2010).

In a symposium paper, researchers suggest that the  $\omega$ -3 ALA component in FXO contributes to the antiatherogenic effect via anti-inflammatory and antiproliferative mechanisms. They suggest that dietary flaxseed may also protect against ischaemic heart disease by improving vascular relaxation responses and inhibiting the incidence of ventricular fibrillation (Bassett et al 2009).

### Antithrombotic and antiplatelet activities

The question of whether supplementation with ALA affects platelet aggregation appears to now suggest that this is not part of flaxseed's main profile (Kaul et al 2008; Finnegan et al 2003; Austria et al 2008)). A major determinant appears to be the degree of conversion to EPA (Garg et al 1989), and the ratio of  $\omega$ -3 PUFAs to  $\omega$ -6 PUFAs in modulating haemostatic function (Rodriguez-Leyva et al 2010). When there is an increase in

total EPA and reduced AA, due to ALA inhibition of LA conversion, the result is EPA replacing AA in the cell membrane and a decrease in thromboxane synthesis. In addition, SDG, another component of FSO, is metabolised to enterolactone and enterodiol, and these substances may have antiplatelet-activating factor activity, although studies suggest the results are isolated and modest at best. Due to the variable lignan content of FSO, it is difficult to determine the clinical significance of this (Prasad 1999). Studies assessing the actual anti-aggregatory effect of FSO in humans have produced mixed results.

### Reduced endothelial inflammation

A number of studies have confirmed that consumption of high-dose FSO reduces endothelium inflammation. One study assessing the cardiovascular effects of a diet in which 6.5% of total kilocalorie intake was contributed by ALA and compared with the Standard American Diet (SAD) showed that the ALA-enriched diet produced a 75% reduction in C-reactive protein, a 19% reduction in cellular adhesion molecule and a 15.6% reduction in vascular cellular adhesion molecule (VCAM) (Zhao et al 2004). An earlier study had reported these findings, demonstrating a 28% reduction in VCAM with additional reductions in soluble E-selectin (17%) (Thies et al 2001). ALA levels examined as part of a plasma cholesterol fraction have been found to be negatively correlated with CRP concentrations (Klein-Platat et al 2005). Research in the mouse model demonstrated that flaxseed (0.4 g/day) inhibits the expression of inflammatory markers like interleukin (IL)-6, mac-3 and vascular cell adhesion molecule-1 (VCAM-1) in aortic atherosclerotic tissue (Dupasquier et al 2007).

### Lipid-lowering effect

Whole flaxseed is the form most commonly investigated in lipid-lowering studies, because the high fibre content and ALA have been speculated to act synergistically, therefore there are relatively few studies using FSO. Those that have been conducted with FSO have produced conflicting results with an almost 50/50 weighting of research showing no effect (Austria et al 2008, Harper et al 2006, Kaul et al 2008, Schwab et al 2006) or a positive one. At worst, FSO has produced increased fasting triacylglycerol concentrations and lower HDL cholesterol (Bemelmans et al 2002, Finnegan et al 2003, Wilkinson et al 2005). At best, it has been described in earlier studies as having comparable effects with bioequivalent doses of fish oils (Harris 1997, Singer et al 1986). The reality probably lies somewhere in between; however, further investigation is required. The results of a small study of 57 men by Wilkinson et al (2005), who substituted 45 g of fat per day with 15 g/day ALA derived from FSO over 12 weeks, adds to the puzzle. While confirming the mixed cardiovascular effects noted above, this treatment group also demonstrated a reduction of total

cholesterol by 12.3% in comparison to a reduction of 7.3% in the group receiving equivalent LA. While another study comparing the effects of an ALA-rich (6.8 g/day) versus EPA/DHA-rich (1.6 g/day) diet in mildly hypercholesterolaemic elderly subjects over 6 weeks revealed improved lipid responses in the ALA than the EPA/DHA group (Goyens & Mensink 2006).

The same equivocal trend is evident from studies assessing the effects of FSO on lipoproteins. Zhao's trial (2004) using an ALA-enriched diet produced a reduction in apolipoproteins A1 and B, the latter by almost 10%, however, more recent studies administering  $\geq 3$  g/day of ALA from FSO over 6–26 weeks failed to demonstrate any effect on lipoprotein particle or size concentrations (Goyens & Mensink 2006, Harper et al 2006b). In spite of these seemingly disappointing findings, some researchers note a preventive effect against cardiovascular morbidity associated with increased ALA consumption in the substantial Lyon diet study was not accompanied by cholesterol changes and therefore may point to an alternative mechanism (Kaul et al 2008). Additionally, the context of diet may be important. In a rat model, rats fed a high-fat, high-fructose diet supplemented with lignan-enriched flaxseed powder (LEFP) showed an improvement in lipid profile, as well as reduced bodyweight and fat accumulation and blood pressure control, compared to the high-fat, high-fructose diet, the normal control diet and the normal diet supplemented with LEFP (Park and Velasquez 2012). In a healthy rat model, supplementation with 20% FS raised HDL-cholesterol, and reduced LDL-cholesterol, glucose and uric acid indicating preventive potential of FS for CVD (Tomaz Pacheco et al 2011).

### Antiarrhythmic

Four studies have identified an antiarrhythmic effect mediated by ALA (Albert et al 2005, Ander et al 2004, Christensen et al 2005, Djoussé et al 2005), although one meta-analysis concluded otherwise (Matthan et al 2005). Although the majority of research has been conducted in animals, one of the most interesting human trials involved 106 women with a mean age of 59.5 years referred for coronary angiography due to suspected coronary artery disease. Following adipose sampling for ALA levels and monitoring of 24-hour heart rate variability (HRV), it was concluded that a positive and independent association was present between ALA in adipose tissue and HRV, which was even stronger in smokers (Christensen et al 2005).

### Antiatherogenic

Earlier positive findings and promising epidemiological data have been substantially challenged by RCTs of FSO in atherosclerosis. Following earlier positive outcomes in cardiovascular disease trials with whole flaxseed, a 1999 study showed that a low-ALA variety could produce comparable results with the earlier trials, suggesting that the

antiatherogenic properties of flaxseed are independent of its ALA content (Prasad 1999).

More recent large-scale epidemiological studies continue to suggest a relationship between higher ALA intake and reduced coronary artery calcification (Djouisse et al 2005); however, there is ongoing criticism that important variables have not been sufficiently accounted for, such as corresponding reductions in *trans*-FAs (Harris 2005, Wilkinson et al 2005).

### Antiproliferative

ALA has demonstrated the capacity to inhibit tumour progression in animal models of mammary tumour (Chen et al 2002, Cognault et al 2000); however, the clinical significance of these findings needs to be examined further. An immunostimulant action, which is both eicosanoid and non-eicosanoid mediated, has been suggested as one possible mechanism of action. Another theory suggests that through ALA's competitive inhibition of LA, tumour cells may not receive sufficient LA, which would inhibit further cell growth (Johnston 1995). It is interesting to observe that higher dietary ALA intake is associated with a reduction in cancer deaths; however, this is not seen with higher EPA/DHA intakes, suggesting that the protective effect is not reliant on the conversion of ALA to EPA/DHA (Cunnane 1995). In addition, results from epidemiological studies show an association between low ALA consumption in humans and increased cancer deaths in general (Dolecek 1992).

Animal studies testing SDG and its metabolites from the seeds have produced promising results and suggest that they may act as selective oestrogen receptor modulating agents and therefore play a protective role against oestrogen-dependent cancers (Kitts et al 1999, Wang et al 2005).

### Hypotensive

The mechanism for ALA's potential hypotensive action remains to be elucidated and in light of the bulk of negative findings, more research to support these current results is necessary (Paschos et al 2007). Research investigating the effects of FS on inflammation and carotid diameter in morbidly obese patients may point to a possible mechanism. Researchers found that after 12 weeks of flaxseed supplementation, large artery diameter and inflammatory markers deteriorated less compared with controls whose clinical course continued to deteriorate (Faintuch et al 2011). In a review of flaxseed on cardiovascular effects, flaxseed was proposed to protect against the loss of endothelial-dependent vascular function, which is induced by hypertensive or cholesterolaemic conditions (Bassett et al 2009). The effects of flaxseed on the preservation of arterial relaxation requires further investigation.

### Insulin sensitising

Preliminary animal studies suggested a protective role for ALA against the development of insulin

resistance and an ability to counter the associated oxidative stress (Ghafoorunissa & Natarajan 2005, Suresh & Das 2003). However, a series of clinical trials examining high-dose FSO in patients with type 2 diabetes failed to demonstrate any positive effect on glycaemic control (Barre et al 2008, Schwab et al 2006). Nor was any effect demonstrated in post-menopausal women in circulating levels of insulin and IGF-1 or C-peptide (Sturgeon et al 2011).

### CNS development

Animal studies present some evidence for FSO in the fetal and early development of the central nervous system (CNS) in rats. The importance of essential fatty acids (EFA), especially omega-3 FAs, in the CNS development of newborns is known. It was found that there were significant increases in the brain weight of newborn pups from mothers fed with FSO, and that  $\omega$ -3 FAs were found to be incorporated into the brain tissue of the pups (Almeida et al 2011). In a further study, body growth was shown to be adequate and brain development, incorporating omega-3 FA into the tissue, was increased up to 52 days post-birth, representing equivalent childhood and adolescence of rats (Ferreira et al 2011). In a study of behavioural development and habituation to environment, brain weight was superior in the FSO rats, as was aggregation of omega-3 FA in the brain tissue. Habituation and behavioural management in this group was superior demonstrating lower levels of stress (de Menezes et al 2011).

### Antioxidant

The health benefits and preventative capacity of antioxidants for chronic diseases and ageing is well documented; however, in recent years, peptides with antioxidant capacity have gained interest. These peptides are reported to be released from the parent protein by gastrointestinal enzymes and/or microflora or in vitro by stimulated digestion using isolated enzymes (Silva et al 2013). The preliminary research suggest that Flaxseed protein hydrolysate (FPH) and Flaxseed protein isolate (FPI) may have some antioxidant capacity, and that hydrolysis produced by gastric conversion to produce peptides in vitro may have an optimal range. However, in this study, FPI or FPH did not produce a protective effect on U937 human cell lines. Interestingly, there have been reports of a converse effect where flaxseed supplementation produced an increase in oxidative stress (Bassett et al 2009). Further research is required to understand the potential of flaxseed's antioxidant capacity (Silva et al 2013).

## CLINICAL USE

### Reduced mortality in coronary heart disease

The most likely mechanism by which ALA may prevent coronary heart disease (CHD) mortality is by reducing cardiac arrhythmia (Rodriguez-Leyva

et al 2010). In Western populations, almost 50% of all deaths from cardiovascular disease can be attributed to sudden cardiac death and the majority of sudden deaths are directly caused by acute ventricular arrhythmia (Brouwer et al 2004). A review in 2001 (Lanzmann-Petithory 2001) and a meta-analysis of three studies in 2004 (Brouwer et al) both found in favour of a protective effect from increased ALA consumption against fatal CHD (RR 0.24). The dose associated with this trend was small; only 1–3 g/day ALA higher than controls (Brouwer et al 2004). A study published in 2005, which derived data from the Nurses' Health Study (Albert et al 2005), found that women consuming ALA in the highest two quintiles had a 38–40% lower risk of sudden cardiac death than women in the lowest quintile; however, the protective effect did not extend to other fatal forms of CHD or non-fatal myocardial infarction. A cross-sectional study found that in both men and women high levels of dietary ALA were associated with a shorter QT interval, and suggests a protective effect against abnormally long repolarisation, and therefore risk of ventricular fibrillation (Djoussé et al 2005). Animal data also demonstrated shorter QT intervals and a marked reduction in ventricular fibrillation, and suggest alterations in the calcium/sodium exchange (Ander et al 2004).

Much criticism has been directed at those researchers wanting to extrapolate prescriptive advice from these findings. An editorial by Harris (2005) notes that an early primary prevention study with ALA in CHD has been conducted and that was in the 1960s. The 1-year trial involved 13,578 Norwegian men and compared 10 g of FSO (providing 5.5/day ALA) with a sunflower seed placebo. In the analysis, there was no demonstrable difference in end points between the two groups. Recent attempts to explain this lack of effect, such as high baseline  $\omega$ -3 consumption by this population, appear to be well founded (Mozaffarian et al 2005).

The research regarding ALA found in flaxseed and its effects on CAD is not as mature as the marine  $\omega$ -3 PUFAs, EPA and DHA data, and the role of ALA in human nutrition is still being debated. In a review by Rodriguez-Leyva et al (2010) on the effects of flaxseed, it was reported that results from nine major studies suggest that ALA levels are inversely correlated with primary cardiovascular events. The studies used large sample sizes and extended over a relatively long follow-up time. In animal studies, researchers found that atherosclerosis was significantly prevented by flaxseed supplementation in the hypercholesterolaemic rabbit (Dupasquier et al 2006) and in the cholesterol-fed, low-density lipoprotein (LDL) receptor-deficient mouse; however, the review speculates that because there was relatively poor correlation with cholesterol-lowering effect of flaxseed, the hypolipidaemic effect is likely to be only one of the contributing factors to its antiatherogenic potential (Rodriguez-Leyva et al 2010).

In secondary prevention trials, as stated above, ALA was associated with a decreased risk of recurrent fatal and nonfatal myocardial infarction and cardiac mortality and morbidity (Lyon Diet Heart Study — de Lorgeril et al 1999).

### Anticlotting

There have been a surprising number of studies investigating the influence of ALA from FSO on coagulation and fibrinolysis, and enormous variation in results. Methodological issues have plagued the overall quality of evidence, with small sample sizes, inconsistent methodologies and diverse sample characteristics making interpretation difficult.

One early study compared different dietary ratios of  $\omega$ -6 and  $\omega$ -3 EFAs in relation to prostanoid production in a group of normolipidaemic men (Kelley et al 1993). The high ALA dietary intervention constituted an overall  $\omega$ -6: $\omega$ -3 ratio of 2.7 versus control ratio of up to 27.4. Following the 18 days of the intervention, groups showed significant differences in measured outcomes, notably, that 6-keto-PGF<sub>1 $\alpha$</sub>  was significantly higher following the high ALA diet, but no evidence of significant effect on bleeding time or thromboxane B<sub>2</sub> production. A second study published in the same year also failed to show an effect on clotting; however, the dose of FSO used was only 4.3 g/day (Kelley et al 1993). In contrast, the results of a study using a much larger dose of 40 g/day of FSO over 23 days in 11 healthy men showed that FSO significantly reduced collagen-induced aggregation response when compared to 40 g/day sunflower seed oil (Allman et al 1995).

A follow-up study of 29 healthy males that was conducted over 6 weeks investigated the effects of a diet in which approximately 7% of the total kilocalories from polyunsaturated fat was made up of either an ALA-rich ( $\omega$ -3: $\omega$ -6 = 1:1.2) or LA-rich diet ( $\omega$ -3: $\omega$ -6 = 1:21). The ALA-enriched diet resulted in triple the EPA phospholipid levels compared to the LA-enriched diet, but had no demonstrable effect on coagulation or fibrinolysis, other than an increase in the ratio of activated protein C. The authors speculated that the latter finding may still prove significant, but suggest that future studies should be conducted in patients with vascular pathology, as healthy clotting profiles may have obscured the true effects of FSO (Allman-Farinelli et al 1999).

In the same year, another group of Australian researchers published the results of their study of 17 vegetarian men who were assigned to either a low- or a high-ALA diet (derived from FSO) for 28 days following a run-in baseline diet for 14 days. Again there were no significant differences in prothrombin time, activated partial thromboplastin time or plasminogen activities with the different ALA diets, despite increases in EPA and DPA levels (Li et al 1999).

Since 1994, Mutanen and Freese have conducted many studies assessing the effect of ALA and

LA:ALA ratios on haemostatic factors (Freese et al 1994, Freese & Mutanen 1997, Mutanen & Freese 2001). Their 1997 study was the largest and involved a sample of 46 subjects who were given FSO to provide 5.9 g/day ALA or a fish/sunflower oil combination equal to 5.2 g/day EPA/DHA over 4 weeks. Extensive analysis of the sample throughout the intervention, as well as at the 12-week follow-up, revealed no difference in collagen-induced platelet aggregation, thromboxane production or bleeding time between the two groups, suggesting equivalent anticoagulant effects for FSO and fish oil when consumed in comparable quantities. This was despite smaller increases in EPA levels in the platelets of the subjects taking FSO.

The largest and most recent trial (Finnegan et al 2003) compared the effects of small increases in ALA (4.5 or 9.5 g/day) and EPA and DHA (0.8 or 1.7 g/day EPA + DHA) intake on blood coagulation and fibrinolytic factors over 6 months. The randomised, placebo-controlled, parallel study of 150 moderately hyperlipidaemic subjects found no significant differences in coagulation or fibrinolysis for any intervention.

The most recent review of flaxseed by Rodriguez-Leyva et al (2010) report that although anticoagulant effects of flaxseed have been noted in diabetic patients (Tohgi et al 2004), flaxseed ingestion does not influence platelet function in healthy individuals.

Currently, the evidence is equivocal, but may indicate a minor antiaggregatory role for FSO in high doses. Further research, with more heterogeneous designs, is required to form any valid conclusion.

### Endothelial function

In one 12-week study of healthy subjects aged 55–75 years, low levels of ALA (equivalent to approximately 5 mL/day of FSO) were shown to decrease some markers of endothelial activation (Thies et al 2001). More specifically, ALA decreased the plasma concentrations of soluble VCAM-1 by 16% and soluble E-selectin by 23%.

### High blood pressure

In spite of a large number of studies which failed to demonstrate a relationship between ALA intake and blood pressure, a prospective trial, administering 8 g/day of ALA from FSO to middle-aged dyslipidaemic men over 12 weeks, produced a small but significant reduction in median blood pressure readings of 3–6% ( $\approx 5$  mmHg) when compared to a similarly high intake of LA from safflower oil (Paschos et al 2007). The clinical significance of this result is questionable.

### Lipid-lowering

The largest trial involved over 150 moderately hyperlipidaemic patients in a double-blind, placebo-controlled, 5-arm parallel design conducted over 6 months. Two groups received FSO at different

doses (equivalent to 4.5 g/day and 9.5 g/day of ALA), two groups received bioequivalent levels of EPA/DHA, and one group received LA and served as a control group. Although the higher ALA dose induced comparable changes in serum and cell membrane EPA levels to the fish oil group, ALA failed to significantly lower lipid levels, whereas EPA and DHA reduced triacylglycerides (Finnegan et al 2003).

Alternatively, a shorter study of only 2 weeks supplementing with much higher doses of FSO (60 mL/day) or sunflower oil or 130 g/day of mackerel in hypertensive males produced positive results. Subjects taking either FSO or consuming fish experienced an equal decrease in serum triglycerides, total cholesterol and LDL cholesterol (Singer et al 1986). Interestingly, FSO intake resulted in only marginal increases in EPA levels, suggesting that lipid-lowering activity is not reliant on conversion to EPA.

One possible explanation for this comes from the results of a number of trials conducted by Prasad (Prasad 1997, 1999, Prasad et al 1998), who investigated low-ALA FSO and later isolated extracts of the lignan SDG and found significant lipid-lowering effects in animal models. In rabbits, administration of the lignan at high doses produced significant changes to blood lipids, including a 33% reduction in total cholesterol, 35% reduction in LDL cholesterol and an astonishing increase of over 140% in HDL cholesterol by week 8 (Prasad 1999). As exciting as these results are, it is difficult to determine the clinical significance of these findings because the lignan content of FSO is variable. It is possible that the high dose of FSO (60 mL/day used by Singer et al 1986) contained a substantial amount of SDG, which could explain the effects seen; however, this is speculation. Results from a rat study confirmed these effects of lignin SDG on lowering serum total and LDL-cholesterol levels and hepatic lipid accumulation. There was also a reduction in body weight gain (Felmlee et al 2009).

In research investigating the effects of supplementation in healthy volunteers with fish oil, flaxseed oil and hempseed oil, compared with placebo, none of the groups showed any differences in lipid parameters, although the flaxseed group showed a transient increase in ALA levels (Kaul et al 2008). Choice of subjects may be a factor in interpreting the effects of PUFA supplementation in healthy individuals. Prospective studies in at-risk populations may be required to elucidate the effectiveness of PUFAs on cardiovascular health.

Fukumitsu et al (2010) have also reported on the effects of the lignan SDG intake on hypercholesterolaemia and liver disease risk factors in moderately hypercholesterolaemic men. They found that 100 mg SDG significantly reduced the ratio of LDL/HDL cholesterol at 12 weeks. The participants also had a significant decrease in hepatic biomarkers, indicating a protective effect for hepatic disease risk in moderately hypercholesterolaemic men.

In a recent study, high-lignan flaxseed (FLX) decreased total cholesterol, LDL and oxidised-LDL in 36 healthy men and women. The difference in effect between high-lignan FLX and regular lignin FLX on oxidised-LDL was highly significant. The potential for decreasing oxidised-LDL is important, as it is an independent risk factor for CVD (Almarino et al 2013).

Interestingly, Akpolat et al (2011) report a significant decrease in the serum cholesterol and lipid levels in hyper-lipidaemic rats fed a high cholesterol diet treated with FXO. This was accompanied by a decreased deposition of neutral lipid, and prevented renal injuries associated with hypercholesterolaemia in these rats.

In an animal study, a rise in serum cholesterol was induced by ovariectomy in five groups of hamsters. Results found that both FLX and FXO more than doubled the hepatic protein levels, and researchers suggest that increased bile acid synthesis is only one of the major cholesterol-lowering mechanisms of FLX and FXO (Lucas et al 2011).

In an RCT crossover trial of 36 hypercholesterolaemic men and women, researchers found that FXO consumption significantly reduced total cholesterol by 11%, LDL:HDL ratio by 7.5% and significantly decreased E-selectin concentration, which is an inflammatory biomarker. The cardioprotective potential of FXO may be through lipid-lowering effects, and the mechanism of action may include anti-inflammatory effects (Gillingham et al 2011).

In a review by Bassett et al (2009), researchers report on multiple clinical dietary interventions, stating that daily flaxseed consumption can modestly reduce circulating total cholesterol (TC) by 6–11%, and low-density lipoprotein (LDL) by 9–18% in normolipidaemic humans, and by 5–17% for TC and 4–10% for LDL cholesterol in hypercholesterolaemic patients, as well as lowering various markers associated with atherosclerotic CVD in humans. The review suggests that the dietary fibre and lignan content provides the hypocholesterolaemic action, and that flaxseed oil fractions may, in fact, increase circulating lipid levels (Bassett et al 2009).

### Anti-inflammatory effects

Inflammation from a variety of causes, such as infectious disease or hyperlipidaemia, has a deleterious effect on vascular function and is a major contributor to atherosclerosis (Bassett et al 2009). There have been inconsistent results of studies of flaxseed and its anti-inflammatory effects. Many studies that have been mentioned in this monograph report little or no change to serum levels of IL-6, TNF- $\alpha$ , CRP and soluble adhesion molecules (Dodin et al 2008, Hallund et al 2008, Kaul et al 2008). However some studies have reported an anti-inflammatory action. Faintuch et al (2007), in an investigation of obese adults, had significantly lower inflammatory markers (CRP, SAA, fibronectin) after 2 weeks of flaxseed supplementation. Three further studies reported beneficial effects on inflammation markers

(Caughey et al 1996, Hallund et al 2008, Thies et al 2001). These inconsistencies require further clarification in future studies, but it is possible that the anti-inflammatory benefits are more pronounced in compromised individuals.

### Menopausal symptoms

A recent RCT of 38 post-menopausal women examined the effectiveness of partially defatted ground flaxseed in bread on number of daily hot flushes, a menopausal index (Kupperman Menopausal Index (KMI)) and endometrial thickness. Plasma lipid profile (total cholesterol and HDL, LDL and VLDL cholesterol fractions and triglycerides) and the hormones oestradiol, FSH, TSH and free thyroxin were also measured. Both the flaxseed and the placebo group had significant, but similar, reductions in hot flushes and the menopausal index following 12 weeks of treatment. There were lower levels of triglycerides in the flaxseed group, and HDL, but higher LDL concentrations. Both groups had unaffected endometrial thickness. The authors acknowledge that urine tests to confirm levels of enterodiol and enterolactone were not performed (Simbalista et al 2010). However, the outcomes from a randomised study in Brazil showed lower frequency scores for hot flushes and a tendency for lower KMI scores in the flaxseed extract and the SDG groups as compared with placebo. Consistently with the previous studies there were no changes in biomarkers of oestrogenic effects to endometrial thickness, or on the vaginal epithelium (Constantino Colli et al 2012).

More recently in an RCT of healthy menopausal women, flaxseed was not found to be effective in reducing either the severity or the frequency of hot flushes (Carlson et al 2011). Additionally, in a RCT of menopausal women with or without breast cancer, flaxseed bars with 410 mg of lignans versus placebo for 6 weeks found both groups had a reduction in hot flushes, but this was not significantly different, and both experienced mild gastrointestinal effects likely to be due to the fibre content of the bars (Pruthi et al 2012).

In a large, well-controlled RCT of 179 menopausal women, flaxseed supplementation versus wheatgerm placebo for 12 months was investigated for its effect on markers of CVD risk. FS was found to increase  $\omega$ -3 FA (total, docosapentaenoic and ALA), but demonstrated a limited effect on apolipoprotein metabolism (Dodin et al 2008). Similarly, in a placebo crossover study, 22 healthy menopausal women consumed a low-fat muffin with or without the flaxseed lignin SDG, daily. Levels of C-reactive protein (CRP) were significantly reduced in the SDG group, with CRP being a biomarker of inflammation. CRP levels increased in the placebo group over the course of the trial. However, there were no differences in concentrations of other inflammation biomarkers (IL-6, TNF- $\alpha$ , soluble intracellular adhesion molecule-1, soluble vascular

cell adhesion molecule-1 and monocyte chemoattractant protein-1) (Hallund et al 2008).

### Lung disease

A group of researchers has been investigating the effects of flaxseed on various forms of lung disease and genetic changes seen. Their results suggest that flaxseed has a protective role in the mouse model on acute and chronic lung injury (Christofidou-Solomidou et al 2011, Kinniry et al 2006, Lee et al 2008, Lee et al 2009). They have confirmed that it takes 3 weeks of supplementation in the mouse model for the flaxseed lignans to reach steady state, and in their latest research looked at specific gene groups shown to be relevant to acute lung injury. The results showed that a significant proportion of the genes were differently expressed following exposure to flaxseed supplementation, including genes in protective pathways. They provide valuable insight into modulation of gene expression in lung tissue and how they might be related to protective mechanisms, confirming therapeutic applications of flaxseed on lung disease (Dukes et al 2012). These exciting results need to be followed up with human trials.

### Appetite suppression and weight maintenance

In a study investigating the impact of dietary flaxseed on appetite and post-meal lipaemia in young men, an inhibitory effect was seen on the hunger-signalling hormone ghrelin on the day consumption,

combined with a delay in gastric emptying observed when FS was in a high mucilage form. However, subsequent energy intake was not affected (Kris-tensen et al 2013). This same group of researchers previously demonstrated an increased sensation in satiety and fullness, and subsequent energy intake when flaxseed was taken in a tablet or a drink form, compared with controls (Ibrügger et al 2012). In animal models a significant reduction in body mass following FS supplementation has been observed (Ferreira Medeiros de Franca Cardozo et al 2011, Felmlee et al 2009); however, this should be viewed with caution as an increase in lipid cell size and redistributed accumulation around internal organs rather than subcutaneous distribution may be responsible for the observed effect.

Increased excretion has been noted for flaxseed supplementation above, and further research notes that partially defatted flaxseed meal (PDFM) in constipated mice significantly increased stool frequency and weight in both the normal and the constipated mice (Xu et al 2012).

### Insulin sensitivity/metabolic syndrome

It has been proposed that FSO may be of benefit in insulin resistance (IR) based on its possible cardioprotective activities; however, direct evidence of improved insulin sensitivity remains elusive. One small study published in 1997 demonstrated improved systemic arterial compliance in 12 subjects with suspected IR, fed a high dose of ALA over 12

#### **Clinical note — Are vegetarians at risk of omega-3 deficiency?**

Omnivores can obtain  $\omega$ -3 long-chain PUFAs in two ways: from the partial conversion of dietary ALA or directly through the consumption of fish, eggs or animal products (Li et al 1999). Lacto-ovovegetarians obtain  $\omega$ -3 EFAs from the conversion of plant-based ALA and a limited amount of preformed EPA and DHA from milk, dairy products and eggs; however, their EFA content is highly dependent upon animal diets. In contrast, strict vegetarians and vegans are at risk of inadequate  $\omega$ -3 EFA, DHA and EPA intake because they are solely reliant on plant-based ALA, which has poor conversion to  $\omega$ -3 EFA metabolites in the body and they have no dietary intake of preformed DHA or EPA.

This has been demonstrated in studies in which lower plasma and platelet levels of  $\omega$ -3 EFAs have been identified in vegetarians compared with omnivores, together with lower EPA and DHA levels (Arterburn et al 2006). For vegetarians and vegans, increased consumption and conversion of ALA has been proposed as a strategy to ensure omega-3 adequacy; however, the evidence to date suggests that this is not effective (Burdge 2004, Phinney et al 1990).

Average daily intake of ALA has been estimated at 1.3–1.5 g in the general population and may be

lower in vegetarians and vegans. Based on current conversion calculations, general consumption levels already fall short of EPA and DHA requirements. Studies investigating increased ALA consumption at 9.5 g/day, the equivalent of approximately 17 mL FSO, found this increased EPA and DPA, yet failed to improve DHA concentrations, which further proves that ALA is not an effective substitute for animal-derived omega-3 EFAs (Burdge 2004).

To complicate matters, there is evidence suggesting that high intakes of ALA downregulate the delta-6-desaturase enzyme, therefore inhibiting its own conversion (Arterburn et al 2006, Gerster 1998). Vegetarian diets are also notoriously rich in the  $\omega$ -6 EFA, LA, which if consumed in significantly higher quantities than omega-3 will further retard conversion of ALA (Kris-Etherton & Skulas 2005). Alternatively, background omega-3 deficiency has been speculated to improve conversion efficacy, making vegetarians and vegans potentially superior converters (Arterburn et al 2006).

Vegans and vegetarians are recommended to consume additional sources of ALA, such as algae, that may contain some preformed EPA and DHA in an attempt to reduce risk of deficiency (Kris-Etherton & Skulas 2005, Li et al 1999).

weeks, although an additional finding in this study was evidence of slight deterioration in insulin sensitivity (Nestel et al 1997). Another study using relatively low-dose FSO (1.7 g/day ALA) in normoglycaemic adults found no changes in glycaemic response (Curran et al 2002). A series of clinical trials examining high-dose FSO in patients with type 2 diabetes failed to demonstrate any positive effect on glycaemic control (Barre et al 2008). Similarly, a study examining milled flaxseed (FS) or flaxseed oil (FXO) in bakery products did not affect glycaemic control in adults with well-controlled type 2 diabetes. However compared with the control group, who experienced a 4% weight gain, the FXS and FXO group gained no weight, suggesting possible prevention of weight gain by flax (Noto et al 2010).

In a study of 25 overweight or obese men and post-menopausal women with pre-diabetes it was found that when participants consumed 0, 13 or 26 g ground flaxseed for 12 weeks, glucose decreased, insulin decreased and homeostatic model assessment decreased on the 13 g intervention, but not the 26 g intervention compared with 0 g. Fructosamine, high sensitivity C-reactive protein, adiponectin and high-sensitivity interleukin-6 had no significant differences (Hutchins et al 2013). Similarly, in a study of 173 Chinese with risk factors of metabolic syndrome, it was found that participants receiving lifestyle counselling (LC) plus 30 g/day flaxseed supplementation (LCF groups), compared with LC alone, had a significant increase in total erythrocyte  $\omega$ -3 PUFAs, ALA, eicosapentaenoic acid and docosapentaenoic acid, and a decrease in total  $\omega$ -6 PUFAs and  $\omega$ -6,  $\omega$ -3 ratio. Arachidonic acid increased significantly in the LC group, presumably due to low levels of ALA. However, there were no additional benefits seen on biomarkers of inflammation, endothelial dysfunction, thrombosis and oxidative stress (Zong et al 2013).

The beneficial effect of FS may be in prevention of complications of diabetes. Tao et al (2008) found that high dietary intake of ALA was associated with lower odds of peripheral neuropathy. Velasquez et al (2003) found in an animal model that FS consumption ameliorated nephropathy in type 2 diabetes mellitus.

## Anticancer effects

### Breast and colon cancer

Bougnoux et al (1994) made an important observation when they demonstrated an inverse relationship between ALA levels in breast tissue and risk of lymph node involvement and visceral metastases in breast cancer. This has been followed up with larger studies of similar design (Klein et al 2000, Maillard et al 2002) and one meta-analysis, all yielding comparable results (Saadatian-Elahi et al 2004).

FS contains two main bioactive anti-cancer components, FS oil (FXO) and plant lignans (a class of phyto-oestrogens). FXO represents 40% of FS, but

has more than 50% as the  $\omega$ -3 fatty acid, ALA. The predominant plant lignan is secoisolariciresinol diglucoside (SDG) which can be converted into the 'mammalian lignans' enterodiol and enterolactone by intestinal bacteria, and has been reported to possess the oestrogenic properties of lignans (Chen et al 2011). The data indicate that those women with the highest breast tissue concentrations of ALA have a relative risk of breast cancer between 0.36 and 0.39, while other FA levels fail to exhibit a statistically significant relationship. Interestingly, an epidemiological study has identified an association between low consumption of ALA in humans and increased cancer deaths in general (Dolecek 1992).

In an in vitro study, SDG and two other lignan isolates from FSO, secoisolariciresinol and anhydrosecoisolariciresinol, were shown to modulate the growth of human breast cells, with the most significant decrease of cell growth at 50–100 microM (Attoumbre et al 2010).

In athymic mouse models, with low-circulating oestrogen concentrations, SDG, FS and the lignin-rich fraction FS hull (FH) were compared for the effect of breast tumour growth. All treatments significantly inhibited cell proliferation, FS and SDG induced significantly higher apoptosis and FS and SDG significantly decreased expressions of various tumour biomarkers, including downregulating ER- and growth factor-mediated cell signalling, but the lesser effects of FH may indicate a need for higher doses (Chen et al 2009). In a further study by these researchers, the  $\omega$ -3 FA-rich cotyledon fraction of FS (FC), alone or in combination with tamoxifen, was examined for effect on breast cancer cells in athymic mice. FC was found to reduce the growth of oestrogen-receptor (ER) positive (ER+) breast tumours alone and in combination with tamoxifen, partly through modulating ER and growth factor-mediated signalling pathways (Chen et al 2011). In a study of ovariectomised (OVX) athymic mice, SDG and FXO were compared alone and in combination on established ER+ human breast tumours. All treatments reduced the tumour growth; however, SDG had the greatest effect, mainly through reduction of cell proliferation as opposed to increasing apoptosis. SDG alone lowered biomarkers indicating an effect involving modulation of the ER- and growth factor receptor-mediated signalling pathways confirming previous studies (Sagggar et al 2010).

Abrahamsson et al's (2012) study demonstrated a significant positive correlation between oestradiol and in vivo levels of the pro-inflammatory cytokine IL-1 $\beta$  in breast tissue and abdominal subcutaneous fat, and a significant negative correlation with IL-1Ra and oestradiol, which exerts an inhibitory effect on IL-1 $\beta$ . Tamoxifen or a dietary supplement of FS produced significant increases in levels of IL-1Ra, suggesting a potential therapeutic target.

In a large prospective analysis of the Ontario Women's Diet and Health Study (2002–03), researchers investigated associations between consumption of flaxseed and flax breads and breast

cancer risk, with confounding factors accounted for. A significant association with breast cancer risk reduction was observed for flaxseed (OR = 0.82 [95% CI, 0.69–0.97]) and flax bread (OR = 0.77 [95% CI, 0.67–0.89]) (Lowcock et al 2013).

In a recent study in athymic mice, the potential for dietary FS to enhance the effectiveness of trastuzumab (TRAS), which is a first line therapy for the treatment on HER2 (human epidermal growth factor receptor 2) overexpressing breast cancer, was conducted. HER2 is overexpressed in about a quarter of breast cancers and results in often highly metastatic, aggressive tumours, and provides a relatively poor prognosis. FS was found to not further improve TRAS in tumour reduction; however, a significant improvement was seen in overall survival of the mice (Mason et al 2013). In a mechanistic study, researchers examined the link between flaxseed supplementation and urinary levels of oestrogen metabolites that may be involved in the development of breast cancer. They found no evidence to support shifts in oestrogen metabolism pathways from flaxseed supplementation for postmenopausal women (Sturgeon et al 2010).

In a commentary by Patterson (2011), the evidence for flaxseed and breast cancer is discussed. In a large RCT of 1140 postmenopausal patients with breast cancer, those who had the highest levels of serum enterolactone concentrations (highest quartile) had a reduced risk of overall mortality by 42%, and a distant disease risk reduction of 38% (Buck et al 2011). The biological plausibility of this is supported by a meta-analysis indicating that enterolactone biomarkers are indeed associated with a breast cancer risk reduction of 28% (Zaineddin et al 2012). However, Patterson is clear that naturally occurring biomarkers, signifying perhaps not more than a healthy lifestyle with well balanced dietary intake, does not necessarily equate to continued health benefits and disease risk reduction with further supplementation with flaxseed lignans.

Therefore, until prospective human trials are completed, the evidence for flaxseed supplementation for breast cancer treatment or risk reduction is uncertain, but may be promising.

SDG is reported to have a broad range of biological effects as a chemopreventive agent against the development of breast, prostate and colon cancers, and has potential antioxidant activity (Attoumbre et al 2010).

Currently, the only evidence from interventional studies using FSO as a chemoprotective agent is provided by animal trials, which demonstrate that dietary FSO is effective in preventing colon tumour development (Dwivedi et al 2005). In a recent study of Sprague Dawley rats, both flaxseed and its total non-digestible fraction (TNDF) exhibited a preventive effect against colon cancer. Two tablespoons (human daily dose) were administered daily. The treatments induced cell cycle arrest, and in an analysis of the expressed genes, an association with the presence of dietary antioxidants linked to the

cell wall of flaxseed was demonstrated (Hernández-Salazar et al 2013).

### Prostate cancer

There is much debate surrounding research into the hypothesised link between ALA and the risk of prostate cancer. Giovannucci, a prolific prostate cancer researcher, has contributed to numerous papers on this topic, deriving data from large epidemiological or prospective cohort studies, including The Health Professionals Follow-Up, The Physician's Health Study and the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study (Gann et al 1994, Giovannucci et al 1993, Leitzmann et al 2004, Mannisto et al 2003). The conclusions oscillate between a positive independent association between increased ALA intake and prostate cancer risk (Gann et al 1994, Giovannucci et al 1993, Leitzmann et al 2004) to no significant association (Mannisto et al 2003). Further support of ALA as a risk factor has come from a large Norwegian epidemiological study (Harvei et al 1997), a review by Astorg (2004) and a meta-analysis by Brouwer et al in 2004. Although the majority of published data appear to implicate ALA as a prostate cancer risk factor, it is worthy of note that none of the trials were interventional and many relied exclusively on food frequency questionnaires rather than independent biochemical indices of ALA. Other researchers have also presented sound arguments against this theory, such as those articulated by de Lorgeril and Salen (2004), which query the quality of evidence being considered, the exclusion of trials that demonstrated minor risk reduction with increased ALA intake (Schuurman et al 1999) and other weaknesses of the study designs. Additional criticisms include the lack of distinction in the sources of dietary ALA, with red meat an independent risk factor for prostate cancer, being a major dietary source of ALA in some studies (Brouwer et al 2004).

In a study of 147 patients with prostate cancer, a presurgical trial of flaxseed supplementation (30 g/day) for approximately 30 days was examined for effects on prostatic tumour expression of NFκB, VEGF and Ki67. A significant correlation between intake of plant lignan and urinary concentrations of total enterolignans, enterolactone and enterodiol (main lignans of FS) was observed. The results showed an inverse association between urinary concentrations of total enterolignans and enterolactone with Ki67, and a near-significant inverse association with enterodiol. A near statistical significance was observed for NFκB and enterolactone. The authors concluded that FS enterolignans may hinder cancer cell proliferation via VEGF-associated pathways (Azrad et al 2013). However, further studies are required to elucidate the effects of FS on prostate cancer.

### DOSAGE RANGE

- Anticlotting: 5.9 g/day ALA.
- Improved endothelial function: 2 g/day ALA.

- Lipid-lowering: 60 mL/day FSO.
- Reduced CHD mortality: 1–3 g/day ALA.
- Reduced cancer (esp breast) risk: 2 tsp/day.

A key consideration with FSO supplementation is product quality. Due to the high potential for FSO to become oxidised, ingestion of inadequately manufactured or preserved FSO could result in higher intakes of peroxides. It is recommended that only refrigerated FSO packaged in opaque containers be used. Once opened, the product should be consumed within a few weeks of opening and kept stored in the fridge.

### ADVERSE REACTIONS

FSO may cause loose stools and gastrointestinal distress in some individuals (Austria et al 2008). There is a report of an allergic reaction to FSO, with a 40-year-old woman experiencing ocular pruritis and weeping followed by generalised urticaria and nausea, and vomiting within 10 minutes of taking a spoonful of linseed oil. A subsequent skin prick test produced a positive response to linseed. It remains unclear, however, whether this patient consumed FSO or linseed oil, which is denatured and unfit for human consumption (Alonso et al 1996).

### SIGNIFICANT INTERACTIONS

None known.

### CONTRAINDICATIONS AND PRECAUTIONS

- Hypersensitivity to flaxseed/linseed.
- Prostate cancer.
- Pregnancy and lactation.

There are a number of studies that link increased ALA intake with a higher risk of prostate or aggressive prostate cancer. Although the evidence is preliminary and widely debated, it is recommended that at-risk individuals avoid high-dose consumption of FSO and only consume FSO that is packaged in opaque containers and refrigerated.

### PATIENTS' FAQs

#### *What will this supplement do for me?*

Regular consumption of flaxseed oil, in the presence of balanced linoleic acid (omega-6) intake, may reduce cardiovascular mortality and possibly the risk of some cancers; however, this remains speculative.

#### *When will it start to work?*

This will depend on the dosage taken and indication for use.

#### *Are there any safety issues?*

Long-term high doses may compromise immune function in susceptible individuals.

Preliminary evidence suggests a possible link between high ALA intake and increased risk of prostate cancer; however, this is controversial.

### PREGNANCY USE AND USE DURING LACTATION

There is some animal evidence to suggest safety concerns when using flaxseed during gestation and lactation. In female Wistar rats, flaxseed use during the perinatal and post-weaning periods improved the offsprings' spatial ability, but did so to the detriment of growth (Fernandes et al 2011). However the research suggests that consumption during lactation does not interfere with reproductive/sexual maturation of female rat offspring (Leal Soares et al 2010).

In the most recent animal research, evidence suggests that extensive use of flaxseed during lactation is not desirable, as maternal supplementation produces a decrease in adiposity of offspring and an increase in pituitary leptin signalling, and higher thyroid leptin receptor in adulthood, indicating induction of insulin resistance in adult offspring. These offspring also demonstrated a higher adult subcutaneous and visceral adipocyte areas, with no change in body fat mass (Sarto Figueiredo et al 2013).

### Practice points/Patient counselling

- Good quality, cold-pressed FSO is a good source of the essential fatty acid ALA, which is often deficient in the Western diet. Capsules are more stable than the bottled oil which must be stored in a dark bottle, refrigerated after opening and consumed within a few weeks.
- The polyunsaturated fatty acids found in FSO, particularly ALA, are precursors of eicosanoids and influence many important physiological processes. Additional actions may be attributed to the variable amount of lignan present in FSO, but which is found in higher concentrations in the actual seed.
- FSO has demonstrated anti-inflammatory, immunological, minor antiplatelet and chemopreventive effects and a range of beneficial actions within the cardiovascular system; however, large RCTs are still required to determine the role of FSO in clinical practice.
- FSO is not an adequate substitute for animal sources of  $\omega$ -3 EFAs. Most studies of oral FSO demonstrate only moderate increases in EPA, while DHA remains unchanged. Strict vegetarians and vegans using FSO as  $\omega$ -3 EFA substitute may be at risk of EPA and DHA deficiency.
- There is some evidence to suggest that daily ingestion of an additional 1–3 g of ALA (equivalent to 5 mL FSO) may reduce the incidence of some cancers and coronary heart disease mortality; however, this remains speculative.

## Folate

**HISTORICAL NOTE** Folic acid was isolated from spinach leaves in 1941 and synthesised in 1946; hence, its name comes from the Latin *folium*, which means leaf.

### OTHER NAMES

Folacin, vitamin B<sub>9</sub>, folic acid, pteroylmonoglutamic acid (PGA)

### BACKGROUND AND RELEVANT PHARMACOKINETICS AND CHEMICAL COMPONENTS

Folate is the generic term for a large family of chemically similar trace compounds that fall within the vitamin B group. Folic acid is the most oxidised and stable form and the one characteristically used in supplements and food fortification. Folate found in animal sources is present in a 'free form' and is readily absorbed; however, aside from the organ meats, animal products are notoriously poor sources. Folate found in plant foods exists in conjugated forms, which require deconjugation by zinc-dependent enzymes in the gut prior to absorption. (Kelly 1998). This step is inhibited by chronic alcohol ingestion and some foods, including oranges

and legumes (Gropper et al 2009). Secondary to this difference, the average bioavailability of natural folate is half that of the synthetic form (e.g. 55–66% versus ≈ 100% (Carmel et al 2006, Kelly 1998). Small amounts of folate are endogenously produced by bacteria in the intestines, but this appears to be predominantly lost via the faeces (Gropper et al 2009).

Dietary folate and synthetic folic acid alike then undergo complex conversion into folate's active forms, e.g. tetrahydrofolate (THF). This occurs via a multistep pathway now proposed to occur solely within the liver (Wright et al 2007). In contrast, a less common supplemental form of folate — folinic acid (5-formyltetrahydrofolate or 5-formylTHF), as an intermediate folate metabolite — bypasses some of these steps to readily form 5,10-methylenetetrahydrofolate (5,10-formylTHF) (Kelly 1998, McGuire et al 1987, Priest et al 1991).

Secretion into the bile of the THF derivatives and their subsequent reabsorption through the

enterohepatic circulation enable redistribution throughout the body. Distribution of folate appears to be regulated via an unknown mechanism, ensuring increased availability to those tissues demonstrating rapid cell division (Gropper et al 2009). Although many of the biochemical pathways in which folate is involved act to regenerate the nutrient, there is still a significant amount that is broken down and eliminated, chiefly in the urine.

**Clinical note — Food fortification with folate: still not enough for pregnant women?**

In 1997, voluntary folic acid fortification of foods was introduced in Australia and New Zealand to improve the folate status, particularly of pregnant women. Following this, a study evaluating mean serum folate levels in over 20,000 Australian women aged 14–45 years found that although concentrations had increased by 19%, the prevalence of poor folate status in this age group had only reduced from 8.5% to 4.1% (Metz et al 2002). Several state-based studies since 1997 have shown a variety of improvements in a range of measures, including haematological markers, folate awareness and supplementation rates among Australian women (Brown et al 2011, Chan et al 2008, du Plessis et al 2008, Hickling et al 2005) and corresponding reductions in NTD births have varied from 17% to 40%; however, some researchers suggest that this decrease occurred in the first 2 years following fortification and the launch of awareness campaigns, and that there has been no further reduction since this time (du Plessis et al 2008). Unsurprisingly, an economic evaluation of the Australian mandatory fortification determined that while it was a cost-effective approach offering substantial long-term benefits with respect to life years gained and quality-adjusted life years, mandatory supplementation alone would be insufficient to achieve folate status required for NTD prevention (Rabovskaja et al 2013). Although fortification programs, including mandatory fortification of bread flour in Australia and New Zealand (FSANZ 2007), provide some measure of protection for women of reproductive age, supplementation is still required. Unfortunately, widespread public health campaigns have had limited success and many women remain unaware of the need to take supplements prior to pregnancy, or are aware but still fail to use supplements (du Plessis et al 2008, Metz et al 2002). In Australia, only 36% and 46% of new mothers in Victoria and New South Wales, respectively, took folate supplements in 2006, with even lower rates reported for women of low socio-economic or non-English speaking backgrounds (Watson et al 2006) and women aged 20–24 years. The last group also experiences the highest rate of NTD births (du Plessis et al 2008).

**Clinical note — A challenge to the perceived safety and superiority of synthetic folic acid?**

Given its relative stability in processing and enhanced bioavailability, synthetic folic acid in food fortificants and supplements has long been regarded as more reliable than natural dietary sources for ensuring folate adequacy (Kelly 1998). This, in turn, has led to widening implementation of mandatory folate fortification programs aimed at the prevention of neural tube defects (NTDs). Recently, however, the safety of increased exposure to synthetic folic acid has been thrown into question. Individuals who consume high doses ( $\geq 400$  mcg/day) exhibit unmetabolised folic acid in their blood, a form that does not naturally occur in human physiology (Kelly 1998, Lucock 2004, 2006, Sauer et al 2009, Smith et al 2008, Sweeney et al 2007, Troen et al 2006, Wright et al 2007). While this will eventually be hepatically converted into a natural folate derivative, there is speculation regarding the interim effects, with evidence of competition between the unmetabolised folic acid and the main active folate form methyl-THF at receptors and their subsequent down-regulation on cell surfaces (Sauer et al 2009, Smith et al 2008). Particular at-risk groups identified by researchers include those individuals taking anti-folate medications, folate-replete cancer patients and elderly patients with B<sub>12</sub> deficiency (Smith et al 2008, Wright et al 2007), while others question the long-term safety for the unborn fetus (Kelly 1998). Until further research is conducted in this area, the implications remain unclear.

## FOOD SOURCES

Good dietary sources of folate are fresh green leafy vegetables, such as cabbage and spinach, asparagus, broccoli, sprouts, mushrooms, legumes, nuts and fortified cereals and organ meats.

Food preparation and processing can destroy up to 100% of the naturally occurring folate, as it is sensitive to light and air but especially heat; therefore, raw foods, as well as fortified foods, are considered superior sources, which in Australia provide 100 mcg per serve (Gropper et al 2009, Hickling et al 2005).

## DEFICIENCY

Folate deficiency is not uncommon and can develop within just 4 months of an inadequate diet (Carmel et al 2006, Gropper et al 2009, Wilson et al 1991).

In light of folate's fundamental role in DNA synthesis, deficiency of this nutrient will predictably impact most on those cells and tissues that exhibit a high turnover (e.g. blood and the cells in the gastrointestinal tract), which also applies to those

stages of development with increased rates of growth, such as pregnancy and fetal tissue development.

### Signs and symptoms of deficiency

- Macrocytic/megaloblastic anaemia
- Fatigue
- Psychological symptoms such as irritability and depression (Reynolds 2002)
- Headache
- Hair loss
- Nausea
- Insomnia (Pelton et al 2000)
- Peripheral neuropathy
- Myelopathy (Okada et al 2014)
- Tendon hyperreflexivity
- Diarrhoea
- Weight loss
- Cerebral disturbances (Botez 1976), cerebral cortex atrophy and cognitive decline
- Increased blood levels of homocysteine

### Primary deficiency

This develops in response to inadequate dietary intake and can be caused by a diet generally lacking in fresh, lightly cooked vegetables. Risk is increased in patients with *MTHFR* gene polymorphisms, in people receiving total parenteral nutrition (TPN), chronic alcoholics, phenylketonuria patients on restricted diets, patients with sickle cell anaemia and the institutionalised elderly (Carmel et al 2006, Wahlqvist 2002).

### Folate enzyme polymorphisms

Single allele substitution in the gene encoding for the N5,10-methylenetetrahydrofolate reductase enzyme, responsible for converting folate into its methylated 'active' form, results in several possible polymorphisms. Individuals who are homozygous for the *MTHFR* C677T polymorphism (2–16% white populations) convert the active folate form at only 30% of the normal capacity, while the *MTHFR* A1298C genotype produces an enzyme with 60% of the unaffected enzyme activity (Gilbody et al 2007). Homozygotes for either polymorphism are at a significantly increased risk of folate deficiency and cannot maintain adequacy with recommended dietary intake levels (NHMRC 2006).

### Secondary deficiency

Secondary deficiency is caused by compromised absorption, increased excretion or increased demands or losses. Inadequate absorption can occur in malabsorption syndromes such as coeliac and Crohn's disease, with long-term use of certain medications such as phenytoin, sulfasalazine, cimetidine, antacids and oral contraceptive pill (OCP), in congenital malabsorption states and in blind loop syndrome (Beers & Berkow 2003), especially when combined with suboptimal dietary intake (Carmel et al 2006). In chronic kidney disease, down-regulation of folate transporters in the intestine, heart, liver and brain

can lead to reduced intestinal absorption of folate (Bukhari et al 2011). Significantly impaired absorption has also been observed in HIV patients (Revell et al 1991).

Besides impaired absorption, inadequate use can occur with concurrent vitamin B<sub>12</sub> or C deficiency, smoking (Gabriel et al 2006, Okumura & Tsukamoto 2011) or acute or chronic alcoholism (Hamid & Kaur 2007). A genetic variation in folate requirement has also been identified, as a congenital enzyme deficiency exists in approximately 13% of the Western population (Ma et al 1996). In these cases, total or partial absence of the enzyme responsible for the final step in converting folate to its major active metabolite (methylenetetrahydrofolate reductase) results in decreased plasma levels (Kumar & Clarke 2002). Therefore, these individuals have a higher folate requirement than others without this congenital enzyme deficiency and display increased susceptibility to folate deficiency.

A number of pharmaceutical drugs, such as folic acid antagonists (e.g. methotrexate), can affect status by interfering with absorption, use and conversion to its active forms. In such cases, oral folic acid supplements are sometimes given to reduce side effects, although it may marginally reduce drug efficacy (Kumar & Clarke 2002, Strober & Menon 2005). Oral isotretinoin treatment may induce folic acid deficiency, although the mechanisms underlying this observation remain unclear (Karadag et al 2011).

Additionally, there are several subpopulations with increased demands for folic acid, such as pregnant and lactating women, the elderly and patients with malignancies, haemolytic anaemias such as sickle cell disease, chronic exfoliative skin disorders or achlorhydria (Gropner et al 2009). Extra losses have also been reported in haemodialysis patients.

The chronic use of alcohol during pregnancy may be associated with reduced folate transport to the fetus (Hutson et al 2012). The ratio of serum folate in maternal blood compared to umbilical cord blood at time of delivery was significantly lower in pregnancies with chronic and heavy alcohol exposure ( $P = 0.014$ ), further emphasising the need for abstinence from alcohol during pregnancy.

### Excess folic acid

Adults and children with phenylketonuria may be at risk of receiving folic acid at higher doses than daily recommendations as a result of high folic acid content in protein substitutes (Stølen et al 2013). These patients should be individually monitored for nutrient status, as the effects of very high doses, in particular in children, is uncertain.

### MAIN ACTIONS

Folate's actions are all secondary to its ability to donate methyl groups and its central role, therefore, in one-carbon metabolism.

## Coenzyme

As a key methyl donor, folate is involved in a variety of reactions important for the metabolism of amino acids and nucleic acids.

### DNA and RNA synthesis

Folate plays an essential part in the production of purines and pyrimidines that make up DNA, making it a critical nutrient in relation to cell division and repair of genetic material, and is generally required for genomic stability. Subsequently, folate plays an indirect role in the synthesis of transfer RNA.

### Production of the active form of B<sub>12</sub>

Folate and B<sub>12</sub> are intrinsically linked; for example, the conversion of B<sub>12</sub> into methylcobalamin is dependent upon the presence of a THF derivative.

### Reduction of homocysteine levels

Folate, via B<sub>12</sub> activation, donates a methyl group to homocysteine facilitating its recycling back to methionine. Together with vitamin B<sub>6</sub>, necessary for homocysteine catabolism, folate effectively lowers homocysteine levels.

### Synthesis of S-adenosyl-l-methionine (SAME)

Following regeneration of methionine from homocysteine, the methyl group donated by folate is then taken up by SAME, enabling it to become a carbon donor in multiple transmethylation reactions throughout the body, including neurotransmitter synthesis (Hendler & Rorvik 2001).

### Amino acid metabolism

Folate is involved in the synthesis of some of the non-essential amino acids such as serine and glycine. It is also required for the conversion of histidine into glutamate (Gropper et al 2009).

## CLINICAL USE

The conditions for which folate is indicated as a potential treatment are primarily due to an existing deficiency, through either primary or secondary pathways. Research has focused particularly on those conditions in which folate deficiency is a consequence of medication use and the benefits of improved folate status.

### Prevention and treatment of deficiency

Commonly, folic acid supplements are used to correct identifiable deficiency states, such as macrocytic anaemia, or given as preventive treatment to those patients at risk of deficiency, such as in malabsorption syndromes or taking long-term folate antagonist medication. Increased oral intake of folate has been found to be effective, even in cases of malabsorption due to the passive diffusion evident with pharmacological doses (Carmel et al 2006).

## Preconception and during pregnancy

### Neural tube defects

Poor folate status either 1 month before conception or during the first trimester of pregnancy is an independent risk factor for NTD in the newborn. One study has suggested that the increased risk could be as high as 10-fold (Daly et al 1995). Despite a wealth of scientific evidence and global health promotion campaigns, it would appear many pregnant women still fail to meet folate intake requirements (Manniën et al 2013, Timmermans et al 2008). It is estimated that, worldwide, only 25% of folic acid-preventable spina bifida and anencephaly are currently being prevented through folic acid fortification (Youngblood et al 2013). Interestingly, a study from Northern Ireland found that women who had been pregnant previously were less likely to follow folate intake recommendations compared to women in their first pregnancy ( $P = 0.001$ ), highlighting the need to emphasise supplementation irrespective of previous pregnancy experience (McNulty et al 2011).

The continued supplementation of 400 mcg folic acid daily in the second and third trimester of pregnancy has been found to increase maternal and placental cord blood folate status, and prevent the increase in homocysteine concentration that otherwise occurs in late pregnancy (McNulty et al 2013). The clinical implication on pregnancy outcomes or early childhood development requires further investigation.

Intervention trials for pregnancy have routinely used 400 mcg folic acid/day; however, there is some suggestion that routine ingestion of only 100 mcg folate from fortified food would prevent the majority of NTDs. Studies have also been conducted on women with a previous NTD birth, with benefits demonstrated at doses of 4 mg/day. There is a general consensus among researchers and health authorities that due to the inconsistent nature of natural food sources, taking a supplement or incorporating fortified foods is the most reliable way to increase levels sufficiently (Cuskelly et al 1996). A maternal red blood cell folate concentration >906 nmol/L is thought to be optimal for lowering risk (Pietrzik et al 2007).

The prevalence of NTD-affected pregnancies has been reported as up to 75% higher in obese women and up to threefold higher for women who are severely obese (Rasmussen et al 2008, Stothard et al 2009). An observational study found obese women to have lower serum folate levels but increased red blood cell folate concentrations, which may be due to body mass index and tissue type affecting the distribution of folate (Tinker et al 2012).

### Other neonatal outcomes

While a number of other birth defects besides NTD have been attributed to folate deficiency in recent times, including Down syndrome (Eskes 2006) and cleft lip and/or palate (CL/P), a 2010 Cochrane

review concluded that there was no statistically significant evidence of any effects of folate supplementation on prevention of cleft palate, cleft lip, congenital cardiovascular defects, miscarriage or other birth defects (De-Regil et al 2010).

A more recent case-control study from the Netherlands found that regular folic acid supplementation during 0–12 weeks after conception was associated with increased risk of cleft formation in the offspring (OR 1.72, 95% CI 1.19–2.49) (Rozena et al 2013). Despite this, available evidence surrounding the role of folic acid in non-NTD birth defects is still contradictory (Bean et al 2011, Hollis et al 2013); as such, the role that supplementation has in the aetiology of these conditions still remains unclear.

Data from numerous studies have suggested that supplementation with folic acid prior to conception and during early pregnancy may reduce autism spectrum disorder (ASD) risk (Berry 2013, Schmidt et al 2012). Analysis of the Norwegian Mother and Child Cohort Study ( $n = 85,176$ ) found that the maternal supplementation from 4 weeks before to 8 weeks after the start of pregnancy was associated with a lower risk of autistic disorder, the most severe form of ASD, in children (adjusted OR 0.61, 95% CI 0.41–0.90) (Surén et al 2013). Using the same data, another study identified that folic acid supplementation or dietary folate did not protect against spontaneous pre-term delivery; pre-conceptual folic acid supplementation starting more than 8 weeks before conception was associated with an increased risk of pre-term delivery (hazard ratio 1.19, 95% CI 1.05–1.34) (Sengpiel et al 2013).

Higher folate levels are linked to the prevention of miscarriages, decreased risk of intrauterine growth retardation, increased birth weight in the offspring of smoking mothers (Sram et al 2005) and increased rates of twin pregnancies, from both natural and in vitro fertilisation (IVF) conception (Haggarty et al 2006). Folic acid supplementation may modify some of the adverse effects of maternal smoking on neonatal outcomes and fetal growth, particularly during the first trimester, although no effect on risk of preterm birth or on risk of 'small size for gestational age' at birth (Bakker et al 2011).

A recent Cochrane review concluded that folic acid supplementation was associated with an improved mean birth weight (mean difference (MD) 135.75, 95% CI: 47.85–223.68) and with a reduction in megaloblastic anaemia incidence (RR 0.21, 95% CI 0.11–0.38) (Lassi et al 2013). Conversely, this review also found that folic acid supplementation had no conclusive benefit on pregnancy outcomes such as preterm birth (RR 1.33, 95% CI 0.73–1.38), stillbirths/neonatal deaths (RR 1.33, 95% CI 0.96–1.85) or some haematological parameters including pre-delivery anaemia (RR 0.62, 95% CI 0.35–1.10), mean pre-delivery haemoglobin level (MD  $-0.03$ , 95% CI  $-0.25$ – $0.19$ ), mean pre-delivery serum folate levels (standardised mean difference 2.03, 95% CI 0.80–3.27) and mean

pre-delivery red cell folate levels (SMD 1.59, 95% CI  $-0.07$ – $3.26$ ).

A large population-based cohort study ( $n = 193,554$ ) found that daily supplementation with 400 mcg folic acid did not prevent preeclampsia or gestational hypertension in Chinese women (Li et al 2013). Periconception folate supplementation was found to be associated with lower uteroplacental vascular resistance and higher blood pressures during pregnancy in a population-based cohort study ( $n = 5993$ ) (Timmermans et al 2011). These observed effects were small and remained within normal physiological ranges, and did not correlate with risk of preeclampsia or gestational hypertension.

A case-control study in Chinese mothers found that folic acid supplementation was associated with significantly reduced risk of congenital heart defects (Li et al 2013). Supplementing with folic acid for a longer period of time appeared to be more effective in reducing the risk of heart defects. Similarly, a preliminary study found that mothers with the *MDR1* 3435T allele who did not use folic acid during the 4 weeks prior to conception until 10 weeks post-conception were at an increased risk of congenital heart defects in their offspring (OR 2.8, 95% CI 1.2–6.4) (Obermann-Borst et al 2011). Further studies are suggested to clarify this finding. Interestingly, several studies have failed to demonstrate a significant relationship between the *MTHFR* C677T genotype and CL/P (Boyles et al 2008, Butali et al 2013, Chevrier et al 2007); however, this may be confounded by concurrent folic acid supplementation in some individuals.

### Childhood diseases

There is a small amount of evidence suggesting folic acid supplementation during early pregnancy may increase the risk of asthma and allergic diseases (Häberg et al 2009, Hollingsworth et al 2008). Despite this, a 2013 systematic review and meta-analysis concluded that there was no evidence of an association between maternal folic acid supplementation and increased risk of asthma in children (RR 1.01, 95% CI 0.78–1.30) (Crider et al 2013). Due to limitations of current studies, further high-quality studies may be of benefit (Ownby et al 2009).

### OCP-induced folate deficiency

Long-term use of the oral contraceptive pill (OCP) (>5 years) has historically been associated with a progressive decrease in serum folate levels, of up to 40%, which could feasibly result in changes to cognition and mood, increased risk of macrocytic anaemia and increased risk of NTD in newborns once use has ceased. Results from some studies suggest this last concern may be unfounded (Lusana et al 2003, Sütterlin et al 2003).

There are a number of proposed mechanisms for folate depletion with OCP use, including concurrent depletion of B<sub>12</sub>, which is involved in the regeneration pathway of THF (Bieleberg 1991), and impaired folate resorption (Sütterlin et al 2003).

## Hyperhomocysteinaemia

Together with vitamins B<sub>12</sub> and B<sub>6</sub>, folic acid has been shown to reduce high plasma levels of homocysteine (Hcy). Of the three, folate appears to have the strongest effect (Voutilainen et al 2001). A randomised dose-response clinical trial found that for adults with existing folate deficiencies, there was a trend towards reduced homocysteine levels with increasing folic acid dose (Anderson et al 2010). Supplementation in healthy adults with adequate folate status did not appear to reduce homocysteine.

Although elevated Hcy has been implicated as a risk for cardiovascular disease (including atherosclerosis and coronary artery disease), cerebrovascular disease, peripheral vascular disease and venous thromboembolism (Clarke et al 1991, den Heijer et al 1996, Malinow et al 1989, Selhub et al 1995), exudative age-related macular degeneration (Nowak et al 2005), noise-related hearing loss (Gok et al 2004), cognitive dysfunction, posttraumatic stress disorder (Jendricko et al 2008), breast cancer incidence in postmenopausal women (Gatt et al 2007) and adverse pregnancy outcomes (Bjorke Monsen & Ueland 2003) including postnatal depression (Behzadi et al 2008), clinical trials are ongoing to determine the clinical relevance of these associations.

## Bone health and fracture risk

Elevated Hcy has been identified as a strong risk factor for osteoporotic fractures (Abrahamsen et al 2006, Green et al 2007, McLean et al 2008, Rejnmark et al 2008). While a significant association between the *MTHFR* C677T polymorphism and fractures has also been demonstrated, this is only significant when coupled with low reported intake of folate, B<sub>12</sub>, B<sub>2</sub> and B<sub>6</sub> (Abrahamsen et al 2006). This has led some researchers to conclude that the response rate to folate treatment among an osteoporotic population is likely to be as little as 2% (Abrahamsen et al 2006). This may explain the lack of positive effect on bone turnover seen in an RCT of hyperhomocysteinaemic (>5 mmol/L) older patients treated with 1 mg folate, 500 mcg B<sub>12</sub> and 10 mg B<sub>6</sub> treated for 2 years, in spite of significant Hcy lowering (Green et al 2007). Similarly, 800 mcg daily folic acid supplemented for 4 months in 31 women with Hcy > 10 micromol/L failed to identify any significant effect on bone turnover markers compared to placebo despite lowering of Hcy ( $P = 0.007$ ) (Keser et al 2013).

## Cardiovascular protection and treatment

In spite of two early meta-analyses which concluded that risk of ischaemic heart disease could be reduced by 16% following a decrease in Hcy of 3 mmol/L (Homocysteine Study Collaboration 2002, Wald et al 2002), there are few folate interventional studies in established hyperhomocysteinaemic cardiovascular populations and recent studies have produced mixed findings.

In patients with kidney disease, two recent meta-analyses have yielded conflicting conclusions concerning the effect of folic acid supplementation on cardiovascular disease. A 2013 meta-analysis (9 RCTs,  $n = 8234$ ) determined that folic acid supplementation reduced the risk of cardiovascular disease in patients with kidney disease, in patients with folate deficiency, diabetes or advanced and end-stage renal disease (RR 0.85, 95% CI 0.77–0.94) (Qin et al 2013a). Conversely, a 2012 systematic review and meta-analysis (11 RCTs,  $n = 10,951$ ) determined that folic acid-based homocysteine lowering does not reduce cardiovascular events in patients with kidney disease (RR 0.97, 95% CI 0.92–1.03) and thus should not be used solely for CVD prevention in this population (Jardine et al 2012).

An interesting trial investigating the benefits of combined B vitamins (5 mg folic acid and high-dose B complex, both administered twice weekly) to patients with a history of cardiovascular events has revealed that those participants whose Hcy decreased within the first 3 months demonstrated significantly reduced cardiovascular risk over the next 5 years; however, no protection was conveyed for slower responders (Siragusa et al 2007). While another small study of B vitamins in hyperhomocysteinaemic elderly subjects failed to improve blood pressure (McMahon et al 2007), elevated Hcy secondary to impaired kidney function in this population group cannot be excluded as a confounding variable.

## Alzheimer's dementia and impaired cognitive function in the elderly

Findings such as the prevalence of folate deficiency in the elderly, increasing Hcy levels with age, evidence of an inverse relationship between total plasma Hcy levels and cognitive function and preliminary evidence of correlation between Hcy and plasma amyloid peptide levels in Alzheimer patients (Aisen et al 2008) have attracted attempts to link the phenomena, providing an explanation for neurodegenerative disorders.

In spite of this, and a large number of investigations of B vitamins, very few have restricted participation to only hyperhomocysteinaemic individuals, which may partly explain their negative findings. The Folic Acid and Carotid Intima-Media Thickness (FACIT) trial, however, administered 800 mcg/day over 3 years to participants with elevated baseline Hcy ( $\geq 13$  mmol/L), producing a mean increase in serum folate of 576% and 26% reduction in plasma Hcy (Durga et al 2007). Treated subjects demonstrated significant improvements in three of the six cognitive testing domains (memory, information processing speed and sensorimotor speed), leading the authors to conclude that folic acid is an effective agent for improving cognitive function that tends to decline with age.

In patients with organic brain disease including Alzheimer's and vascular dementia, again only one

study has restricted participation to hyperhomocysteinaemic individuals, administering 5 mg folic acid together with 1 mg B<sub>12</sub> daily over 2 months (Nilsson et al 2001). As this stands alone in its positive findings, it is suggestive that Hcy is a key indicator of likelihood for response to B vitamin supplementation (Nilsson et al 2001).

It is important to note that hyperhomocysteinaemic patients suffering dementia do not typically co-present with macrocytic anaemia, as might be expected (McCaddon et al 2004). Therefore, the neurological and haematological features of B<sub>12</sub> and folate deficiency are often unrelated in these patients.

### Diabetes mellitus

An RCT ( $n = 48$ ) of overweight and obese men with type 2 diabetes mellitus found that folic acid supplementation (5 mg daily for 8 weeks) significantly reduced HbA<sub>1c</sub> by 8% ( $P = 0.005$ ), reduced serum insulin by 16.2% ( $P = 0.02$ ), reduced insulin resistance by 20.5% ( $P = 0.04$ ) and reduced plasma homocysteine by 21.2% ( $P = 0.000$ ) (Gargari et al 2011).

More recently, a systematic review and meta-analysis of 4 studies ( $n = 183$ ) also found that daily supplementation of 5 mg folic acid in patients with type II diabetes mellitus significantly reduced plasma total homocysteine levels (Sudchada et al 2012). However, the meta-analysis concluded that the effect of folic acid on HbA<sub>1c</sub> levels was not found to be significant and that further large-scale studies with larger sample sizes would be required to accurately determine any effect of folic acid in type 2 diabetes mellitus.

### Renal transplant recipients

Combination vitamin B treatment (folate, B<sub>12</sub> and B<sub>6</sub>) may be of benefit in renal transplant patients, according to an RCT of 56 renal transplant patients, which found that vitamin supplementation with folic acid (5 mg/day), vitamin B<sub>6</sub> (50 mg/day) and vitamin B<sub>12</sub> (400 mcg/day) for 6 months reduced the progression of atherosclerosis, as evidenced by a significant decrease in carotid intima-media thickness. Additionally, a significant decrease in homocysteine levels was observed (Marcucci et al 2003).

### Restenosis after percutaneous coronary intervention

An RCT found that treatment with vitamin B<sub>12</sub> (cyanocobalamin 400 mcg/day), folic acid (1 mg/day) and vitamin B<sub>6</sub> (pyridoxine hydrochloride 10 mg/day) for 6 months significantly decreased the incidence of major adverse events, including restenosis, after percutaneous coronary intervention (Schnyder et al 2002). By contrast, one trial demonstrated an increased risk of in-stent restenosis in those patients intravenously administered 1 mg of folic acid, 5 mg of vitamin B<sub>6</sub> and 1 mg of vitamin B<sub>12</sub> followed by daily oral doses of 1.2 mg of folic acid, 48 mg of vitamin B<sub>6</sub> and 60 mcg of vitamin B<sub>12</sub> for 6 months (Lange et al 2004). Further

research with more consistent study designs is required to elucidate the true effects.

### Idiopathic recurrent miscarriage (IRM)

Maternal hyperhomocysteinaemia and poor folate status are risk factors for recurrent embryo loss and for first early embryo loss (George et al 2002). There has also been conflicting evidence in relation to the role of *MTHFR* polymorphisms and pregnancy, although many studies point towards increased risk of recurrent spontaneous abortion. One explanation for the discrepant results may be that the numbers of study participants have been relatively small (Zetterberg 2004). Although researchers encourage the periconceptual use of both folate and B<sub>12</sub> to reduce these risks, there is a lack of interventional studies in this area other than one investigation of combined aspirin (100 mg/day) and folic acid (5 mg/alternate days) throughout gestation, on top of initial (12 weeks) prednisone and progesterone treatment (Tempfer et al 2006). This treatment yielded higher live birth rate compared with no treatment in women with IRM.

### Cardiovascular disease protection and treatment independent of homocysteine status

In the absence of a causal relationship between Hcy and cardiovascular disease, what remains most promising for folate are studies illustrating its protective effects, mediated through other mechanisms. This has led some researchers to suggest that folate deficiency may be the primary cause of an increased vascular risk and that elevated Hcy levels should principally be considered an indicator of low folate status rather than a pathogenetic marker (Verhaar et al 2002). Demonstrations of in vitro antioxidant activity, effects on co-factor availability and direct and indirect interactions with the endothelial NO synthase enzyme have been proposed as plausible mechanisms, through which folate may prevent endothelial dysfunction (Antonades et al 2007, Das 2003, Verhaar et al 2002).

Several meta-analyses have been conducted that assess the impact of folate alone or in combination on cardiovascular and all-cause mortality, including in individuals with preexisting cardiovascular or kidney disease, and have concluded that the treatments conveyed no significant benefits (Bazzano et al 2002, Bleys et al 2006, Leung et al 2010, Yang et al 2012). This was confirmed in a recent meta-analysis ( $n = 27,418$ ) which concluded that folic acid supplementation had no significant effect on coronary revascularisation, coronary artery bypass grafting, percutaneous coronary intervention, coronary restenosis or total revascularisation (Qin et al 2014).

Combined B vitamins failed to reduce cardiovascular risk in high-risk women (Albert et al 2008), improve mortality and cardiovascular event frequency in patients with coronary artery disease (Ebbing et al 2008), failed to protect against cardiovascular events over 40 months (Bonna et al 2006) and failed to prevent vascular events in

patients with a stroke history after 3.9 years (Potter et al 2008).

On a more promising note, 51 heart transplant recipients who took 15 mg/day of methyltetrahydrofolate for 1 year following transplantation were found at their 7-year follow-up to have reduced all-cause mortality with a relative risk (RR) 0.53 when compared to the placebo group (Potena et al 2008).

### Stroke

Several studies show the cardiovascular protective effects of folic acid, including the predictive value of low folate status on stroke risk (Bazzano et al 2002, Verhaar et al 2002).

Primary prevention with folic acid was found to effectively reduce the risk of stroke in a large-scale meta-analysis ( $n = 16,841$ ; RR 0.82) (Wang et al 2007). The greatest beneficial effect was seen in subjects who received folic acid for longer than 3 years. A more recent 2012 meta-analysis of 26 RCTs similarly suggested there may be a modest benefit of folic acid supplementation in stroke prevention (Yang et al 2012).

### Carotid intima-media thickness

Several studies have observed a beneficial effect of folic acid supplementation on markers of atherosclerosis, such as carotid intima-media thickness (Ntaios et al 2010, Vianna et al 2007).

A 2012 meta-analysis of 10 RCTs ( $n = 2052$ ) found that folic acid supplementation was effective in reducing the progression of carotid intima-media thickness, a measure of atherosclerosis progression ( $P < 0.001$ ) (Qin et al 2012). In particular, subjects with chronic kidney disease or high cardiovascular risk appeared to benefit from folic acid supplementation.

### Hypertension and glucose control

In a multi-centre RCT, the combination of folic acid (400 mcg or 800 mcg) with enalapril (10 mg), an ACE inhibitor, was no more effective than enalapril alone in reducing blood pressure over 8 weeks (Mao et al 2008). The same study found that in subjects with hyperglycaemia, the combination of enalapril and 800 mcg folic acid significantly reduced fasting plasma glucose compared to enalapril alone and enalapril with 400 mcg ( $P < 0.015$ ). Conversely, 8-week folic acid supplementation (400 mcg/day) in elderly women ( $n = 122$ ) resulted in increased overnight fasting blood glucose concentrations (baseline:  $84.8 \pm 1.0$  mg/dL; at 8 weeks:  $98.2 \pm 5.2$  mg/dL,  $P < 0.01$ ) (Chmurzynska et al 2013). When this cohort was stratified by *MTHFR* genotype, significant differences in HDL-cholesterol before and after supplementation were observed, with levels almost 10% lower in T-allele carriers than in CC homozygous subjects ( $P < 0.05$ ).

Another small study, employing high-dose folate (10 mg/day) in patients with a recent history of acute myocardial infarction, demonstrated improved

endothelial function (Moens et al 2007). These positive findings were independent of Hcy levels at baseline or changes to Hcy throughout the trial.

### Cognitive decline, dementia and Alzheimer's disease prevention or treatment independent of homocysteine status

Independent of Hcy, folate is implicated in cognition and neurodegeneration due to its ability to improve nitric oxide levels in the brain and facilitate synthesis of neurotransmitters (Malouf & Grimley Evans 2008). Additionally, atrophy of the cerebral cortex results from folate deficiency. Despite an abundance of epidemiological evidence and a limited number of studies showing a positive correlation between folate status and dementia, the role of folic acid supplementation in cognition remains unclear.

A 2008 Cochrane review examining the effects of folic acid supplementation, with or without vitamin B<sub>12</sub>, concluded that there was no consistent evidence that folate had any beneficial effect on cognitive function of healthy or cognitively impaired subjects (Malouf & Grimley Evans 2008). This was corroborated by a 2010 meta-analysis which found no effect of folic acid, with or without other B vitamins, on cognitive function within 3 years of the start of treatment.

Of the evidence available, including trials examined by the Cochrane review, a 2002 review has estimated that 71% of acute hospital admissions with severe folate deficiency have organic brain syndrome, compared with 31% of controls (Reynolds 2002). Low baseline serum folate also predicted dementia in a sample of 625 individuals followed over 2.4 years (Kim et al 2008), with onset of dementia significantly associated with exaggerated declines in folate and B<sub>12</sub> and increases in Hcy, which may, however, have been the result of concomitant weight loss. In spite of this knowledge, the results of studies investigating supplemental folic acid have been equivocal and warrant closer examination of the disparate methodologies.

A review by Balk et al in 2007, which sub-analysed folic-acid-only treatments (three RCTs, using 750 mcg to 15 mg/day over 5–10 weeks) in elderly patients who were either healthy or cognitively impaired, found that while folic acid was not universally effective, there was evidence to suggest that patients with low baseline folate (<3 ng/mL) may significantly benefit.

Several studies investigating folic acid, either alone or in combination with other B vitamins, for slowing cognitive decline in Alzheimer's disease have failed to demonstrate an effect, independent of the hyperhomocysteinaemic population (Aisen et al 2008). One small study using 1 mg folic acid/day in conjunction with cholinesterase inhibitors over 6 months did, however, point towards an additive effect on patients' function (rather than cognition per se) regardless of Hcy (Connelly et al 2008); however, a similar study using higher doses of

combined B vitamins failed to produce any statistically significant benefits (Sun et al 2007).

### Anticonvulsant-induced folate deficiency

Anticonvulsant medications such as phenytoin, carbamazepine and valproate reduce serum folate status. Individual studies have estimated an incidence of 15% folate deficiency in this group, compared with 2% for control groups (Froscher et al 1995). However, the figure may be as high as 97% with long-term phenytoin therapy (Rivey et al 1984). This may be due to increased use of folate in drug metabolism and/or decreased mucosal absorption (Berg et al 1992, Pelton et al 2000). Often, folic acid supplements are recommended to avoid deficiency, but this requires close supervision to ensure drug efficacy is not substantially reduced (Rivey et al 1984). A series of published case reports documenting NTD births to women supplemented with folic acid 5 mg/day while on anticonvulsants has thrown into question whether this commonly recommended dose is sufficient or whether concomitant administration of other B vitamins, especially B<sub>6</sub>, may be necessary (Candito et al 2007).

### Psychiatric illness

Over the past three decades, a vast number of case reports, open studies and, to a lesser extent, case-control studies have been published on the topic of psychopathology and folate deficiency. Many report a high incidence of serum folate deficiency in patients with symptoms of depression and various psychiatric disorders, particularly in geriatric populations (Reynolds 2002). For instance, one review identified that rates of deficiency varied between 8% and 50% in patients with various psychiatric disorders, including depression and schizophrenia (Young & Ghadirian 1989). Two large studies, involving over 350 patients diagnosed with acute psychiatric presentations, identified low folate levels or frank deficiency (31% and 12% respectively). The patients with the most marked deficiency were also the group with the highest percentage of inpatients (Carney et al 1990). Another study of similar design found that 30% of 224 newly admitted psychiatric patients had low serum folate (<3.5 ng/mL) compared to just 2.4% of controls, and that patients with low folate were 3.5-fold more likely to present with depressive features (Lerner et al 2006). Disturbingly, the researchers also identified a significant trend between folate deficiency and hospital readmissions.

### Depression

#### Aetiological role

It has been estimated that 15–38% of depressed people are folate deficient (Alpert & Fava 1997, Lerner et al 2006). Studies have also demonstrated that low dietary folate consumption (<256 mcg/day) (Tolmunen et al 2004), low serum folate (<3.5 ng/mL) (typically co-occurring with B<sub>12</sub>

deficiency) (Gilbody et al 2007, Lerner et al 2006) and an *MTHFR* C677T genotype (OR 1.36) are all independently associated with an increased risk of depression (Gilbody et al 2007, Kelly et al 2004). One study found that while folic acid supplementation did not reduce the risk of depression during and up to 8 months after pregnancy, it appeared to protect against depression for up to 21 months postpartum (Lewis et al 2012). This effect was more pronounced in those with the *MTHFR* C677T TT genotype ( $P = 0.01$ ). The lesser-studied *MTHFR* A1298C genotype (although more active than the C677T genotype, but still 40% underactive) also demonstrates a weak positive relationship with depression incidence; however, more studies are required (Gilbody et al 2007). Following on from these findings, serum folate has also been negatively correlated with depression severity and duration in some, but not all, studies (Kim et al 2008). One proposed explanation for these inconsistencies is that low folate and elevated Hcy are only found in a sub-group of depressed patients; in particular, those who experience increased anger and hostility as part of their depression (Fraguas et al 2006).

Additional studies also highlight an association between antenatal and postnatal depression and elevated Hcy or low folate levels but not serum B<sub>12</sub> nor dietary intake of these two nutrients (Abou-Saleh et al 1999, Miyake et al 2006) and depression in antenatal and postnatal patients, with Hcy naturally peaking in the third trimester (Abou-Saleh et al 1999, Behzadi et al 2008). The link between folate and B<sub>12</sub> and depression has been hypothesised to be via Hcy and independent of this, due to its methylation role generally (Bottiglieri 2005, Coppen & Bolander-Gouaille 2005, Das 2008, Gilbody et al 2007, Lerner et al 2006, Roberts et al 2007, Tiemeier et al 2002).

#### Therapeutic role

Given the volume of evidence linking folate with depression, it is surprising that so few clinical trials have been conducted. A Cochrane systematic review of three RCTs involving 247 depressed people suggested that, on the limited evidence available, folate shows potential as an augmenting agent, but speculated that its effectiveness might be restricted to folate-deficient patients (Taylor et al 2003). The studies included in this review used 500 mcg folic acid, 15 mg or 50 mg of methyltetrahydrofolate once daily and lasted from 8 weeks to 6 months.

More recent studies, particularly in the elderly, who exhibit high rates of both folate deficiency and depression, have investigated the effects of broad-scale nutritional supplementation (meeting recommended daily intakes (RDIs) for all essential micronutrients) over a 6-month period with promising results. Red cell folate and serum B<sub>12</sub> values rose in supplemented individuals in accordance with significantly reduced scores on depression scales (Gariballa & Forster 2007). Prophylactic treatment

of non-depressed elderly men with 2 mg folic acid, 25 mg B<sub>6</sub> and 400 mcg B<sub>12</sub>, in another study, however, failed to reduce depression incidence over 2 years (Ford et al 2008).

#### Improves response to standard antidepressants

Research investigating folate's adjunctive role in depression treatment has escalated in recent years and there is now evidence of an impaired fluoxetine response in patients with low folate levels, with response rates dropping from 44.7% in subjects with normal serum folate to only 7.1% of deficient patients (<2.5 ng/mL) (Papakostas et al 2004a, 2004b), as well as a potentiating effect when only 500 mcg/day of folic acid is added to fluoxetine (Coppen & Bailey 2000). Reduced folate levels have also been associated with reduced response to sertraline (Alpert et al 2003). Poor folate status negatively impacts response time (+1.5 weeks) (Papakostas et al 2005) and relapse rates during continuation of fluoxetine (42.9% relapse in patients with low folate levels versus 3.2%) (Papakostas et al 2004a, 2004b), independent of B<sub>12</sub> and Hcy levels.

#### Schizophrenia

Folate has been implicated in schizophrenic aetiology since the 1950s with one-carbon metabolism abnormalities proposed as a distinct hypothesis at a similar time (Regland 2005). With current knowledge linking the two, there has been renewed interest in the role of folate in this disorder. In particular, folate deficiency fits with the neurodevelopmental theory, implicating malnutrition amongst other environmental stressors during gestation in the subsequent susceptibility to neurological disorders of offspring (Applebaum et al 2004, Gilbody et al 2007, Haidemenos et al 2007, Muntjewerff & Blom 2005). Specifically, elevated Hcy in the third trimester has been associated with significantly elevated risk. This theory is supported in part by the parallel increases in NTD births and schizophrenia incidence in populations affected by famine (Muntjewerff & Blom 2005). Further evidence of folate's role comes from elevated Hcy and a high incidence of the *MTHFR* C677T genotype which are frequently, but not consistently, found in this patient group (Kemperman et al 2006, Regland 2005). A meta-analysis of links between this folate polymorphism and schizophrenia found an odds ratio of 1.44 (Gilbody et al 2007).

Several studies in adult schizophrenic patients have reported increased rates of active folate deficiency. One, in addition to this, demonstrated an inverse relationship between serum folate and degree of negative symptoms and a positive association between Hcy and extra-pyramidal symptoms (Goff et al 2004). There have been several case reports of successful treatment using 15–30 mg folate together with B<sub>12</sub> injections (1 mg every 10 days) and *N*-acetylcysteine (200 mg twice daily) (Regland 2005), as well as a study which administered a combination of 2 mg folic acid, 25 mg B<sub>6</sub> and 400 mcg

B<sub>12</sub> to schizophrenic patients with baseline Hcy > 15 mmol, which produced improvements in both clinical features and neuropsychological test performance (Levine et al 2006).

#### Other neurological and psychiatric presentations

Significantly decreased red cell folate (not serum) has been documented in both phases of bipolar disorder (Hasanah et al 1997), as well as frequently found in patients chronically treated with lithium (Coppen & Bolander-Gouaille 2005). There is also preliminary evidence of mildly elevated Hcy in post-traumatic stress disorder (PTSD) sufferers; however, more thorough investigation is required to confirm this tentative association (Jendricko et al 2008).

A 2011 Cochrane review determined that there are insufficient high-quality data to determine the effect of folic acid on fragile X-syndrome patients (Rueda & Ballesteros 2011).

#### Chemopreventative role

Epidemiological, animal and human studies all suggest that folate status may affect the risk of developing cancers in selected tissues; however, the exact nature of this relationship continues to elude researchers (Bollheimer et al 2005, Powers 2005). One current theory points to the negative synergism between ageing and folate inadequacy, producing aberrations in one-carbon transfer such as gene hypomethylation, implicated in potentially carcinogenic genomic changes (Jang et al 2005). Despite the wealth of studies available concerning folate and cancer risk, recent meta-analyses of over 50,000 subjects concluded that folic acid supplementation did not substantially increase or decrease incidence of site-specific cancer during the first five years of treatment (RR 1.06, *P* = 0.10) (Vollset et al 2013). This large-scale study also found no significant effect of folic acid supplementation on the incidence of cancer within the breast, prostate, lung, large intestine or any other specific site. Conversely, a meta-analysis by Qin and colleagues (2013) found that folic acid supplementation was associated with a significantly reduced risk of melanoma (RR 0.47) although no significant effect was observed with total cancer incidence, colorectal cancer, prostate cancer, lung cancer, breast cancer or haematological malignancy (Qin et al 2013b).

Previously, high folate intake was purported to have an almost universally protective effect. An extensive review of the role of the *MTHFR* C677T polymorphism in cancer risk concluded that, in spite of the poor folate status associated with this polymorphism, however, many studies identify it as protective against a range of cancers (Sharp & Little 2004). In addition to this, a group of Swedish researchers have demonstrated that the relationship between serum folate and colorectal cancer follows a bell-shaped curve distribution (Van Guelpen et al 2006). Speculation regarding the role of additional

co-factors involved in folate activity has also emerged (Powers 2005).

Folate's actions, however, still constitute a plausible cancer risk modulator, due to its critical role in the production, methylation and repair of DNA, regulation of cell turnover and suppression of excessive proliferation (Choi & Mason 2000, 2002).

### Colon cancer

The link between folate status and colorectal cancer was first suggested as a result of 1990s epidemiological findings. Subsequent rodent studies further strengthened the theory, when chemically induced colorectal carcinogenesis was shown to be enhanced under dietary folate deprivation and reduced with folate administration (Cravo et al 1992, Kim et al 1996). The *MTHFR* C677T genotype has been identified as a risk factor (OR 1.34), compounded by dietary folate below median intakes (Murphy et al 2008). Based on a recent systematic review and meta-analysis, folate may be associated with a protective effect against colorectal cancer (Kennedy et al 2011); however, this is not yet definitive as some studies show no effects. A 2013 meta-analysis of RCTs concluded that long-term folic acid use (3.5 years) did not increase or decrease the occurrence of new colorectal adenomas in patients with history of adenoma (RR any adenoma 0.98; RR advanced adenoma 1.06) (Figueiredo et al 2013). Similarly, in subjects with a history of colorectal cancer, a 2008 multicentre RCT found 0.5 mg/day folate did not reduce the risk of colorectal adenoma recurrence (RR any adenoma 1.07; RR advanced adenoma 0.98) (Logan et al 2008). Additionally, a large placebo-controlled RCT ( $n = 5442$ ) of women at high risk of cardiovascular disease found that use of B-vitamins, including folate, was not associated with the prevention of colorectal adenoma, with no apparent benefit or harm being identified (Song et al 2012).

### Breast cancer

While the epidemiological evidence with respect to dietary folate and breast cancer risk has produced equivocal results, more consistent evidence points to low folate intake as a risk factor only when combined with increased alcohol consumption (Larsson et al 2007, Mahoney et al 2007). This negative synergy is further supported by evidence that maintaining adequate folate intake, usually via supplementation, can reduce or eliminate the excess risk due to increased alcohol consumption (Mahoney et al 2007). A comparable detrimental additive effect has been demonstrated between the *MTHFR* genotype and low folate intake (OR 2.80) (Suzuki et al 2008).

### Cervical cancer

Folate deficiency may increase the risk of cervical cancer in individuals infected with high risk human papilloma virus (HR-HPV) (Piyathilake et al 2004).

Evidence suggests a diet rich in fruit and vegetables generally (OR 0.52), and folate independently (OR 0.55), reduces the risk of developing cervical cancer (Ghosh et al 2008); however, much of the other evidence pertaining to a protective relationship has been ambiguous and results from intervention studies on cervical cancer have been inconsistent (Henaio et al 2005, Kwanbunjan et al 2005, Sedjo et al 2003). The most surprising finding is that the *MTHFR* genotype appears protective against cervical cancer (Shekari et al 2008), enhanced further by a concomitant low intake of B<sub>2</sub> (Piyathilake et al 2007).

The most promising RCT involved 47 patients taking an OCP who demonstrated mild to moderate intraepithelial dysplasia. A dose of 10 mg folic acid daily over 3 months resulted in significantly lower biopsy scores in the treatment group and a significant reduction in cytology scores from baseline (Butterworth et al 1982). Other studies have shown that folic acid treatment does not alter the course of disease in patients with pre-established cervical dysplasia (Childers et al 1995).

### Other cancers

A protective role for folate in the prevention of a growing number of other cancers, e.g. prostate (Marchal et al 2008), lung (Suzuki et al 2007), pancreas (Suzuki et al 2008) and nervous system cancers (Milne et al 2012, Sirachainan et al 2008), has been tentatively made. Due to the limited or, in some cases, conflicting evidence that is available, more research is required to validate these preliminary findings (Rycyna et al 2013).

In a case-control study, maternal folic acid supplementation before and during pregnancy may reduce the risk of childhood acute leukaemia (OR 0.4) (Amigou et al 2012). This study also suggested that genotypes homozygous for any of the *MTHFR* polymorphisms or carrying both *MTRR* variant alleles may also be a risk factor for developing acute leukaemia; however, this study had some limitations thus further research is recommended.

### Periodontal disease

A series of RCTs have shown that rinsing with a solution of folate (5 mg/dose) twice daily alleviates gingival inflammation in all age groups and in pregnant and non-pregnant women (Pack 1984, Thomson & Pack 1982). Treatment results in a significant reduction in inflammation without altering plaque levels or folate serum status and appears to be more successful than oral supplements (Vogel et al 1976).

Preliminary evidence suggests that topical folate may also have a role in controlling gingival hyperplasia associated with long-term phenytoin use (Drew et al 1987).

### Methotrexate toxicity

Methotrexate is a cytotoxic drug with folate antagonist properties. In part, its efficacy is dependent on

this effect, but severe deficiency symptoms such as macrocytic anaemia are sometimes induced (Lambie & Johnson 1985). Co-administration of folic acid or folinic acid has been investigated as preventive treatment, with both forms capable of reducing drug side effects (Ortiz et al 1998, Strober & Menon 2005). A 2013 Cochrane review found a statistically significant and clinically important reduction in the incidence of GI adverse effects, hepatic dysfunction and methotrexate discontinuation in methotrexate patients with rheumatoid arthritis receiving folic or folinic acid (Shea et al 2013). A trend towards a reduction in stomatitis was observed; however, this did not reach statistical significance.

### Sickle cell anaemia

In the past, folate supplements were recommended to patients with sickle cell anaemia, but more recent studies show that clinically significant folate deficiency occurs in a very small percentage of these patients and other nutrients may be indicated (Reed et al 1987).

### Vitiligo

Although a number of uncontrolled studies testing combination treatments have been promising, folate has never been assessed as a sole treatment. As such, it is difficult to determine its role in the treatment of this condition. In previous studies, a combination of oral folic acid and vitamin B<sub>12</sub>, together with increased sun exposure, has produced response rates in the vicinity of 50% (Juhlin & Olsson 1997). A controlled study by a different group of researchers found that exposure to a specific band width of UV radiation produced repigmentation in 92% of subjects, irrespective of vitamin supplementation (Tjioe et al 2002).

### Erectile dysfunction

The combination of folic acid (5 mg daily) with tadalafil (10 mg every other day) was found to be more effective in improving sexual function than tadalafil alone (10 mg every other day) in an RCT of 83 patients with type 2 diabetes mellitus (Hamidi Madani et al 2013). Due to limitations in study design, including failure to obtain baseline serum folate levels or serum testosterone levels, more research into the clinical implication of this finding is recommended.

## DOSAGE RANGE

### Australian RDI (NHMRC 2006)

- 400 mcg/day for adults; up to 1 mg/day in deficiency states.
- Up to 600 mcg/day is recommended as the Suggested Dietary Target to reduce chronic disease risk in adults.
- 600 mcg/day in pregnancy.
- 500 mcg/day during lactation.

## According to clinical studies

- Preconception care or early pregnancy supplementation: 400–600 mcg/day.
- Preconception and pregnancy supplementation in women with a previous NTD birth: 4 mg/day.
- Idiopathic recurring miscarriage: aspirin (100 mg/day) and folic acid (5 mg/alternate days) throughout gestation plus prednisone and progesterone treatment for first 12 weeks.
- Anticonvulsant-induced deficiency: 15 mg/day (under supervision).
- Prevention of cervical cancer: 800–10,000 mcg/day.
- Prevention of breast cancer in high alcohol consumers: 400 mcg/day.
- Alzheimer's dementia in the presence of elevated Hcy: 800 mcg/day.
- Alzheimer's dementia with normal Hcy: 1 mg/day in combination with cholinesterase inhibitors.
- Cognitive decline in elderly with folate deficiency: 750 mcg/day.
- Depression: minimum of 2 mg or sufficient dose to reduce elevated homocysteine as stand-alone treatment.
- Depression as an augmenting agent with standard antidepressants: 500 mcg/day.
- Acute psychiatric presentation: 15–30 mg methylfolate daily in combination with standard psychotropic treatment.
- Hyperhomocysteinaemia: 500–5000 mcg/day.
- Cardiovascular protection in patients with elevated Hcy: 5 mg/day with high-dose B complex.
- Cardiovascular protection in heart transplant recipients or patients with recent history of MI: 10–15 mg/day.
- Methotrexate toxicity: 5 mg/week.
- OCP-induced folate deficiency: 2 mg/day.
- Periodontal disease: rinse mouth with a solution of folate (5 mg/dose) twice daily.
- Prevention of restenosis after percutaneous coronary intervention: 1 mg in combination with vitamin B<sub>12</sub> (400 mcg) and vitamin B<sub>6</sub> (10 mg) daily.
- Schizophrenia with marked negative symptoms: 2 mg/day in combination with 25 mg/day B<sub>6</sub> and 400 mcg/day B<sub>12</sub>.
- Sickle cell anaemia: 1 mg/day.
- Ulcerative colitis: 15 mg/day.
- Vitiligo: 2–10 mg/day.

## ADVERSE REACTIONS

Adverse reactions appear to be limited to oral doses greater than 5 mg/day. Reactions include a generalised urticaria associated with an allergic response, nausea, flatulence and bitter taste in the mouth, irritability and excitability.

One study found high-dose folic acid supplementation in children aged 6–30 months was associated with an increased risk of persistent diarrhoea (Taneja et al 2013).

## SIGNIFICANT INTERACTIONS

### Antacids

Reduce folic acid absorption — separate doses by 2–3 hours.

### Anticonvulsants (phenytoin)

Reduced folate levels frequently develop with long-term use, but macrocytic anaemia is rare (Lambie & Johnson 1985). Supplementation can reduce toxicity, which is a beneficial interaction, although medical supervision is advised.

### Cholestyramine (e.g. Questran)

Reduced folate absorption — observe patient for signs and symptoms of folate deficiency and separate doses by at least 4 hours.

### Gastric acid inhibitors (proton-pump inhibitors)

Reduced folic acid absorption — separate doses by 2–3 hours.

### Methotrexate

Methotrexate is a folate antagonist drug. Folate supplementation can reduce toxicity, which is a beneficial interaction; however, it may reduce the efficacy of methotrexate (Al-Dabagh et al 2013) — medical supervision advised.

### Oral contraceptives

Folate levels are reduced with long-term use of the OCP, particularly those with high oestrogen content; therefore, increased intakes may be required for women undertaking long-term use.

### Pancreatin

Reduced folate absorption (Kelly 1998) — separate doses by 2–3 hours.

### Pyrimethamine (e.g. maloprim)

Impairs the use of folate and, as such, supplementation with folic acid may be beneficial.

### Sulfasalazine

Folic acid can reduce drug absorption — separate doses by 2–3 hours.

### Trimethoprim

Trimethoprim is a folate antagonist drug. Supplementation can reduce toxicity, which is a beneficial interaction — medical supervision advised.

### Zinc

At high doses (>15 mg/day), minor zinc depletion may develop (Carmel et al 2006, Kelly 1998) — observe patients for signs and symptoms of zinc deficiency.

### Practice points/Patient counselling

- Folate is involved in a number of important biochemical pathways required for health and wellbeing, in particular development and cell growth.
- Folate supplements are often given to correct deficiencies or prevent deficiency in people at risk, such as those with malabsorption syndromes (e.g. coeliac disease and Crohn's disease), long-term use of certain medications such as phenytoin, sulfasalazine, cimetidine, antacids and the OCP, in congenital malabsorption states and blind loop syndrome, chronic alcoholism, HIV infection, the institutionalised elderly, pregnant and lactating women.
- It is considered to be the most important supplement to be taken by women in the weeks leading up to conception and during the first 12 weeks of pregnancy, in order to significantly reduce the risk of NTD in newborns. Food fortification is not considered sufficient.
- Both tablet and multivitamin softgel capsules have similar bioavailability profiles, with both peak level and total serum folate similar between each dosage form. Time to peak concentration appears slower in softgel capsules compared to tablets (Maki et al 2012).
- Other uses for folic acid supplements include reducing homocysteine levels (often in combination with vitamins B<sub>12</sub> and B<sub>6</sub>), reducing primary cardiovascular disease risk and cancer risk in general, periodontal disease (as a topical application), depression, schizophrenia and other psychiatric presentations and vitiligo.

### CONTRAINDICATIONS AND PRECAUTIONS

Use of folate supplements may mask a B<sub>12</sub> deficiency state by correcting an apparent macrocytic anaemia without altering progression of neurological damage. It is recommended that patients be screened for vitamin B<sub>12</sub> deficiency.

### PREGNANCY USE

According to the Australian Drug Evaluation Committee (1999), folate is considered to be safe to take during both pregnancy and lactation. Retrospective analysis of a trial of folate in pregnancy in the 1960s has suggested a possible increase in all-cause mortality and breast cancer in pregnant women taking 5 mg/day folate; however, this finding could be due to a number of factors unrelated to folate (Bland 2005, Charles et al 2004). The only context requiring special consideration is those pregnant women taking anticonvulsant medication (see Significant interactions).

## ! PATIENTS' FAQs

### *What will this supplement do for me?*

Folic acid is essential for health and wellbeing. Supplements have a critical role in preventing NTD in newborns and may also reduce the risk of primary cardiovascular disease and improve brain function in Alzheimer's dementia and non-Alzheimer's dementia and depression. It can also reduce the toxic effects of some medicines and may reduce the risk of developing some forms of cancer.

### *When will it start to work?*

This depends on the indication.

### *Are there any safety issues?*

The major concern with high doses of folate is that they may mask an underlying vitamin B<sub>12</sub> deficiency and allow it to progress unnoticed, which means that a vitamin B<sub>12</sub> deficiency should be excluded. It also interacts with some drugs in both a potentially harmful and a beneficial way. High doses should not be used in patients with a history of bowel polyps or adenomas.

# Garlic

G

**HISTORICAL NOTE** Garlic has been used as both a food and a medicine since antiquity. Legend has it that garlic was used in ancient Egypt to increase workers' resistance to infection and later used externally to prevent wound infection. Other ancient civilisations have also used it medicinally. Sanskrit records document the use of garlic approximately 5000 years ago and the Chinese have been using it for over 3000 years. One of the uses of garlic was as a treatment for tumours, a use that extends back to the Egyptian Codex Ebers of 1550 BC (Hassan 2004). Louis Pasteur was one of the first scientists to confirm that garlic had antimicrobial properties. Garlic was used to prevent gangrene and treat infection in both world wars. Traditionally, garlic has been used as a warming and blood-cleansing herb to prevent and treat colds, flu, coughs and menstrual pain and to expel worms and other parasites.

## COMMON NAME

Garlic

## OTHER NAMES

Ail, ajo, allium, camphor of the poor, da-suan, knoblauch, la-juan, poor man's treacle, rustic treacle, stinking rose

## BOTANICAL NAME/FAMILY

*Allium sativum* (family Liliaceae)

## PLANT PART USED

Bulb, and oil from the bulb

## CHEMICAL COMPONENTS

Garlic bulbs contain organosulfur compounds (OSCs), protein (mainly alliinase), amino acids (such as arginine, lysine, threonine and tryptophan), fibre, lipids, phytic acid, saponins, beta-sitosterol and small quantities of vitamins and minerals, such as vitamin C, vitamin E, beta-carotene, chromium, iron and selenium (Duke 2003). Of the numerous constituents present, it is the alliin component and resultant degradation products, such as allicin and ajoene, that produce much of the herb's pharmacological activity. These are formed when garlic is crushed or chewed and alliin is exposed to the enzyme alliinase. According to Commission E, 1 mg of alliin produces 0.458 mg of allicin (Blumenthal 2000). Allicin is unstable and degrades to various sulfides depending on the conditions. Steam distillation converts water-soluble thiosulfanates to lipid-soluble diallyl sulfides (DAS), whereas oil maceration results in the production of ajoenes and vinylthiines (Stargrove et al 2008).

The pharmacological actions of the herb are due to its organosulfur components: alliin, allyl cysteine, allyl disulfide and allicin (Chung 2006). In garlic oil, there are three major OSCs: diallyl trisulfide (DATS), DAS and diallyl disulfide (DADS) (Liu et al 2006). In aged garlic the sulfur compounds are metabolites of  $\gamma$ -glutamylcysteine; including water-soluble S-allylcysteine (SAC) and its metabolites S-allylmercaptocysteine (SAMC) and S-methylcysteine (Tsai et al 2012).

## MAIN ACTIONS

### Antioxidant

Garlic and many of its constituents have strong antioxidant activity and is capable of directly scavenging free radicals, and indirectly enhancing endogenous antioxidant systems such as glutathione, superoxide dismutase (SOD), catalase and glutathione peroxidase (Arhan et al 2009). This has been demonstrated in vitro and in vivo (Arhan et al 2009, Hassan et al 2010).

When tested individually, the four main chemical classes of garlic, allyl disulfide, alliin, allicin and allyl cysteine, have been shown to exhibit different patterns of antioxidant activity. Alliin scavenges superoxide via the oxanthine oxidase system; alliin, allyl cysteine and allyl disulfide act as hydroxyl scavengers; and allyl disulfide prevents lipid peroxidation (Chung 2006). SAC has also been shown to scavenge reactive oxygen and nitrogen species, including superoxide anion, hydrogen peroxide, hydroxyl radical and peroxynitrite anion (Medina-Campos et al 2007).

According to in vitro tests, garlic prevents cadmium- and arsenic-induced oxidative damage by inducing endogenous antioxidant defence mechanisms (Chowdhury et al 2008, Ola-Mudathir et al 2008, Suru 2008). A later study demonstrated the protective effects of DADS from garlic on human osteoblasts exposed to cigarette smoke (Ehnert et al 2012).

In vivo studies suggest protection from radio-frequency electromagnetic radiation associated with mobile phone use via the reduction of protein oxidation (Avci et al 2012), and cardioprotection with aged garlic on doxorubicin-induced cardiotoxicity (Alkreaty et al 2010, 2012). Large doses of garlic (500 mg/kg) improved sperm viability and partially preserved seminiferous tubule histological organisation after 28 days when compared to controls, most likely due to an antioxidant mechanism (Asadpour et al 2013).

Antioxidant activity and lower levels of oxidative stress have further been demonstrated in several clinical studies for garlic supplementation. One

study used a dose of garlic 0.1 g/kg/day for 1 month; this was shown to induce a significant reduction in erythrocyte malondialdehyde (an indicator of oxidative stress) and significantly increase levels of SOD and glutathione peroxidase (Avci et al 2008). Similarly, oral garlic (250 mg/day) taken for 2 months caused a significant reduction in markers of lipid peroxidation in people with essential hypertension compared to normotensive controls (Dhawan & Jain 2005).

### Protection against ischaemic and reperfusion injury

Prophylactic administration of garlic protects against renal and hepatic ischaemia/reperfusion injury in vitro and in a rat model (Kabasakal et al 2005, Sener et al 2005) prevents ischaemic and perfusion injuries after testicular torsion and detorsion in rats (Unsal et al 2006). More recently, pre-feeding mice with garlic attenuated oxidative damage in isoproterenol-induced myocardial infarction (MI) via the nitric oxide (NO) signalling pathway (Khatua et al 2012).

### Anti-inflammatory activity

Fresh garlic extracts and garlic oil exert anti-inflammatory action in various models. Mechanisms of action identified include a direct action upon Toll-like receptor-mediated signalling pathway, inhibiting NF-kappa activation (Youn et al 2008), modification of the expression of cyclooxygenase (COX) activity (Thomson et al 2000) and suppression of inducible nitric oxide synthase (iNOS) and NO production (Liu et al 2006). The sulfur compounds Z- and E-ajoenes and their sulfonyl analogues have been shown to suppress lipopolysaccharide-promoted NO and prostaglandin E<sub>2</sub>-mediated NF-κB-induced expression of iNOS/COX-2 genes (D Lee et al 2012). Lee et al investigated the anti-inflammatory action of DAS in articular chondrocytes and synovial fibroblasts harvested from patients undergoing joint replacement for osteoarthritis. Incubation with DAS inhibited the upregulation of COX-2 expression in synovial cells and chondrocytes and ameliorated crystal-induced synovitis through the inhibition of NF-κB (Lee et al 2009). Mice infected with malaria (*Plasmodium yoelli* 17XL) then treated with allicin 3 mg or 9 mg/kg had increased inflammatory mediators tumour necrosis factor, interferon-gamma, interleukin-12 (IL-12), p70, and NO; and immune cells, CD4<sup>+</sup> T cells, dendritic cells and macrophages were significantly higher in the treatment group, resulting in longer survival in a dose-dependent manner (Feng et al 2012).

### Inhibits platelet aggregation and antithrombotic effects

In vitro studies indicate that garlic inhibits platelet aggregation through multiple mechanisms, including inhibition of COX activity and thromboxane A<sub>2</sub> formation, via the suppression of intraplatelet Ca<sup>2+</sup> mobilisation and by increasing cAMP and cGMP

levels. The antioxidant action of garlic also increased platelet-derived NO, and interaction with glycoprotein IIb/IIIa receptors reduces platelets' ability to bind to fibrinogen (Allison et al 2006, Chan et al 2007, Rahman 2007).

Importantly, the method of garlic preparation can influence its antiplatelet activity in humans (Lawson et al 1992, Rahman & Billington 2000), yet microwaving, oven heating at 200°C or submersion in boiling water for 3 min has shown no reduction in inhibition of platelet aggregation as compared to raw garlic (Cavagnaro et al 2007).

The clinical significance of the in vitro findings is hard to determine, as a double-blind, placebo-controlled crossover study of 14 volunteers concluded that solvent-extracted garlic oil had minimal or no effect on platelet aggregation. Researchers found that administration of garlic 9.9 g over 4 h exerted little or no effect on both collagen and adenosine 5'-diphosphate (ADP)-induced aggregation. Adrenaline-induced aggregation did, however, exert a slight but significant ( $P < 0.05$ ; 12) reduction (Wojcikowski et al 2007).

### Stimulates fibrinolysis

A significant increase in fibrinolysis has been observed in several clinical tests for both raw and fried garlic, which appears to be dose-dependent (Bordia et al 1998, Chutani & Bordia 1981, Gadkari & Joshi 1991). A recent controlled animal study found a statistically significant decrease in plasma fibrinogen and increase in clotting time in treatment groups receiving doses of raw garlic 750 and 1000 mg/kg, respectively, in comparison to that of 500 mg/kg (Gorinstein et al 2006). Odourless garlic has been shown to stimulate fibrinolytic activity via accelerated tissue plasminogen activator-mediated plasminogen activation and to inhibit the formation of thrombin, leading to suppression of coagulation (Fukao et al 2007).

### Antiatherosclerotic activity

Evidence from in vitro, animal and human research has shown that garlic supplementation significantly reduces the atherosclerotic process (Campbell et al 2001, Durak et al 2002, Ferri et al 2003, Koscielny et al 1999, Kwon et al 2003, Orekhov et al 1995, Tsai et al 2012). Early research demonstrated that garlic significantly decreases accumulation of aortic tissue cholesterol, fatty-streak formation and the size of atherosclerotic plaque in vivo (Campbell et al 2001).

The adherence of leucocytes/monocytes to endothelium is also implicated in early-stage atherogenesis. In vitro studies have shown that incubation with garlic compounds significantly inhibits the oxidation of low-density lipoprotein (LDL) (Lau 2006), prevents adhesion of monocytes to IL-1alpha-stimulated endothelial cells (Rassoul et al 2006), suppresses oxidised LDL-mediated leucocyte adhesion to human endothelial cells (Lei et al 2008) and inhibits the uptake of oxidised LDL and CD36

expression (homocysteine-induced) by human macrophages (Moriyama et al 2011).

A critical review conducted on *in vitro* studies established that garlic inhibits enzymes involved in lipid synthesis, platelet aggregation and oxidation of LDL, while increasing antioxidant status (Rahman & Lowe 2006). Results from several published animal studies further exhibit antiatherogenic effects and have investigated the mechanisms responsible (Durak et al 2002, Ferri et al 2003, Kwon et al 2003). One *in vivo* study found that garlic activated antioxidant systems and decreased peroxidation in aortic tissue (Durak et al 2002), whereas ajoene inhibited smooth-muscle cell proliferation in another (Ferri et al 2003). The administration of 9 mg/kg of pure allicin in an animal model was found to reduce atherosclerotic plaque, Cu<sup>2+</sup> binding to LDL, macrophages and the inhibition of LDL and oxidised LDL degradation. Allicin was also found to directly bind to lipoproteins, suggesting a further mechanism of action (Gonen et al 2005).

Similar results have been obtained using ultrasound techniques. Koscielny et al (1999) conducted a long-term randomised, double-blind, placebo-controlled trial involving 152 volunteers to determine whether garlic powder supplements (Kwai 900 mg daily) directly alter plaque volumes in carotid and/or femoral arteries. After 4 years' treatment, garlic intake significantly reduced the expected increase in arteriosclerotic plaque volume by 5–18%, with a slight regression also observed. A subsequent re-evaluation of the results found that significant effects were limited to women (Siegel & Klussendorf 2000).

In a multifactor prognostic evaluation of high-risk patients assessing risk of coronary heart disease (CHD), MI and sudden death, prolonged administration of Allicor containing 150 mg of dehydrated garlic powder in a slow-release form significantly reduced multifactor risk of CHD in both genders. However, reduced risk of MI and sudden death was achieved significantly in men, but not in women. A pilot study suggests that incremental benefits were identified when evaluating the role of garlic therapy in coronary artery calcification with patients also on concomitant statin therapy (Budoff 2006).

A published review suggested that the antiatherosclerotic action of garlic, while dose-dependent, is a valuable component in an atherosclerosis-preventing diet (Gorinstein et al 2007). A need for the standardisation of garlic products has been called for, to enable the opportunity to evaluate and draw conclusions from research findings (El-Sabban & Abouazra 2008).

A possible role for garlic in the prevention of cerebrovascular damage has been postulated through a reduction in levels of beta-amyloid and apoptosis, associated with the pathogenesis of Alzheimer's disease (Borek 2006). S-allyl-L-cysteine, an OSC purified from aged garlic extract (AGE), exerted an anti-amyloidogenic activity *in vitro*, protecting against amyloid-beta-induced neuronal cell death,

inhibiting amyloid-beta fibril formation and defibrillating amyloid-beta preformed fibrils (Gupta & Rao 2007, Gupta et al 2009, Imai et al 2007, Ishige et al 2007).

### Reduces serum cholesterol levels

Two recent meta-analyses confirm that long-term garlic treatment modestly reduces total cholesterol levels (Ried et al 2013, Zeng et al 2012). Garlic powder capsules (mainly Kwai) are the most studied preparation; however the AGE preparations appear to have slightly stronger cholesterol-lowering activity than other forms.

A critical review published in 2006 suggests that garlic and its constituents exert a capacity to inhibit the enzymes involved in cholesterol and fatty acid synthesis, particularly mono-oxygenase and 3-hydroxy-3-methyl-glutaryl-CoA reductase (Rahman & Lowe 2006).

A 75% inhibition of cholesterol synthesis was achieved in garlic-treated human hepatoma cells without any evidence of cytotoxicity. Results indicated that compounds containing allyl-disulfide or allyl-sulfhydryl have the strongest inhibitory effect, likely to be through mediation of sterol 4-alpha-methyl oxidase (Singh & Porter 2006). Administration of high-dose (500 mg/kg) raw garlic extract to rats showed a significant (38%) reduction in triglycerides and cholesterol (Thomson et al 2006).

The capacity for modulating lipids may be attributed to the release of allicin through enzyme activation. A clinical crossover study involving 50 renal transplant patients involved the ingestion of one garlic clove daily for 2 months, either by swallowing or chewing. The swallowing route achieved a significant reduction in systolic blood pressure (SBP) and malondialdehyde (MDA) but no change in lipid parameters. However, chewing garlic achieved a reduction in cholesterol and a significant reduction in triglycerides, MDA and systolic and diastolic blood pressures, but no changes in high-density lipoprotein (HDL) or LDL (Jabbari et al 2005).

The metabolic activity of garlic has been studied in an obese rat model which compared three interventions to controls (garlic, exercise, garlic plus exercise). While all groups showed positive effects on cholesterol lowering, obesity and inflammation, the combination of garlic plus exercise group showed the greatest effects ( $P < 0.001$ ) (Seo et al 2012).

Garlic's beneficial effects on serum lipids have been shown to decline following cessation of treatment, suggesting that long-term supplementation is required. A reduction in cholesterol and triglycerides and an increase in HDL were achieved in 30 participants with elevated blood cholesterol ingesting 5 g of raw garlic twice daily for 42 days. However, following a 42-day washout period, cholesterol and triglycerides increased and HDL decreased (Mahmoodi et al 2006). This study was repeated in 30 participants with blood cholesterol >245 mg/dL, with decreases in total blood

cholesterol ( $P < 0.001$ ) and triglycerides ( $P < 0.01$ ), while HDL-C was increased ( $P < 0.01$ ); these results were again reversed after a 42-day washout period (Hosseini et al 2013). Earlier clinical evidence also supports these results (Bordia et al 1998, Sobenin et al 2005).

### Hypoglycaemic activity

Animal studies have shown that garlic and its constituents exhibit a hypoglycaemic action (Hattori et al 2005, Jelodar et al 2005) and produce significant changes in glucose tolerance and insulin secretion (Liu et al 2005, Padiya et al 2011). An antioxidant isolated from garlic, S-allyl cysteine sulfoxide, was found to stimulate insulin secretion from beta cells in rats (Augusti & Sheela 1996). Oral administration of garlic extract for 14 days significantly decreased serum glucose in streptozotocin-induced diabetic rats but not in normal rats. The garlic extract was also compared to that of glibenclamide, a known antidiabetic drug, and was found to be more effective (Eidi et al 2006). A similar study using garlic oil found no effect on oral glucose tolerance acutely, but did report significantly improved oral glucose tolerance at 4, 8, 12 and 16 weeks (Liu et al 2006). A study in a diabetic animal model showed garlic 100 mg/kg significantly reduced blood glucose levels and increased serum insulin levels in dogs when compared to controls. The effect was comparable to metformin (Mosallanejad et al 2013). A similar study in rabbits testing several doses of garlic extract in both normal and diabetic test animals found that the highest dose (350 mg/kg) had the strongest effect and significantly lowered blood glucose compared to controls in both cohorts. Levels of triglycerides and cholesterol also significantly reduced in both groups compared to controls, 4 h after administration. When compared to metformin, garlic had greater lipid-lowering activity whereas metformin was superior for hypoglycaemic activity (Sher et al 2012).

### Antihypertensive activity

Numerous clinical studies have identified mild to moderate antihypertensive activity with various garlic preparations when used for at least 12 weeks (Andrianova et al 2002, Dhawan & Jain 2005, Ried et al 2013, Silagy & Neil 1994, Stabler et al 2012, Tsai et al 2012). Although the mechanism of action has not been fully elucidated, evidence from in vivo research suggests that both the renin-angiotensin system and the NO system are responsible for this activity (Al-Qattan et al 2006, Mohamadi et al 2000). A controlled animal study found that both raw and aged garlic produced a reduction in induced elevated SBP compared to control. A reduction in pulse pressure was also achieved in the aged garlic-treated group (Harauma & Moriguchi 2006). Rats receiving a conjugate of allicin and captopril (allylmercaptocaptopril) showed a greater reduction in blood pressure and improved cardiac hypertrophy than those receiving captopril alone.

Allylmercaptocaptopril improved, whereas captopril impaired, fasting glucose tolerance (Ernsberger et al 2007). A similar study compared the effect of a fresh garlic homogenate (125–250 mg/kg) and its bioactive sulfur compound S-allylcysteine sulfoxide (SACS) in potentiating antihypertensive and cardioprotective activities of captopril (30 mg/kg) in rats. The combined treatment of garlic plus captopril was more effective than either alone and significantly reduced SBP, cholesterol, triglycerides and glucose in a dose-dependent manner (Asdaq & Inamdar 2010). In particular, a synergistic effect was seen for the blood pressure-lowering activity.

### Enhances microcirculation

Jung et al (1991) found that, 5 hours after the administration of garlic powder (Kwai: total dose 900 mg garlic powder), a significant increase in capillary skin perfusion (55%) occurred in healthy volunteers, whereas Kiesewetter et al (1993a) showed a 48% increase with a dose of 800 mg garlic.

### Antimicrobial and immune-enhancing activities

Garlic and its components have been demonstrated in vitro to exert a direct and indirect activity against various pathogens, including bacteria (both Gram-negative and Gram-positive), fungi and parasites. Antimicrobial sensitivity tests conducted on *Escherichia coli*, *Shigella* spp., *Salmonella* spp. and *Proteus mirabilis* found that no isolates were resistant to garlic; moreover, Gram-negative isolates were found to be highly sensitive to garlic in comparison to ciprofloxacin and ampicillin (Eja et al 2007).

Multiple chemical components in garlic demonstrate immunomodulating activity, including garlic sulfur compounds, lectins ASA I and II, agglutinins, proteins and fructans (Chandrashekar & Venkatesh 2009, Clement & Venkatesh 2010, Clement et al 2010, Chandrashekar et al 2011).

Allicin was initially believed to be chiefly responsible for the antimicrobial activity of garlic. Research found it to exert antibacterial activity against a wide range of Gram-negative and Gram-positive bacteria, including multidrug-resistant enterotoxigenic strains of *Escherichia coli*, *Staphylococcus aureus*, *Mycobacterium tuberculosis*, *Proteus* spp., *Streptococcus faecalis* and *Pseudomonas aeruginosa*; antifungal activity, particularly against *Candida albicans*; antiparasitic activity against some of the major human protozoan parasites such as *Cryptosporidium parvum*, *Trichomonas vaginalis*, *Entamoeba histolytica* and *Giardia lamblia* and antiviral activity (Ankri & Mirelman 1999, Davis 2005, Gaafar et al 2012, Ibrahim 2013, Tessema et al 2006). Allicin has been found to exert an antimalarial action in vitro and in vivo (Coppi et al 2006, Feng et al 2012) and to significantly enhance the effect of amphotericin B against *Candida albicans* in vitro and in vivo, mediated through oxidative damage to *C. albicans* (An et al 2008, 2009). Additionally, in vitro investigations have identified the capacity of allicin to activate macrophage activity

(Dong et al 2011, Ghazanfari et al 2006) and inhibit macrophage apoptosis (Cho et al 2006).

Ajoene, another important antimicrobial constituent, has been attributed to more biological activities in vitro and in vivo, including antifungal and antiparasitic actions (Ledezma & Apitz-Castro 2006), with greater antiviral activity than that of allicin, according to one in vitro test (Weber et al 1992), plus an interesting anti-leech effect (Eftekhari et al 2012).

The role of garlic in oral hygiene and the pathogenesis of dental disease has been investigated. All isolates of *Streptococcus mutans* identified in human carious teeth were sensitive to garlic extract, suggesting a role for garlic in mouthwashes for the prevention of dental caries (Fani et al 2007). This antimicrobial effect against streptococci was found to continue for 2 weeks posttreatment (Groppo et al 2007). Garlic extract was also found to significantly kill *Porphyromonas gingivalis* and its protease enzymes, indicating a role in the treatment of periodontitis (Bakri & Douglas 2005). A randomised trial of 56 patients found garlic paste to be as effective as that of clotrimazole solution in suppressing signs of oral candidiasis (Sabitha et al 2005).

#### *Helicobacter pylori* infection

Several in vitro and in vivo tests have shown that garlic has activity against *H. pylori* (Chung et al 1998, Jonkers et al 1999, O'Gara et al 2000); however, results from clinical studies are equivocal. Two studies found that a combination of garlic and omeprazole produced synergistic effects against *H. pylori* (Cellini et al 1996, Jonkers et al 1999). A rapid anti-*H. pylori* action of garlic oil was observed in artificial gastric juice, suggesting it as a useful treatment (O'Gara et al 2008).

#### Antineoplastic and chemopreventive effects

Garlic was first used over 3500 years ago in Egypt for the treatment of cancer. Garlic, and, in particular, its OSCs, including allicin, DAS, DADS, DATS and ajoene, have been investigated for their chemoprotective actions (Shukla & Kalra 2007). Many review articles have identified the multiple mechanisms by which garlic's compounds exert anticarcinogenic properties.

Garlic OSCs demonstrate a capacity to modulate detoxification enzyme systems often responsible for the activation of carcinogens (Yang et al 2001); for example, DAS and its metabolites have been found to competitively inhibit the metabolism of cytochrome P450 2E1 substrates in vitro (Brady et al 1991). This inhibitory activity has been shown in rat nasal mucosa (Hong et al 1991) and hepatocytes (Brady et al 1991). In addition, garlic OSCs increase the expression of phase II enzymes by enhancement of detoxification of activated carcinogenic intermediates such as quinone reductase and glutathione transferases (Bianchini & Vainio 2001, Rose et al 2005). Phase II enzyme modulation by OSCs has been reported in forestomach and lung cancer in

mice (Singh et al 1998), and hepatoma cells (Chen et al 2004). Further investigations have established garlic OSCs' capacity to upregulate gene expression of glutathione S-transferase.

Garlic OSCs have been shown to suppress neoplastic cell formation by inhibition of cell cycle progression, leading to cellular accumulation in the G2/M phase (Frantz et al 2000, Zheng et al 1997). Human colon cancer cells treated with DADS have not only been seen to arrest the G2/M phase: concomitant alterations were also seen to DNA repair and cellular adhesion factors (Knowles & Milner 2003), with increases in cyclin B1 expression and p53 expression leading to cellular apoptosis (Jo et al 2008, Song et al 2009). DATS also induced apoptosis in primary colorectal cancer cells via mitochondrial-signalling pathways (Yu et al 2012), while treatment with DATS was reported to be more effective in arresting the G2/M phase of the cell cycle than DADS or DAS in human prostate cells (Xiao et al 2005). However DADS induced apoptosis in prostate cancer cells through modulation of the insulin growth factor pathway and the resulting inhibition of Akt phosphorylation, which resulted in reduced expression of antiapoptotic molecules and increased expression of proapoptotic signalling molecules (Arunkumar et al 2012). In human cervical cell cancer lines (Ski) DAS caused apoptosis via p53-induced cell cycle arrest and mitochondrial disruption (Chiu et al 2013).

Treatment with garlic and its compounds has been shown to display characteristics of mitotic arrest, exhibiting alterations to tubulin network and chromatin condensation (Herman-Antosiewicz & Singh 2005). Treatment of human colon cells with garlic-derived compound SAMC resulted in depolymerisation of microtubules and cytoskeleton disruption (Xiao et al 2005). Similarly, DATS treatment induced rapid microtubule disassembly and cell cycle arrest in human colon cancer cells (Hosono et al 2008).

Garlic and its constituents have demonstrated actions that modify apoptotic pathways mostly through regulation of antiapoptotic Bcl-2 and proapoptotic Bax and Bac proteins (Herman-Antosiewicz et al 2007). For example, modification to transcription ratios of Bax/Bcl-2 proteins following treatment with OSCs has induced apoptosis in neuroblastoma and lung cancer cells (Hong et al 2000), breast cancer cell lines (Nakagawa et al 2001) and prostate cancer cells (Arunkumar et al 2012, Xiao et al 2004). Another mechanism shown to induce cellular apoptosis following treatment with OSCs is the induction of reactive oxygen species (ROS) generation (Song et al 2009, Sriram et al 2008). DATS has been shown to induce ROS, reduce cell viability, increase apoptosis and inhibit cell migration in human breast cancer cells, but not in normal breast tissue cells (Chandra-Kuntal et al 2013). It has also been shown to induce ROS-related mitochondrial membrane disruption in hepatic cancer cells (Kim et al 2012). Additionally

regulation of Akt-Bad (protein kinase B) pathway (Arunkumar et al 2012, Xiao & Singh 2006) and increased free intracellular calcium (Lin et al 2006) have been demonstrated. Malignant cells appear to be more sensitive to OSC-mediated apoptosis than normal cells (Chandra-Kuntal et al 2013, Powolny & Singh 2008). Garlic OSCs' protective qualities include increased histone acetylation by the inhibition of histone deacetylase, leading to cancer cell growth inhibition; for example, treatment of rodent erythroleukaemia and human leukaemia cells with DADS increases H4 and H3 histone acetylations (Lea & Randolph 2001). Increased acetylation has also been reported with treatment of OSCs in human colon cancer cells (Druesne et al 2004), breast cancer cells (Altonsy et al 2012) and prostate cancer cells (Arunkumar et al 2007). Similar research has been repeated in many different human cancer cell lines (Tsai et al 2012).

Finally, in vitro studies in human and animal cell lines indicate garlic and/or its constituents' ability to inhibit angiogenesis and metastasis. In human colon cancer cells, AGE was shown to inhibit angiogenesis by reducing endothelial cell motility, inhibiting tube formation, proliferation and invasion (Matsuura et al 2006). Administration of alliin exerted a dose-dependent inhibition of fibroblast growth factor-2-induced human endothelial cell tube formation and angiogenesis (Mousa & Mousa 2005). Similarly, treatments with DATS, DADS and DAS have been shown to inhibit capillary-like tube formation, cellular proliferation and migration (Thejass & Kuttan 2007). DADS was also found to inhibit angiogenesis by inhibiting the activation of matrix metalloproteinase (Thejass & Kuttan 2007). In human breast tumour cells, SAC reduced cell adhesion and invasion through expression of E-cadherin and reduced expression of matrix metalloproteinase-2 (Gapter et al 2008). In animal studies, intravenous administration of ajoene significantly inhibited lung metastasis of melanoma cells (Taylor et al 2006) and AGE inhibited sarcoma cell migration (Hu et al 2002). A mouse model of inserted fibrosarcoma showed treatment with AGE reduced tumour progression and significantly improved survival with CD4<sup>+</sup>/CD8<sup>+</sup> T-cell modulation (Fallah-Rostami et al 2013).

There are many published reviews confirming garlic and its constituents' chemoprotective capacity in various human cancer cell lines (Herman-Antosiewicz et al 2007, Moriarty et al 2007, Nagini 2008, Powolny & Singh 2008, Seki et al 2008, Shukla & Kalra 2007). It is suggested that future research should focus on pharmacokinetics and pharmacodynamics in humans (Powolny & Singh 2008).

## OTHER ACTIONS

### Hepatoprotective effects

AGE has a glutathione-sparing effect in the liver and specifically elevates reduced glutathione content, thereby enhancing endogenous protective mechanisms,

according to in vitro tests (Wang et al 1999). The protective effects of a single simultaneous dose of garlic oil have been demonstrated on acute ethanol-induced fatty liver in mice, by significantly inhibiting elevation of MDA levels, restoring glutathione levels and enhancing SOD, glutathione reductase and glutathione S-transferase activities (Zeng et al 2008). More recent studies with organosulfur components from garlic have also demonstrated hepatoprotective effects in vivo (D'Argenio et al 2013, Xiao et al 2013) and a small clinical trial demonstrated a dose-dependent protective effect of a garlic oil and diphenyl-dimethyldicarboxylate (DDM) supplement, as measured by aspartate aminotransferase and alanine aminotransferase levels in patients with chronic hepatitis, with the greatest benefit seen in doses of 75–100 mg of DDB and 100–150 mg of garlic oil (M Lee et al 2012).

### Homocysteine-lowering action

AGE exhibits homocysteine-lowering action that indicates its potential for the treatment of cardiovascular disease (Yeh & Yeh 2006). A pilot study conducted in patients with cardiovascular disease showed that pretreatment for 6 weeks with AGE significantly reduced the effects of acute hyperhomocysteinaemia (Weiss et al 2006). It is postulated that the homocysteine-lowering action of AGE is due to its ability to inhibit CD36 expression and OxLDL uptake in macrophages involved in the formation of atherosclerotic lesions (Ide et al 2006).

### Inhibits CYP 2E1 and induces P-glycoprotein

According to in vitro and animal studies, garlic and some of its components may affect various cytochromes (Engdal et al 2009, Fisher et al 2007, Greenblatt et al 2006); however, human research has not produced the same findings (Cox et al 2006, Dalvi 1992, Foster et al 2001, Gurley et al 2002, 2005) and now confirmed that it is only clinically relevant for cytochrome 2E1 and P-glycoprotein with no effects on CYP3A4.

Researchers using human volunteers found that garlic oil reduced CYP2E1 activity by 39%, but had no effect on CYP1A2, CYP2D6 or CYP3A4 activity (Gurley et al 2002). The lack of a clinically significant effect on CYP1A2, CYP2D6 and CYP3A4 activity was confirmed in a later study of 12 elderly healthy volunteers receiving garlic oil for 28 days, followed by a 30-day washout period. Garlic oil had a mild inhibitory effect on CYP2E1 activity (by approximately 22%) (Gurley et al 2005). Additionally, tests with allicin found no effect on CYP3A4 in women receiving docetaxel treatment (Cox et al 2006).

More recently, a clinical study further confirmed no significant effect on CYP3A4 for oral ingestion of garlic extract by human volunteers but a significant induction of P-glycoprotein (Hajda et al 2010). Specifically, the ingestion of garlic extract increased expression of duodenal P-glycoprotein to 131% (95% confidence interval [CI] 105–163%)

and negatively correlated with changes to the average area under the plasma concentration curve of saquinavir, which decreased to 85% (95% CI 66–109%).

Another clinical study identified that co-administration of garlic did not significantly alter warfarin pharmacokinetics or pharmacodynamics in healthy volunteers who had taken a single dose of 25 mg warfarin administered after 2 weeks of pre-treatment with garlic (Mohammed Abdul et al 2008).

### Quality of life

A small open-label study observed the effect of a Japanese garlic extract supplement (Aomori) 500 mg daily on 17 active workers with significant improvements in self-assessed stress, sleep quality, fatigue, dehydroepiandrosterone sulfate and cortisol awakening response, as measurements of improved quality of life (Ohiro et al 2013).

### CLINICAL USE

The use of garlic to treat a variety of conditions is supported by several authorities. Treatment of atherosclerosis, arterial vascular disease, blood lipids, respiratory tract infections and catarrhal conditions has been indicated by the European Scientific Cooperative on Phytotherapy (ES COP). Treatment of hyperlipidaemia and age-related vascular changes with garlic is supported by the expert German panel, the Commission E, while the World Health Organization (WHO) also reports that there are sufficient clinical data to indicate the use of garlic in hyperlipidaemia, age-dependent atherosclerosis and mild hypertension. Many different dietary forms and commercial preparations of garlic have been tested in clinical trials and several meta-analyses have been published to further aid our understanding of its role in practice.

### Cardiovascular disease

Epidemiological studies show an inverse correlation between garlic consumption and progression of CVD in general (Rahman & Lowe 2006). Several intervention studies have also been published producing promising results for various forms of garlic treatment.

A double-blind, placebo-controlled study of 167 patients with hyperlipidaemia demonstrated that Allisor was effective in reducing the 10-year absolute multifactorial risk of cardiovascular diseases (Sobenin et al 2005). Garlic was also found to reduce the 10-year risk of acute MI and sudden death in a double-blind, placebo-controlled study of 51 patients with coronary artery disease receiving Allisor for a 12-month period (Sobenin et al 2007).

Previously, Koscielny et al (1999) conducted a long-term randomised, double-blind, placebo-controlled trial involving 152 volunteers to determine whether garlic powder supplements (Kwai 900 mg daily) directly alter plaque volumes in carotid and/or femoral arteries. After 4 years'

treatment, garlic intake significantly reduced the expected increase in arteriosclerotic plaque volume by 5–18%, with a slight regression also observed. A subsequent re-evaluation of the results found that significant effects were limited to women (Siegel & Klussendorf 2000).

In a multifactor prognostic evaluation of high-risk patients assessing risk of CHD, MI and sudden death, prolonged administration of Allisor significantly reduced multifactor risk of CHD in both genders. However, reduced risk of MI and sudden death was achieved significantly in men, but not in women (Sobenin et al 2005).

Long-term use of AGE (1200 mg/day) appears to retard calcification of coronary arteries according to a placebo-controlled, double-blind, randomised pilot study involving high-risk patients while on a stable course of statin and aspirin therapy (Budoff 2006). Active treatment slowed down progression of disease, as the study showed that patients on placebo (with statin baseline therapy) progressed at a rate of 22.2% per year compared to those also taking AGE, who had a reduced progression to 7.5%.

### IN COMBINATION

In 2009 Budoff et al reported on a well-designed double-blind randomised controlled trial (RCT) of 65 intermediate-risk patients taking statin medication and presenting with subclinical atherosclerosis coronary artery disease. Subjects were treated with a capsule containing 250 mg of AGE, B<sub>12</sub> 100 mcg, folic acid 300 mcg, B<sub>6</sub> 12.5 mg and L-arginine 100 mg or placebo daily for 1 year. The treatment group achieved significantly favourable changes in oxidative biomarkers, vascular factors and reduced progression of atherosclerosis. In 2012, results of an RCT once again found that coronary artery calcification could be significantly decreased with AGE (1200 mg/day), this time used together with coenzyme Q10 (120 mg/day) for 1 year. The placebo-controlled study involved 65 intermediate-risk firemen and found both coronary artery calcium and C-reactive protein significantly decreased with active treatment compared to placebo ( $P = 0.01$ ). Interestingly, only 24.4% of participants were on statin drugs (Zeb et al 2012).

### Hypertension

The current clinical evidence indicates that garlic treatment has a slow-onset blood pressure-reducing effect when taken for approximately 12 weeks; however, it is difficult to quantify the size of effect. It has been tested as a stand-alone treatment or used together with standard antihypertensive medication to produce further reductions in blood pressure. Based on current clinical and preclinical research, the effectiveness of treatment is primarily determined by its content of SAC and ability to yield allixin, although other compounds may also be important.

An early meta-analysis reported in 1994 analysing results from seven trials using Kwai 600–900 mg daily showed a mean reduction of 7.7 mmHg for

SBP and 5 mmHg for diastolic blood pressure (DBP) (Silagy & Neil 1994). Isolating the results of the two placebo-controlled trials involving hypertensive patients, the reduction in SBP was 11.1 mmHg and 6.5 mmHg reduction in DBP with garlic treatment.

In 2000, the Agency for Health Care Research and Quality analysed results from 27 randomised, placebo-controlled trials and reported that results were mixed, with occasional small reductions reported (Mulrow et al 2000).

In contrast, in 2008 Reinhart et al analysed 10 clinical trials, reporting that garlic reduced blood pressure in patients with an elevated SBP, but not in those with normal SBP. The same year, Ried et al (2008) conducted a meta-analysis of 11 randomised placebo-controlled trials ( $n = 1298$ ) and concluded that garlic preparations are superior to placebo in reducing SBP and DBP in normotensive people and those with hypertension (Ried et al 2008).

In 2012, a Cochrane systematic review confirmed that garlic treatment reduces blood pressure when compared to placebo; however, the magnitude of this effect cannot be accurately quantified. The review analysed the results of two studies ( $n = 87$ ) which met the entry criteria of being randomised, blinded, controlled to treatment, including intention-to-treat data and involving only participants with primary hypertension. One of the included studies reported that 12 weeks of treatment with 200 mg garlic powder (Kwai) three times daily reduced supine SBP by 10–12 mmHg and DBP by 5–9 mmHg and significantly reduced standing SBP by 21 mmHg (from 171 to 150 mmHg) and DBP by 11 mmHg (from 101 to 90 mmHg) (Auer et al 1990). The other study found that 12 weeks' treatment with two capsules of 100 mg high-potency garlic powder taken three times daily produced a statistically significant mean reduction in supine SBP of 16 mmHg (from 178 to 162 mmHg) and supine DBP of 15 mmHg (from 100 to 85 mmHg). Treatment also produced a statistically significant mean reduction in standing SBP of 16 mmHg (from 174 to 158 mmHg) and standing DBP of 16 mmHg (from 99 to 83 mmHg) (Stabler et al 2012).

Due to the limited data available, the Cochrane systematic review was unable to determine whether garlic treatment reduced all-cause mortality, cardiovascular events or cerebrovascular events in hypertensive patients (Stabler et al 2012).

Since then, three further randomised trials have been published. An RCT of 50 participants with uncontrolled hypertension taking standard treatment were given additional AGE 960 mg (standardised to 2.4 mg SAC) or placebo and found active treatment produced a significant reduction in SBP after 12 weeks for people with baseline SBP > 140 mmHg ( $P = 0.036$ ). There was no significant reduction seen across the whole treatment group, which also consisted of people with SBP < 140 mmHg (Ried et al 2010).

In 2013 the same authors published results of a double-blind, randomised trial comparing three different dosages (240/480/960 mg containing 0.6/1.2/2.4 mg SAC) of AGE (Kyolic aged garlic; extract: High Potency Everyday Formula 112; Wakunaga/Wagner) plus regular treatment in 79 subjects with uncontrolled systolic hypertension. Similar to previous studies, SBP was significantly lowered after 12 weeks of treatment by  $11.8 \pm 5.4$  mmHg compared with placebo ( $P = 0.006$ ). The effect was only seen in the groups taking at least 480 mg daily. Interestingly, the hypotensive effect did not occur in all patients and ranged from -40 mmHg to +5 mmHg across all groups; however this study was unable to predict responder characteristics. Mild gastrointestinal side effects were reported, mainly in the highest-dose group (Ried et al 2013).

A traditional Japanese garlic homogenate (300 mg/day)-supplemented diet was compared to placebo in a randomised, double-blind study involving 81 participants with prehypertension or mild hypertension. Once again, treatment for 12 weeks induced significant reductions in SBP (-6.6 mmHg to -7.5 mmHg) and DBP (-4.6 mmHg to -5.2 mmHg) compared to placebo with no major side effects. Importantly, the effect was only clinically relevant in subjects with hypertension (Nakasono et al 2013).

### Hyperlipidaemia

The most recent meta-analyses confirm that long-term garlic treatment modestly reduces total cholesterol levels. Garlic powder capsules (mainly Kwai) are the most-studied preparation; however the AGE preparations appear to have slightly stronger cholesterol-lowering activity than the powder forms.

In 2000, a meta-analysis of 13 clinical trials concluded that garlic reduces total cholesterol levels significantly more than placebo; however, the effects can only be described as modest (Stevinson et al 2001). The same year, a systematic review and meta-analysis were published by the Agency for Health Care Research and Quality, which analysed results from 44 studies with lipid outcomes (Mulrow et al 2000). Most studies involved fewer than 100 volunteers and randomisation techniques were unclear in 82% of the studies. Pooled data from the placebo-controlled trials reporting changes in total cholesterol levels found a significant average reduction in total cholesterol levels of 7.2 mg/dL after 4–6 weeks, using any form of garlic, and a reduction of 17.1 mg/dL at 8–12 weeks. Results at 20–24 weeks were not significant and thought to be due to low statistical power, fewer long-term studies or a time-dependent effect of garlic.

Two meta-analyses have been published more recently. The first, in 2012, analysed results from 26 RCTs and did not discriminate between preparation or dose, finding that total cholesterol and triglycerides were significantly reduced ( $P = 0.001$ ), with the most marked outcomes seen in people with higher

triglyceride levels and long-term interventions. The most-studied preparation was garlic powder, mainly Kwai brand, with doses ranging from 600 to 900 mg, whereas four studies used garlic oil and three studies used AGE. The duration of treatment ranged from 2 weeks to 1 year and no other lipid parameters were affected. Further, the review surmises that total cholesterol is most affected by aged garlic and powdered garlic, while triglycerides were most affected by powdered preparations (Zeng et al 2012).

In 2013, Ried et al published a meta-analysis of 37 RCTs ( $n = 2,298$ ) which produced similar results: a significant cholesterol-lowering effect of garlic preparations compared with placebo and that the cholesterol-lowering treatment effect was more pronounced in trials of longer duration. The best effects were obtained when the intervention was used for longer than 12 weeks. More specifically, interventions >2 months in those with total cholesterol >200 mg/dL ( $\sim 5.2$  mmol/L) had significant reductions in total cholesterol by  $17 \pm 6$  mg, reduction in LDL cholesterol by  $9 \pm 6$  mg/dL, only marginal improvements in HDL cholesterol ( $1.5 \pm 1.3$  mg/dL) and no significant improvement in triglycerides. Subgroup analysis by single type of garlic preparation suggested a greater cholesterol-lowering effect for AGE than for garlic powder, and a borderline effect for garlic oil. The effect of garlic on HDL cholesterol levels was significant but small and most pronounced for garlic oil and the effect on triglycerides was non-significant overall (Ried et al 2013).

### Comparative studies

Two clinical studies have compared different garlic preparations with pharmaceutical cholesterol-lowering medicines. Garlic taken as 300 mg three times daily (Kwai) produced similar lipid-lowering effects to 200 mg Bezafibrate (a hypolipidaemic fibrate) three times daily in subjects with primary hyperlipidaemia (Holzgartner et al 1992), whereas Clofibrate 500 mg was more effective than an essential oil extract of 50 g raw garlic (Arora & Arora 1981). The administration of 600 mg of fish oil with 500 mg of garlic pearls (garlic oil) per day to 16 hypercholesterolaemic subjects with a total cholesterol above 220 mg/dL for 60 days was found to reduce total cholesterol, LDL, serum triglyceride and very-low-density lipoprotein (Jeyaraj et al 2005).

Commission E approves the use of garlic as an adjunct to dietary changes in the treatment of hyperlipidaemia (Blumenthal 2000).

### Diabetes mellitus (plus hyperlipidaemia)

Garlic may be of benefit to people with diabetes, according to the available clinical research; however mixed results hamper the interpretation of results.

In the 1990s, one double-blind study reported that 800 mg garlic powder taken daily for a period of 4 weeks reduced blood glucose concentrations by

### Clinical note — Not all garlic preparations are the same

One of the difficulties encountered when interpreting the research available for garlic is comparing the effects of different preparations, which often have not been tested for the presence of important constituents or allicin-releasing potential. It is known that fresh garlic and dried garlic powder contain alliin. When cut, crushed, chewed or dehydrated, the enzyme alliinase is rapidly released, which allows the biotransformation of alliin to active organo-sulfur compounds. Some other forms may only contain alliin, and not the necessary alliinase component, thus compromising allicin-releasing potential. An example of the manufacturing process affecting potency has been suggested for a commercial garlic product known as Kwai, which has often been used in cholesterol research (Lawson et al 2001). According to a 2001 experiment, substantial differences were found between tablets manufactured before 1993 (the years when all but one of the positive trials were conducted) and those manufactured after 1993 (the years when all of the negative trials were conducted). Kwai products manufactured after 1993 released only one-third as much allicin as older preparations. Those preparations from before 1993 disintegrated more slowly, protecting alliinase from acid exposure and inactivation.

11.6% (Kiesewetter et al 1993b); however, another study using a higher dose of 3 g/day over 26 weeks found no effects (Ali & Thomson 1995).

Ten years later, a 12-week, placebo-controlled, single-blind, randomised study found that treatment with a garlic tablet (Garlex: Bosch Pharmaceuticals, 300 mg, containing 1.3% allicin) twice daily, together with a diet and exercise plan, resulted in a significant reduction in total cholesterol of 28 mg/dL (12.03%) compared to placebo (Ashraf et al 2005). The study involved 70 patients with type 2 diabetes and newly diagnosed dyslipidaemia.

The metabolic action of Allicor (INAT-Farma, Russia) was investigated in a 4-week, double-blind, placebo-controlled study of 60 type 2 diabetic patients taken off their hypoglycaemic medication. Active treatment resulted in better metabolic control compared to placebo as measured by several parameters. In particular, a significant decrease in serum triglyceride levels was observed after 3 weeks of treatment, and by the end of the study the difference from baseline levels accounted for 36% ( $P < 0.05$ ). Additionally, fasting blood glucose levels decreased and were maintained at the mean levels below 7.0 mmol/L during the whole study period whereas they began to rise in the placebo group (Sobenin et al 2008). Allicor contains 150 mg of dehydrated garlic powder in a slow-release form and the dose used was 300 mg twice daily.

In contrast, a short-term double-blind placebo-controlled crossover trial of 26 people with type 2 diabetes found no change in endothelial function, vascular inflammation, insulin resistance or oxidative stress when 1200 mg of AGE was added to usual treatment for 4 weeks followed by a 4-week washout period (Atkin 2011).

In the past few years, several more clinical studies have been published, one comparing garlic to metformin and others adding garlic to metformin treatment to see if further benefits develop.

A single-blind placebo-controlled, escalating dose study was conducted with 210 people with type 2 diabetes comparing the effects of garlic 300, 600, 900, 1200, 1500 mg, metformin and placebo for 24 weeks. Results showed significant effects ( $P < 0.005$ ) for both fasting blood sugar and HbA<sub>1C</sub> with the higher garlic doses (1200 and 1500 mg) compared to placebo, both being comparable to metformin (Phil et al 2011).

#### *Adjunctive therapy to metformin*

An RCT involving 60 participants taking metformin 500 mg twice daily compared the addition of garlic 300 mg three times daily or placebo over a 24-week test period. Results showed that adding garlic to the treatment induced an improvement in both glycaemic control and cholesterol markers ( $P < 0.005$ ) compared to placebo (Ashraf et al 2011). Most recently an open-label study of 60 obese patients with type 2 diabetes compared the effects of stand-alone metformin 500 mg twice daily to metformin and garlic 250 mg twice daily for 12 weeks. Combination treatment resulted in significantly improved postprandial blood glucose levels ( $P < 0.001$ ), total cholesterol, triglycerides, LDL ( $P < 0.05$ ), adenosine deaminase ( $P < 0.01$ ) and C-reactive protein ( $P < 0.05$ ); however changes in HbA<sub>1C</sub> were not significantly different between the two groups (Kumar et al 2013).

#### **Antiplatelet effects**

Antiplatelet effects of garlic are well recognised, but the dose at which this becomes significant remains uncertain. Results from a 1996 double-blind study have identified a dose of 7.2 g/day of AGE as significantly inhibiting platelet aggregation and adhesion (Steiner et al 1996). In contrast, a double-blind, placebo-controlled crossover study of 14 volunteers concluded that solvent-extracted garlic oil had minimal or no effect on platelet aggregation. Researchers found that administration of garlic 9.9 g over 4 hours exerted little or no effect on both collagen and ADP-induced aggregation. Adrenaline-induced aggregation did, however, exert a slight but significant ( $P < 0.05$ ; 12) reduction (Wojcikowski et al 2007).

#### **Peripheral arterial occlusive disease**

In 2000, Mulrow et al reported on two double-blind placebo-controlled trials in participants with atherosclerotic lower-extremity disease. One study

of 64 participants showed that pain-free walking distance increased by approximately 40 m with standardised dehydrated garlic (Kwai 800 mg daily), compared with approximately 30 m with placebo over 12 weeks. The other study of 100 participants (Mulrow et al 2000) showed that a combination treatment of garlic oil macerate/soya lecithin/hawthorn oil/wheatgerm oil significantly increased the maximum walking distance (114%) compared to placebo (17%) ( $P < 0.05$ ). A 2008 Cochrane review found only one study meeting quality criteria and having a diagnosis of peripheral vascular atherosclerosis. The study included 78 participants, with garlic powder coated tablets 200 mg twice a day being no better than placebo for measured outcomes of walking distance and subjective symptoms after 12 weeks (Jepson et al 2008).

#### **Infection**

Garlic oil is effective against numerous bacteria, viruses and fungi, including *Staphylococcus aureus*, methicillin-resistant *Staphylococcus aureus* and several species of *Candida*, *Aspergillus* and *Cryptococcus neoformans* in vitro (Davis et al 1994, Tsao & Yin 2001, Yoshida et al 1987). As such, it has been used both internally and externally to treat various infections and prevent wound infection.

#### **Tinea pedis, tinea corporis, tinea cruris**

A trial comparing the effects of three different strengths of ajoene cream (0.4%, 0.6% and 1%) with 1% terbinafine applied twice daily found the cure rate to be 72% for 0.6% ajoene, 100% for 1% ajoene and 94% for 1% terbinafine after 60 days (Ledezma et al 2000).

#### **Vaginitis**

Taken internally as a 'natural antibiotic' or applied topically in a cream base, garlic is used to treat vaginitis. The considerable antibacterial activity of garlic provides a theoretical basis for its use in this condition, but controlled studies are not available to determine its effectiveness.

#### **Common cold prevention**

A 12-week, double-blind, randomised study involving 146 people demonstrated that allicin-containing garlic preparations significantly reduce the incidence of colds and accelerate recovery compared with placebo (Josling 2001). More specifically, the number of symptom days in the placebo group was 5.01 compared with 1.52 days in the garlic-treated group. Additionally, garlic reduced the incidence of developing a second cold, whereas placebo did not. These results were similar to those reported in a randomised, double-blind, placebo-controlled parallel intervention study of 120 participants given AGE 2.56 g/day for 90 days. At day 45  $\gamma\delta$  T-cell and natural killer cell proliferation were significantly increased, and at day 90 there was no change in cold and flu incidence between the two groups; however the treatment group had fewer symptoms

(21%), fewer sick days (58%) and fewer days lost from school/work (58%) than placebo (Nantz et al 2012).

### *Helicobacter pylori* infection

It has been suggested that gastrointestinal lesions, such as gastric ulcers, duodenal ulcers and gastric cancers, are strongly associated with *H. pylori* infection (Scheiman & Cutler 1999). Medical treatment consisting of 'triple therapy' has a high eradication rate, yet is associated with side effects and has started to give rise to antibiotic resistance. Since garlic intake has been associated with a lowered incidence of stomach cancer, researchers have started investigating whether garlic has activity against *H. pylori*. Several in vitro and in vivo tests have shown garlic to be effective against *H. pylori* (see section on **Main actions**, above). However, to date only a few small clinical trials have been conducted, with disappointing and controversial results (Aydin et al 2000, Graham et al 1999, McNulty et al 2001).

A small pilot study of dyspeptic patients with confirmed *H. pylori* infection found that treatment with 4 mg garlic oil capsules taken four times daily with meals for 14 days did not alter symptoms or lead to *H. pylori* eradication (McNulty et al 2001). Another small study using garlic oil 275 mg three times a day (allicin 800 mcg/capsule) either as stand-alone treatment or in combination with omeprazole (20 mg twice daily) found that both treatments produced similar results (Aydin et al 2000). These results were confirmed in another small clinical study (Graham et al 1999).

### Protective effects against cancer

Whether long-term garlic consumption reduces the risk of cancer is uncertain. A 2001 critical review of the epidemiological evidence suggests a preventive effect for garlic consumption in stomach and colorectal cancers, but not other cancers (Fleischauer & Arab 2001). With regard to gastric cancer protection, case-control studies suggested a protective effect for raw and/or cooked garlic when eaten at least once a week, whereas protective effects against colorectal cancer seem to require at least two servings of garlic per week. A similar view was reported in a 2003 review by Ernst, which stated that the weight of evidence to support the use of allium vegetables, such as garlic, in cancer is clearly positive. However, a 2009 review of 19 human studies evaluated the evidence supporting a relationship between garlic intake and a reduction in risk of different cancers with respect to food labelling. No evidence was found to suggest that garlic consumption reduced the risk of gastric, breast, lung or endometrial cancer, with very limited evidence supporting a reduction in risk of colon, prostate, oesophageal, larynx, oral, ovary or renal cell cancers due to garlic consumption (Kim & Kwon 2009). This has been reinforced by a 2012 systematic review of RCTs that found no benefit in reducing risk of cancer (Ernst & Posadzki 2012). Additionally,

a report on the Nurses' study and Health Professional follow-up study, which followed 76,208 women and 45,592 men for up to 24 years, found no benefit in either dietary garlic or garlic supplement use (Meng et al 2013). Data collected included those using up to one clove of garlic (or equivalent) per day and only 6% of participants used supplements, not enough to perform statistical analysis, and no information on dosage or preparation was collected.

In addition, the Cancer Prevention Study-II investigating colorectal cancer risk in the nutrition cohort of 42,824 men and 56,876 women, whose garlic use was tracked for 7 years, indicated at best a weak protective effect in women, and a slight increase in risk for men (McCullough et al 2012).

### Intervention study in colorectal cancer

A preliminary double-blind, randomised clinical trial in patients with colorectal adenomas — precancerous lesions of the large bowel — produced promising results with the use of high-dose AGE 2.4 mL/day (Tanaka et al 2006). The study of 51 patients measured the number and size of adenomas at baseline and at 6 and 12 months and found that AGE significantly suppressed both the size and the number of colon adenomas in patients after 1 year of treatment ( $P = 0.04$ ). In comparison, the number of adenomas increased linearly in the control group from the beginning.

A systematic review of scientific evidence from all studies conducted over the last decade that examined the effects of garlic on colorectal cancer was conducted. Five of eight case-control/cohort studies suggested that a high intake of raw/cooked garlic produced a chemoprotective effect. Review of 11 animal studies showed a significant anticarcinogenic effect of garlic. Overall, the authors concluded that there was consistent scientific evidence derived from RCT animal studies, despite heterogeneity of human epidemiological studies (Ngo et al 2007).

### Endometrial cancer

Analysis of data from a multicentre, case-control study of 454 endometrial cancer cases and 908 controls found a moderately protective role for allium vegetables on the risk of endometrial cancer, with a significant inverse trend identified for high intakes of garlic (Galeone et al 2008). Topical application of garlic-derived ajoene to tumours of 21 patients with either nodular or superficial basal cell carcinoma resulted in reduction in tumour size in 17 patients. Chemical assays prior to and posttreatment showed a significant decrease in the expression of the apoptosis suppression protein Bcl-2 (Tilli et al 2003).

### OTHER USES

Some early research suggests that garlic may prevent the incidence of altitude sickness (Fallon et al 1998, Kim-Park & Ku 2000) and reduce mosquito numbers (Jarial 2001).

A small Indian trial randomly assigned 41 patients with hepatopulmonary syndrome to receive garlic oil capsules (1–2 g/m<sup>2</sup>/day) or placebo in divided doses over a period of 18 months, with monthly evaluations. After 9 months there was a 24.7% increase in baseline arterial oxygen levels ( $P < 0.001$ ) compared to a 7.4% increase in placebo. There was a 28.4% decrease in the alveolar–arterial oxygen gradient ( $P < 0.001$ ) and a 10.7% reduction in placebo, which was significantly better than placebo ( $P < 0.001$ ). Hepatopulmonary syndrome was reversed in 66.7% of patients in the treatment group compared to 5% in placebo (intention to treat) and at 18-month follow-up two had died in the treatment group compared to seven in the placebo group (De Binay et al 2010). This is an interesting study looking at a condition widely believed to be associated with increased NO production in liver cirrhosis.

## DOSAGE RANGE

### General guide

- Fresh garlic: 2–5 g/day (ensure it is bruised, crushed or chewed).
- Dried powder: 0.4–1.2 g/day.
- AGEs have been studied in amounts ranging from 2.4 to 7.2 g/day.
- Oil: 2–5 mg/day.
- Garlic preparations that will provide 4–12 mg alliin daily.
- Fluid extract (1:1): 0.5–2 mL three times daily.

### According to clinical studies

- Type 2 diabetes: Allicor 300 mg twice daily.
- Hypertension: AGE: 480–960 mg standardised to SAC 4.8 mg/day in divided doses and taken for at least 12 weeks to see maximal results.
- Hyperlipidaemia: 600–900 mg/day.
- Hyperglycaemia: 1200–1500 mg/day.
- Fungal infection: topical 0.4–0.6% ajoene cream applied twice daily.
- Occlusive arterial disease: 600–800 mg/day.

It is important to be aware of the thiosulfinate content, in particular the allicin-releasing ability, of any commercial product to ensure efficacy.

## ADVERSE REACTIONS

### Internal use

Side effects tend to be limited to mild gastrointestinal side effects such as bloating, reflux, flatulence, garlic odour and breath. A dose–response study with hypertensive subjects found 32% of people using AGE at a dose of 960 mg daily experienced mild gastrointestinal side effects compared to 15% taking 480 mg daily. These effects were minimised by taking the garlic treatment in the morning (Ried et al 2013). Others have reported garlic odour and breath, allergic reactions, nausea, abdominal discomfort and diarrhoea (Berthold & Sudhop 1998).

These side effects are more common when garlic is taken on an empty stomach and at doses greater than 1 g.

Headache, myalgia and fatigue were reported in one study using a dose of 900 mg garlic powder (standardised to 1.3% alliin) (Holzgartner et al 1992).

A meta-analysis of 37 RCTs investigating garlic for lipid lowering found no changes in liver function, biochemistry or haematology with use (Ried et al 2013).

### Topical use

An ajoene 0.6% gel produces a transient burning sensation after application, according to one study (Ledezma et al 1999). Garlic has been classified as a type 1 allergen with various reactions, including contact dermatitis, urticaria, asthma, pemphigus and anaphylaxis, being reported. DADS, allylpropyl disulfide and allylmercaptin have been identified as allergens (Tsai et al 2012).

## SIGNIFICANT INTERACTIONS

### Saquinavir, darunavir and ritonavir

Ritonavir toxicity has been reported in AIDS patients co-administering with garlic, most likely due to P-glycoprotein inhibition by allicin in garlic (Tsai et al 2012) — avoid using concurrently (Piscitelli et al 2002).

### Anticoagulants

Theoretically, a pharmacodynamic interaction is possible when using garlic at high doses (>7 g), in excess of usual dietary amounts; however, results from clinical studies cast doubt on this proposition. Published clinical studies have identified no significant action of enteric-coated or aged garlic on warfarin pharmacodynamics or pharmacokinetics. A double-blind, randomised, placebo-controlled pilot study of 48 patients demonstrated that the concomitant use of garlic containing 14.7 mg/day of SAC and warfarin showed no adverse effects (Macan et al 2006). An open-label, three-treatment, randomised, crossover clinical trial involving 12 healthy males, investigating potential effects of garlic and cranberry on warfarin (25 mg single dose), found that two garlic tablets daily containing 2000 mg of fresh garlic bulb equivalent to 3.71 mg of allicin per tablet did not significantly alter warfarin's pharmacokinetics or pharmacodynamics (Mohammed Abdul et al 2008). Use caution with doses >7 g/day.

### Antiplatelet drugs

Theoretically, a pharmacodynamic interaction is possible when using garlic at high doses in excess of usual dietary amounts, although a small clinical study involving 10 adult participants showed garlic had no effect on platelet function (Beckert et al 2007). Observe.

### Antihypertensive agents

Theoretically, potentiation effects are possible when using garlic at high doses in excess of usual dietary amounts — this can be used as adjunctive therapy to produce beneficial results — observe.

### Antihyperlipidaemic agents

Theoretically, potentiation effects are possible when using garlic at high doses in excess of usual dietary amounts — this can be used as adjunctive therapy to produce beneficial results — observe.

### *Helicobacter pylori* triple therapy

Additive effects are theoretically possible. While it is prudent to observe the patient for adverse reactions, the interaction may be beneficial.

### Hepatotoxic drugs

Garlic may exert hepatoprotective activity against liver damage induced by drugs, according to in vitro tests, which suggest a beneficial interaction.

### Paracetamol

In vivo protection from garlic and ajoene on paracetamol-induced hepatotoxicity has been observed (Hsu et al 2006) — beneficial interaction.

### Hydrochlorothiazide

Co-administration may require a reduction in the dose of hydrochlorothiazide due to a pharmacokinetic interaction raising drug serum levels (Asdaq & Inamdar 2009). Cautious use under medical supervision.

### CONTRAINDICATIONS AND PRECAUTIONS

Patients with bleeding abnormalities should avoid high doses of garlic. Although usual dietary intakes are likely to be safe prior to major surgery, suspend the use of high-dose garlic supplements 1 week before, as there is a theoretical increased risk of bleeding.

Avoid if known allergy to sulfurous vegetables. If being used as part of a topical application, a test patch is advised before more widespread application.

### PREGNANCY USE

Garlic is not recommended at doses greater than usual dietary intakes in the first trimester until safety can be confirmed. A small trial in 100 pre-eclamptic primigravida women prescribed 800 mg of a dried garlic powder supplement throughout the third trimester reported no side effects or unexpected birth outcomes (Ziaei et al 2001).

### Practice points/Patient counselling

- Garlic is both a food and a therapeutic medicine capable of significant and varied pharmacological activity.
- It has antioxidant, antimicrobial, modest antiplatelet, antithrombotic, antiatherosclerotic and vasoprotective activities.
- Human research confirms that some garlic preparations lower total cholesterol levels and blood pressure and possibly blood glucose levels in people with type 2 diabetes.
- It also enhances microcirculation and may have anti-inflammatory and immunostimulant activities.
- Garlic is used as a treatment for many common infections, to reduce the incidence of colds, to improve peripheral circulation and to manage hyperlipidaemia and hypertension.
- Topical garlic preparations have been used to treat common fungal infections.
- Several important drug interactions are possible with garlic (see [significant interactions](#), above).

### PATIENTS' FAQs

#### *What will this herb do for me?*

Garlic has many different actions in the body and is used to treat conditions such as elevated blood pressure and cholesterol levels, poor peripheral circulation, higher than normal blood glucose levels and common infections such as the common cold, flu and athlete's foot. Research suggests that it may be effective in all of these conditions; however, in some cases, the effect is small.

#### *When will it start to work?*

This varies greatly, depending on the reason for use. For example, garlic has been shown to improve microcirculation within 5 hours of ingestion, whereas slowing down of the atherosclerotic process or cancer-protective effects are likely to require several years' continuous use.

#### *Are there any safety issues?*

When garlic is taken at doses above the usual dietary levels, it may interact with a number of medications. Also, it should not be taken by people with bleeding disorders.

# Gentian

**HISTORICAL NOTE** The genus *Gentiana* is derived from Gentius, king of ancient Illyria, who is attributed with the discovery of its therapeutic effects (Blumenthal 2000). In ancient Greece and Rome it was used to relieve common gastrointestinal symptoms, much as it is used today. It was first noted in the Chinese medical literature in 50 BC (Willard 1991).

## OTHER NAMES

Gentiana, yellow gentian, wild gentian, bitter wort

## BOTANICAL NAME/FAMILY

*Gentiana lutea* (family Gentianaceae)

## PLANT PARTS USED

Root and rhizome

## CHEMICAL COMPONENTS

Secoiridoid bitter glycosides (swertiamarin, gentiopicroside, amarogentin, sweroside), oligosaccharides, phenolic acids, phytosterols, polysaccharides (inulin and pectin), tannin, lupeol, beta-amyrin triterpenes, xanthenes (genitsine, isogenitsine), xanthone glycosides (gentiosides) and essential oil.

Analysis of several commercially available *G. lutea* samples showed that gentiopicroside is the most prevalent bioactive compound (4.46–9.53%), followed by loganic acid (0.10–0.76%), swertiamarin (0.21–0.45%) and then the xanthone glycosides. The xanthenes, genitsine, isogenitsine and the secoiridoid bitter glycosides, amarogentin were found in concentrations of only 0.02%, 0.11% (Aberham et al 2007) and 0.025–0.4% respectively (European Medicines Agency 2010).

## MAIN ACTIONS

The bitter taste of gentian root is due to the secoiridoid glycosides: gentiopicroside and amarogentin. (Aberham et al 2011, European Medicines Agency 2010) The bitterness values of gentiopicroside and amarogentin are 12,000 and 58 million respectively. Amarogentin is the most bitter natural substance known (Aberham et al 2011, European Medicines Agency 2010). It is through the stimulating effect of this bitter taste that most of the beneficial effects of *Gentiana lutea* are achieved.

### Digestive stimulant

The bitter principles induce reflex excitation of taste receptors and increased saliva, gastric juice and bile secretion, thereby stimulating appetite and digestion according to in vivo experiments. A small human study confirmed that oral administration of gentian root extract increases gastric juice secretion and emptying of the gallbladder (ESCOP 2003). This was also confirmed by the European Medicines Agency report, which states that bitters stimulate the

gustatory nerves in the mouth, leading to increased secretion of gastric fluid and bile (European Medicines Agency 2010).

### Antioxidant

Antioxidant activity has been observed in vitro for the ethyl acetate and chloroform fractions of gentian (Calliste et al 2001). An orally administered crude extract of *Gentiana lutea* (1 g/kg body weight/day) prevented both the reproductive toxicity and oxidative damage induced in rat testes in response to a high, acute dose of ketoconazole (Amin 2008).

In vitro testing of *Gentiana lutea* confirmed antioxidant activity using both the free radical scavenging test, 2,2-diphenyl-1-picrylhydrazyl and cyclic voltammetry. The 50% ethanolic extract showed the highest antioxidant capacity with IC<sub>50</sub> values of 20.6 mcg/mL. The ethanolic and water extracts contained the highest phenolic content (Nastasijevic et al 2012).

### Promotes wound healing

The gentiopicroside, sweroside and swertiamarin constituents from *Gentiana lutea* demonstrate wound-healing properties in animal models, due to increased stimulation of collagen production and mitotic activity (Ozturk et al 2006).

### Analgesic

An animal study has shown that gentiopicroside exerts its analgesic activity by down-regulation of the *N*-methyl-D-aspartate (NMDA) NR2B receptor expression in the anterior cingulate cortex; part of the forebrain responsible for pain transmission and modulation (Chen et al 2008). In this study gentiopicroside (50–200 mg/kg) caused a significant dose-related reduction of persistent inflammatory pain stimuli through the modulation of glutamatergic synaptic transmission in response to peripheral injury (Chen et al 2008).

### Antiaddictive

Gentian significantly reversed overexpression of the GluN2B-containing NMDA receptors and dopamine D2 receptors in the nucleus accumbens (forebrain area involved in drug addiction) during the first week of morphine withdrawal, reducing morphine dependence (Liu et al 2012).

### Anti-inflammatory

In vitro testing of *Gentiana lutea* extracts and its constituents found that gentiopicroside was the strongest inhibitor of myeloperoxidase, a peroxidase enzyme released during neutrophil and monocyte degranulation and inflammation. The inhibition of this enzyme has an anti-inflammatory effect (Nastasijevic et al 2012).

### OTHER ACTIONS

Traditionally, gentian is considered to have stomachic, anthelmintic, antiseptic, anti-inflammatory and tonic activity (Willard 1991).

### Antimicrobial

*Gentiana lutea* leaves and flowers extracts (not the traditional parts used) showed antimicrobial activity against an array of Gram-negative and Gram-positive bacteria and one human yeast pathogen. The minimum inhibitory concentration (MIC) values of the *G. lutea* leaf extract against *Pseudomonas aeruginosa*, *Bacillus subtilis*, *Proteus mirabilis*, *Staphylococcus epidermidis* and *Candida albicans* ranged from 0.12 to 0.31 mg/mL, showing sensitivity to this extract. The most susceptible microorganism to the flower extract of *G. lutea* was *Salmonella enteritidis* (MIC 0.15 mg/mL) (Savikin et al 2009). A gentian root preparation inhibited *Helicobacter pylori* in vitro (Mahady et al 2005) and animal studies with amarogentin have identified antileishmanial properties (Medda et al 1999).

### Antidiabetic

*Gentiana lutea* was tested in an in vitro study to evaluate its inhibitory activity on aldose reductase (ALR2) and thereby its ability to prevent the accumulation of intracellular sorbitol in dysglycaemia. Inhibitory activities against both rat lens and human recombinant ALR2 with IC<sub>50</sub> values of 23–82 mcg/mL were measured. Amarogentin showed the greatest specificity for effective inhibition of ALR2, compared to the other *G. lutea* constituents. Further research in vivo is required to confirm these findings, and if confirmed, *G. lutea* has potential in the prevention or treatment of diabetic complications (Akileshwari et al 2012).

### CLINICAL USE

Gentian root preparations have not been significantly investigated under clinical trial conditions, so evidence is mainly derived from traditional, in vitro and animal studies. It is a popular remedy amongst naturopaths and herbalists.

### Dyspepsia and flatulence

The considerable bitter taste of gentian provides a theoretical basis for its use in dyspepsia and flatulence, for which increased saliva and gastric acid secretion would be beneficial. Commission E and the European Scientific Co-operative on Phyto-medicine (ESCOP) approve its use for this indication (Blumenthal 2000, ESCOP 2003).

### Loss of appetite

The considerable bitter taste of gentian provides a theoretical basis for its use in anorexia, when increased saliva and gastric acid secretions would be beneficial. Commission E and ESCOP approve its use for this indication (Blumenthal 2000, ESCOP 2003).

### Radioprotective

In vitro and ex vivo testing of lymphocytes (peripheral blood mononuclear cells) and human cervix carcinoma (HeLa cell lines) in nine healthy persons given 15 g of *Gentiana lutea* extract and mangiferin (xanthone) showed it may reduce the cytotoxic effect of ionising radiation (6 and 8 Gy doses) without changing the efficacy of irradiation destroying malignant cells. This is significant as the protection of immunocompetent cells during tumour-destructive radiation therapy is clinically important (Menkovic et al 2010).

### OTHER USES

Traditionally, gentian has also been used for gout, amenorrhoea, diarrhoea and worms in the stomach and bowel (Willard 1991). Gentian is also used in alcoholic drinks such as brandy, medicinal wines and vermouth.

#### Clinical note — Herbs in alcoholic drinks

The maceration of herbs and spices in wine was common practice in antiquity, and the invention of aromatised wine, the ancestor of vermouth, has been attributed to Hippocrates (Liddle & Boero 2003). Herbs are still commonly used in alcoholic drink production today, either as flavourings, or as both fermentation substrates and flavouring agents. The volatile components of a herb will provide its distinctive odour, whereas non-volatile constituents can affect some gustatory reactions and produce a physiological effect. Bitter herbs such as gentian are used for flavour, but also because they contain a significant amount of fermentable sugars that can be converted by strains of yeast into ethanol in an alcoholic fermentation process. Examples of other herbs that are used in brandies, flavoured spirits, liqueurs, medicinal wines and vermouth are anise, caraway, cardamom, coriander, dandelion, sage and yarrow (Veljkovic & Stankovic 2003).

### DOSAGE RANGE

#### General guide

- Cut root or dried extract: 2–4 g/day.
- Fluid extract (1:1): 1–2 mL taken 1 hour before meals up to three times daily.
- Tincture (1:5): 3–12 mL/day.
- Infusion: 1–2 g in 150 mL boiled water taken 1 hour before meals and up to three times daily.

**Practice points/Patient counselling**

- Gentian root and its preparations are extremely bitter.
- Gentian preparations stimulate salivation, gastric juice and bile secretion.
- They are used to improve digestion, relieve flatulence and stimulate appetite.
- Gentian has shown potential in pain management, morphine withdrawal, reducing the cytotoxicity of ionising radiation without compromising its effectiveness, as well as the potential to reduce complications in diabetes.
- Little clinical investigation has been undertaken with the herb, so evidence of efficacy relies on traditional and animal studies. More research is needed.
- It should not be used in cases of gastric or duodenal ulcer or hyperacidity.

**ADVERSE REACTIONS**

Headaches have been reported (ESCOP 2003), as have nausea and vomiting with high doses.

**SIGNIFICANT INTERACTIONS**

Interactions are unknown.

**? CONTRAINDICATIONS AND PRECAUTIONS**

Contraindicated in gastric or duodenal ulcers and hyperacidity according to Commission E (Blumenthal 2000, European Medicines Agency 2010).

**! PREGNANCY USE**

There is insufficient reliable information available to make a recommendation.

**! PATIENTS' FAQs****What will this herb do for me?**

Gentian preparations stimulate taste buds when taken orally, and increase gastric juice secretion, thereby improving digestion.

**When will it start to work?**

Effects are expected within several minutes of ingestion.

**Are there any safety issues?**

It should not be used by people with gastric or duodenal ulcers or with gastric hyperacidity.

# Ginger

**HISTORICAL NOTE** Ginger has been used as both a food and a medicine since ancient times. Confucius wrote about it in his Analects, the Greek physician Dioscorides listed ginger as an antidote to poisoning, as a digestive, and as being warming to the stomach in *De Materia Medica*, and the Koran, the Talmud and the Bible all mention ginger. Records suggest that ginger was highly valued as an article of trade and in 13th- and 14th-century England, one pound of ginger was worth the same as a sheep (Rosengarten 1969). Ginger is still extremely popular in the practice of phytotherapy, particularly in traditional Chinese medicine (TCM), which distinguishes between the dried and fresh roots. It is widely used to stimulate circulation, treat various gastrointestinal disorders and as a stimulant heating agent.

## OTHER NAMES

African ginger, Indian ginger, Jamaica ginger, common ginger, rhizoma zingiberis, shokyo (Japanese).

## BOTANICAL NAME/FAMILY

*Zingiber officinale* Roscoe (family Zingiberaceae)

## PLANT PART USED

Rhizome

## CHEMICAL COMPONENTS

The ginger rhizome contains an essential oil and resin known collectively as oleoresin. The composition of the essential oil varies according to the geographical origin, but the chief constituents, sesquiterpene hydrocarbons, which are responsible for the characteristic aroma, are fairly constant.

The oleoresin contains:

- Sesquiterpenes: zingiberene, ar-curcumene, beta-sesquiphellandrene and beta-bisabolene.
- Pungent phenolic compounds: gingerols and their corresponding degradation products, shogaols, zingerone and paradol. Zingerone and shogaols are found in small amounts in fresh ginger and in larger amounts in dried or extracted products (Govindarajan 1982).
- Other constituents: diarylheptanoids galanolactone (diterpenoid), 6-gingesulfonic acid, monoacyldigalactosylglycerols (Awang 1992, Bhattarai et al 2001, Charles et al 2000, Govindarajan 1982, Kikuzaki et al 1991, WHO 2003, Yamahara et al 1992, Yoshikawa et al 1992, 1993).

## PHARMACOKINETICS

Metabolites of [6]-, [8]- and [10]-gingerol as well as [6]-shogaol have been detected as glucuronide and sulfate conjugates in the plasma of healthy human volunteers after oral ingestion of 100 mg–2 gram doses of ginger (Zick et al 2008). A clinical study estimated the half-life of [6]-, [8]- and [10]-gingerol as well as [6]-shogaol and their metabolites to be 1–3 hours in human plasma (Yu et al 2011).

## MAIN ACTIONS

### Anti-emetic

Ginger has demonstrated anti-emetic activity in both experimental models and human studies. It appears that several key constituents are responsible, which exert several different mechanisms. In vivo studies have demonstrated [6]-, [8]- and [10]-gingerol as well as [6]-shogaol exert anti-emetic activity (Abdel-Aziz et al 2006, Kawai et al 1994), most likely by acting on the 5-HT<sub>3</sub> receptor ion-channel complex, either by binding directly to a modulatory site distinct from the serotonin binding site or indirectly via underlying muscarinic receptors. Specific constituents of ginger volatile oil including terpinolene, beta-pinene and alpha-phellandrene were also found to induce an antispasmodic effect via interaction with the 5-HT<sub>3</sub> receptor channel system in rat

ileum (Riyazi et al 2007). Galactone has also been identified as a serotonin-receptor antagonist (Huang et al 1991, Mustafa et al 1993, Yamahara et al 1990). Such mechanisms of action also explain the inhibitory effect of ginger on serotonin-induced diarrhoea and antispasmodic effect on visceral and vascular smooth muscle.

Ginger has been shown to blunt gastric dysrhythmias and nausea evoked by acute hyperglycaemia in humans. The anti-arrhythmic and anti-emetic effects are thought to be due to a blockade of prostaglandins rather than inhibition of their release (Gonlachanvit et al 2003). Ginger has also been shown to reduce radiation-induced gastrointestinal distress and emesis in rat models, which is thought to be due at least in part to its antioxidant properties and the ability to scavenge free radicals and inhibit lipid peroxidation (Sharma et al 2005). Ginger extract displayed comparable radioprotection against radiation-induced taste aversion (CTA) when compared to dexamethasone and ondansetron in male and female rats. The most effective concentration was 1000 microgram/mL of ginger extract, which exerted free radical scavenging of hydroxyl ions and nitric oxide and modulation of CTA (Haksar et al 2006).

### Gastrointestinal activity

Ginger exerts several effects in the gastrointestinal tract, which lead to an improvement in gastrointestinal symptoms. It stimulates the flow of saliva, bile and gastric secretions (Platel & Srinivasan 1996, 2001; Yamahara et al 1985), and has been shown to increase gastrointestinal motility in several animal models and human studies (Gupta & Sharma 2001, Micklefield et al 1999, Phillips et al 1993). In a double-blind RCT involving 24 healthy volunteers, ginger was found to accelerate gastric emptying and stimulate antral contractions (Wu et al 2008), a result that was confirmed in a follow-up double blind RCT using 1.2 g ginger root (Hu et al 2011). Ginger has also been observed to have prokinetic activity in mice in vivo and antispasmodic activity in vitro (Ghayur & Gilani 2005). These findings appear to support the traditional use of ginger in the treatment of gastrointestinal discomfort, colic, diarrhoea and bloating, and its use as a carminative agent. New insight into the mechanisms of the antidiarrhoeal action of a decoction of ginger root indicates that it may modify bacterial as well as host cell metabolism, reducing colonisation of epithelial cells (Daswani et al 2010). In vitro studies confirm cholinergic agonistic activity on postsynaptic M3 receptors, as well as suggesting an inhibitory effect on presynaptic muscarinic autoreceptors; the [6]-gingerol constituent displayed the strongest antispasmodic activity (Ghayur et al 2008).

### Anti-ulcer activity

A number of in vivo studies have identified anti-ulcer activity for ginger extract and several of its isolated constituents. The orally administered

acetone extract of ginger at a dose of 1000 mg/kg and zingiberene, the main terpenoid in this extract, at 100 mg/kg significantly inhibited gastric lesions by 97.5% and 53.6%, respectively. Additionally, the pungent principle, [6]-gingerol at 100 mg/kg, significantly inhibited gastric lesions by 54.5%. These results suggest that both zingiberene and [6]-gingerol are important constituents responsible for ginger's anti-ulcer activity (Yamahara et al 1988). Other constituents demonstrating anti-ulcer properties in gastric ulcer models in rats include betasquiphellandrene, beta-bisabolene, ar-curcumen and shogaol (Sertie et al 1992, Yoshikawa et al 1994). Furthermore, an animal study showed that ginger was able to protect against indomethacin-induced gastric ulceration when administered at 100, 200 and 400 mg/kg, and was comparable in efficacy to the study's reference drug, ranitidine (Anoiske et al 2009).

*Helicobacter pylori* has been identified as a major causative factor in gastric ulcers. In vitro studies have established ginger extract containing gingerols effectively inhibited the growth of 19 strains of *H. pylori* including CagA+ strains (Mahady et al 2003, 2005). While ginger is effective in inhibiting *H. pylori*, its ability to prevent bacterial adhesion to the stomach tissue is limited (O'Mahony et al 2005).

In addition to direct anti-ulcer activity, ginger exerts synergistic effects with the antibiotic clarithromycin in inhibiting different *H. pylori* isolates independent of the organisms' susceptibility to clarithromycin (Nostro et al 2006). Ginger-free phenolic and ginger hydrolysed phenolic fractions were found to be potent inhibitors of gastric cell proton potassium ATPase and *H. pylori*, exhibiting a six-to-eight-fold better potency over lansoprazole (Siddharaju & Dharmesh 2007).

### Hypolipidaemic

Ginger demonstrates significant lipid lowering activity in several animal models and, more recently, a double-blind clinical trial.

High doses of an aqueous extract of ginger (500 mg/kg) significantly reduced serum cholesterol according to an animal study that used oral doses of a raw aqueous extract of ginger administered daily for a period of 4 weeks (Thomson et al 2002). Treatment with ginger methanol and ethyl acetate extracts (250 mg/kg) for 8 weeks also resulted in a significant reduction in lipid levels in vivo (Goyal & Kadnur 2006). Similarly, methanolic and ethyl acetate extracts of dried ginger rhizome significantly reduced fructose-elevated lipid levels and body weight in vivo (Kadnur & Goyal 2005). Reductions in lipid levels were further reported for ethanolic extract of ginger (200 mg/kg for 20 days) by using a streptozocin-induced diabetic rat model. In addition, herbal treatment effectively reduced serum glucose (Bhandari et al 2005).

Effects on triglyceride levels are more difficult to determine, as one study demonstrated that 250 microgram ginger extract/day reduced serum

triglyceride levels by 27% in mice (Fuhrman et al 2000), whereas another study using a high dose of 500 mg/kg found no significant effects (Thomson et al 2002).

An ex vivo study found that 250 mcg/day of a standardised ginger extract significantly reduced plasma cholesterol, triglycerides and LDL cholesterol levels, the LDL basal oxidative state, as well as LDL cholesterol and serum cholesterol's susceptibility to oxidation and aggregation, compared with placebo. Ginger also reduced aortic atherosclerotic lesions by 44% in atherosclerotic mouse aorta (Fuhrman et al 2000).

According to a double-blind controlled clinical trial study of 85 volunteers, ginger (3 g/day) demonstrates clinically significant lipid lowering effects compared to controls. After 45 days of treatment, triglyceride and cholesterol levels were reduced, as well as a reduction in LDL levels and an increase in HDL levels (Alizadeh-Navaei et al 2008).

### Glycaemic response

Ginger improves insulin sensitivity and reduces serum glucose levels in vivo (Al-Amin et al 2006, Goyal & Kandur 2006). The mechanisms underlying these actions are associated with the inhibition of key enzymes controlling carbohydrate metabolism, an insulinotropic effect rather than hypoglycaemic (Islam & Choi 2008), increased insulin release/sensitivity (Goyal & Kandur 2006), resulting in enhanced glucose uptake in peripheral adipose and skeletal muscle tissues. Significant lipid lowering activity further contributes to improving the insulin resistant condition (Li et al 2012).

Gingerols have been identified as the main constituent group responsible for improving insulin sensitivity. In an assay for aldose reductase inhibitors within ginger, five active compounds were isolated and two were found to be inhibitors of recombinant human aldose reductase (Kato et al 2006).

### Anti-inflammatory and analgesic

The anti-inflammatory and analgesic effects reported for ginger are attributed to multiple constituents exerting several different mechanisms.

An acetone extract containing gingerols, shogaols and minor compounds like gingerenone A, [6]-gingerdiol, hexahydrocurcumin and zingerone has been shown synergistically to produce dose-dependent anti-inflammatory effects (Schubbaum & Franz 2000). Other studies have identified the gingerols and diarylheptanoids and gingerdione as the key compounds responsible (Flynn et al 1986, Kiuchi et al 1992).

Investigations on macrophages in vitro found that [6]-shogaol and [6]-gingerol inhibit the expression of inflammatory iNOS and COX-2 proteins (Pan et al 2008). [6]-Gingerol has also been shown to inhibit catalytic activity of iNOS in murine macrophages via attenuation of NF-kappaB-mediated iNOS gene expression (Aktan et al 2006). [6]-Gingerol proved to be useful in treatment of inflammation

by selectively inhibiting the production of inflammatory cytokines of murine peritoneal macrophages without interfering with the antigen-presenting function of the macrophages (Tripathi et al 2007). Ginger extract inhibited interleukin (IL)-12, tumour necrosis factor (TNF)-alpha, IL-1-beta in lipopolysaccharide-stimulated macrophages and significantly reduced T-cell proliferation (Tripathi et al 2008).

Ginger has been found to modulate the arachidonic acid cascade, as COX-1 and -2 and lipoxygenase inhibition has been shown in vitro (Kobayashi et al 1987) and high oral doses of an aqueous extract of ginger (500 mg/kg) significantly lowered serum PGE<sub>2</sub> and thromboxane B<sub>2</sub> levels in rats (Thomson et al 2002). A hydroalcoholic extract of ginger exerted anti-inflammatory and attenuated COX metabolites in rat trachea hyperactivity for 90 minutes and 48 hours after exposure to lipopolysaccharide (LPS). Ginger reduced serum levels of prostaglandin (PGE<sub>2</sub>) and thromboxane (TXA<sub>2</sub>) post LPS exposure (Aimbire et al 2007). Ginger also suppresses leukotriene biosynthesis by inhibiting 5-lipoxygenase, thus distinguishing ginger from non-steroidal anti-inflammatory drugs (NSAIDs). Additionally, ginger extract has been shown to inhibit thromboxane synthase (Langner et al 1998) and a ginger extract (EV.EXT 77) has been found to inhibit the induction of several genes involved in the inflammatory response. These include genes encoding cytokines, chemokines and the inducible enzyme COX-2, thus providing evidence that ginger modulates biochemical pathways activated in chronic inflammation (Grzanna et al 2005). A positive response to ginger administration was also demonstrated in an arthritic animal model whereby a significant reduction in inflammatory cytokines occurred that was superior to indomethacin (Ramadan et al 2011).

Gingerol and [8]-gingerol have been found to evoke capsaicin-like intracellular Ca<sup>2+</sup> transients and ion currents in vitro and it has been suggested that gingerols represent a novel class of naturally occurring vanilloid receptor agonists that contribute to ginger's medicinal properties (Dedov et al 2002). This is supported by the finding that topical application of ginger creams or compresses produce an analgesic capsaicin-like effect on the release of the immunoreactive substance P from primary afferent neurons (Onogi et al 1992). In animal models of chemically induced inflammation, ginger extract reduced oedema that was partly caused by serotonin-receptor antagonism (Penna et al 2003) and has been shown to reduce inflammation in a non-dose dependent manner, and display equivalent efficacy to indomethacin (Anosike et al 2009). Additionally, ginger oil has shown anti-inflammatory activity, significantly suppressing both paw and joint swelling in severe adjuvant arthritis in rats (Sharma et al 1994).

In an animal model of rheumatoid arthritis, both crude ginger extract and gingerols were efficacious

in preventing streptococcal cell wall-induced arthritis. However, the crude ginger extract, which also contained essential oils, was more effective in preventing both joint inflammation and attenuating cellular destruction (Funk et al 2009).

### Antiplatelet

It has been suggested that gingerols and their derivatives represent a potential new class of platelet activation inhibitors, with synthetic gingerols being found to inhibit the arachidonic acid-induced platelet release reaction in vitro in a similar dose range as aspirin possibly due to an effect on COX activity in platelets (Koo et al 2001, Lu 2005, Nurtjahja-Tjendraputra et al 2003, Tjendraputra et al 2001).

Powdered ginger exerted an antiplatelet activity when taken in very high doses of at least 10 g, according to one human study (Bordia et al 1997). A randomised double-blind study found that doses up to 2 g of dried ginger had no effect on bleeding time, platelet aggregation or platelet count (Lumb 1994). This lack of effect has been demonstrated in healthy volunteers (Janssen et al 1996) and those with type 1 diabetes mellitus or coronary artery disease (Bordia et al 1997).

### Antimicrobial and antiparasitic

Ginger extract, several of its main constituents and essential oil of ginger exhibit antimicrobial activity in vitro and in vivo. Ginger extract has been shown to have an antibacterial effect against *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae* and *Haemophilus* collected from throat swabs of infected individuals. The minimum inhibitory concentration of ginger ranged from 0.0003 to 0.7 mcg/mL, and the minimum bactericidal concentration ranged from 0.135 to 2.04 mcg/mL (Akoachere et al 2002). Recent in vitro studies confirmed ginger compounds were effective against *Penicillium* spp., *Escherichia coli*, *Bacillus subtilis* and *Staphylococcus aureus*, with minimal inhibitory concentrations of the oleoresin and essential oil 2 mg/mL and 869.2 mg/mL, respectively (Bellik 2014). The anti-*H. pylori* effects of ginger have also been shown to inhibit *H. pylori* CagA<sup>+</sup> strains in vitro (Mahady et al 2003). Essential oils of ginger have also been shown to have antimicrobial activity against Gram-positive and Gram-negative bacteria in vitro (Martins et al 2001).

Various ginger extracts have demonstrated significant larvicidal potential against larvae of the dengue fever mosquito vector, *Aedes aegypti*. The application of ginger alcoholic and oil-based extracts resulted in complete mortality with no pupal or adult emergence (Kalaivani et al 2012, Kumar et al 2012).

### Ginger constituents

[10]-Gingerol and [12]-gingerol successfully inhibited oral bacteria associated with periodontitis. Ethanol and *n*-hexane extracts of ginger have demonstrated antibacterial activities against the bacteria

*Porphyromonas gingivalis*, *Porphyromonas endodontalis* and *Prevotella intermedia*, associated with periodontal disease, effectively inhibited the growth of these anaerobic Gram-negative bacteria (Park et al 2008). Intraperitoneally administered ginger exerted a dose-dependent antimicrobial activity against *Pseudomonas aeruginosa*, *Salmonella typhimurium*, *Escherichia coli* and *Candida albicans* (Jagetia et al 2003).

Gingerols demonstrated antibacterial activity against *Bacillus subtilis* and *Escherichia coli* in vitro (Yamada et al 1992). [10]-Gingerol was found to potentiate the antibacterial actions of aminoglycosides in vancomycin-resistant enterococci, bacitracin and polymixin B suggesting [10]-gingerol increases membrane permeability of enterococcal cells promoting an enhanced influx of aminoglycosides (Nagoshi et al 2006).

Ginger has also shown antischistosomal activity. Gingerol (5.0 ppm) completely abolished the infectivity of *Schistosoma* spp (blood flukes) in animal studies (Adewunmi et al 1990). Gingerol and shogaol exhibited potent molluscicidal activity in vivo. Shogaol and gingerol have demonstrated anti-nematode activities; 6.25 mcg/mL 6-shogaol destroyed *Anisakis* larvae within 16 hours in vitro, whereas the anti-nematodal medication pyrantel pamoate had no lethal effect at 1 mg/mL (Goto et al 1990).

### Antifungal and antiviral

Ginger constituents have demonstrated antifungal and antiviral activity. Shogaol and zingerone strongly inhibited *Salmonella typhi*, *Vibrio cholerae* and *Trichophyton violaceum*. Aqueous extracts have also been shown to be effective against *Trichomonas vaginalis* (Henry & Piggott 1987). Several sesquiterpenes, but especially beta-sesquiphellandrene, isolated from ginger have also been shown to have antirhinoviral activity in vitro (Denyer et al 1994).

Essential oils of ginger have been shown to have activity yeasts and filamentous fungi in vitro (Martins et al 2001). Such oils have exhibited virucidal activity against aciclovir-sensitive and resistant strains of herpes simplex-1 reducing plaque formation significantly (Schnitzler et al 2007). A further in vitro study has indicated a dose-dependent virucidal activity against herpes simplex-2 is possible by interaction with the viral envelope (Koch et al 2008).

### Antioxidant

Various investigations have confirmed that ginger displays strong in vitro and in vivo antioxidant properties. Orally administered ginger significantly lowered levels of free radicals and raised the activities of endogenous antioxidants, superoxide dismutase and catalase and had a sparing effect on vitamins C and E (Jeyakumar et al 1999). Ginger has been found to protect against lipid peroxidation in the liver (Ahmed et al 2008) and kidney (Asnani & Verma 2007). Ginger root aqueous extract taken orally (500 mg/kg/day) reduced testicular toxicity, including the restoration of sperm function,

testicular steroidogenesis and reproductive organosomatic indices in an animal model, effects which were attributed to the antioxidant activity of ginger (Morakinyo et al 2010).

An in vivo and in vitro research has shown [6]-gingerol to be effective in reducing ultraviolet B (UVB)-induced intracellular reactive oxygen species (ROS), UVB-induced expression of COX-2 and inhibited the translocation of NF-kappaB from cytosol to cell nucleus. Moreover, topical application of [6]-gingerol prior to UVB exposure on hairless mice inhibited COX-2 mRNA, and protein and NF-kappaB translocation (Kim et al 2007).

### Immunomodulation

In vitro and in vivo research suggests that ginger extract exerts some degree of immunomodulatory activity (Ahui et al 2008, Imanishi et al 2006, Tripathi et al 2008).

Ginger exerted an immunosuppressive in vitro lymphocyte proliferation analysis, an effect modulated through IL-2 production (Wilarusmee et al 2002). Ginger oil has also been shown to have immunomodulatory activity in mice, with dose-dependent inhibition of T lymphocyte proliferation and IL-1-alpha secretion and reduced delayed type of hypersensitivity response in vivo (Zhou et al 2006).

### Hepatoprotective

Experimental models of alcohol-induced liver damage previously showed that ginger has significant hepatoprotective effects comparable to those of silymarin (Bhandari et al 2003). The effect appears to be mediated by an antioxidative mechanism. Reversal of ethanol-induced liver damage was achieved following the treatment with 1% ginger for 4 weeks. The hepatoprotective action was mediated by preventing a decline in antioxidant status (Mallikarjuna et al 2008). Pretreatment with an ethanol extract of ginger exerted a protective effect against carbon tetrachloride and paracetamol-induced acute liver damage in rats, with attenuation of serum and liver marker enzymes (Yemitan & Izegbu 2006). In a similar study ginger exerted significant declines in the activities of serum transaminases and alkaline phosphatase and restoration of hepatic oxidative status post administration of a single dose (Ajith et al 2007). More recently, two animal studies comparing ginger to silymarin (an active constituent in St Mary's thistle), oral extracts of ginger were found to attenuate carbon tetrachloride-induced damage of the liver. The first study involved the use of methanolic extract, resulting in reductions of the inflammatory enzymes alkaline phosphatase (ALP) and gamma-glutamyl transpeptidase (GGT) and also showed no symptoms of morbidity or mortality in dosages of up to 5000 mg/kg in rats (Atta et al 2010). In the second, ethanolic extract of ginger significantly increased glutathione, superoxide dismutase and protein levels in addition to reduced aspartate and alanine

aminotransferases (AST and ALT), GGT and bilirubin levels and markedly reduced necrosis and collagen deposition fibrosis (Motawi et al 2011).

### Nephroprotection

Ginger prevented the decline in renal antioxidant status by increasing glutathione-S-transferase activity in an experimental model of nephrotoxicity (Ajith et al 2008). Ginger exhibited a significant dose-dependent nephroprotective role in experimentally induced acute renal damage when administered as a stand-alone treatment (250 mg/kg) and when used in combination with vitamin E (Ajith et al 2007).

### Chemoprotective

The inhibitory effects of ginger and its constituents in tumour development have previously been demonstrated in animal models and human cell lines with activity observed against human breast cancer (Lee et al 2008), ovarian cancer (Rhode et al 2007), gastric cancer (Ishiguro et al 2007) and pancreatic cancer (Park et al 2006).

Antitumour properties have been isolated to several key constituents of ginger including [6]-gingerol, [6]-paradol, shogaols, zerumbone and zingerone and are partly due to an antioxidative and anti-inflammatory mechanism (Kim et al 2005).

Application of ginger or its constituents achieved induction of apoptosis in cancerous cells resulting in suppression of proliferation (Lee & Surh 1998) and apoptosis resulting in cell transformation (Bode et al 2001). The apoptotic effect of ginger constituents was also demonstrated in human promyelocytic leukaemia cells (Wei et al 2005), and an ethanolic extract of ginger also demonstrated cytotoxic activity against cultured non-hormone-dependent cancer cell lines, arresting development in the sub-G1 phase (Sabli et al 2012). The modulation of proteins involved in apoptosis has also been demonstrated in vivo and in vitro prostate cancer models (Shukla et al 2007). [6]-Gingerol administration exerted actions of cell cycle arrest and induction of apoptosis in suppression of hepatoma cells (Yagihashi et al 2008). [6]-Gingerol was also found to exert a direct suppressive effect on colon cancer cell growth and inhibit angiogenesis by reduction in tumour blood supply (Brown et al 2008). [6]-Shogaol has been found to effectively induce apoptotic cell death in human hepatoma p53 mutant cells by way of an intracellular oxidative stress mediated cascade which ultimately leads to cell death (Chen et al 2007), and the same constituent was shown to be a potent inhibitor of MDA-MB-231 breast cancer cell invasion, possibly by down-regulating transcription by targeting the NF-kappaB activation cascade (Ling et al 2010).

Reduction of lipid peroxidation and increased antioxidant activity was attributed to suppression of colon carcinogenesis by ginger in male Wistar rats (Manju & Nalini 2005). Differing types of tumours exhibit high NF-kappa B activity sustaining angio-

genesis and cell proliferation gingerols were found to display properties inhibiting the activation of NF-kappaB (Kim et al 2009, Takada et al 2005).

The activity seen in test tube and animal models may have clinical significance according to a double blind RCT. The trial involved 33 participants with normal risk of colorectal cancer who were given ginger powder (2 g/day) for 28 days. Colon biopsy results showed that compared to placebo, ginger significantly reduced prostaglandin E<sub>2</sub> and the eicosanoid 5-hydroxyeicosatetraenoic normalised to arachidonic acid, indicating that ginger extract may have an inhibitory effect on colon tissue cyclooxygenase and lipoxygenase enzymes in humans (Zick et al 2011).

#### **Clinical note — Ginger and moxibustion — a clinical perspective**

Moxibustion as a part of acupuncture has been well noted in TCM and is widely accepted as a useful complementary and alternative medicine therapy (Okada & Kawakita 2009). Indirect moxibustion utilises ginger slices placed at specific acupuncture points to insulate the skin from burning moxa sticks and provides therapeutic effects via thermal stimulation and sympathetic vibration (Shen et al 2006).

A review of 587 acupuncture and moxibustion randomised controlled papers from 1978 to 2007 conducted by Du et al (2009) demonstrated the growing indications for, and applications of, the use of moxibustion and acupuncture. Clinical trials have shown ginger-partitioned moxibustion to be therapeutically effective in the treatment of child diarrhoea (Liu et al 2003), cervical vertigo (Xiaoxiang 2006), poststroke urination disorders (Liu & Wang 2006), leucopenia induced by chemotherapy (Zhao et al 2007) and rheumatoid arthritis (Xie & Lei 2008).

### OTHER ACTIONS

#### **Antihistamine**

Shogaols and certain gingerols exhibit dose-dependent inhibition of drug-induced histamine release from rat peritoneal mast cells in vitro (Yamahara et al 1995).

#### **Anxiolytic**

A combination of ginger and *Ginkgo biloba* has been shown to reduce anxiety in an animal model (elevated plus-maze test). The effect was similar to diazepam (Hasenohrl et al 1996). A highly non-polar fraction of a ginger extract has been shown to possess anticonvulsant, anxiolytic and antiemetic activities in animals (Vishwakarma et al 2002).

#### **Antifibrotic**

Supplementation with 5 g ginger not only prevented a decrease, but also significantly increased

**Clinical note — Morning sickness**

Nausea and vomiting are the most common symptoms experienced in early pregnancy, with nausea affecting between 70% and 85% of women. About half of pregnant women experience vomiting (Jewell & Young 2002). Hyperemesis gravidarum is more severe and affects between 0.3% and 2% of all pregnant women. It is a multifactorial disease in which pregnancy-induced hormonal changes associated with concurrent gastrointestinal dysmotility and possible *Helicobacter pylori* infection function as contributing factors (Eliakim et al 2000).

fibrinolytic activity in 30 healthy adult volunteers who consumed 50 g fat in a meal in an open clinical study (Verma & Bordia 2001).

**Positive inotrope**

Gingerols and shogaols isolated from ginger have positive inotropic activity, as demonstrated on isolated heart muscle (Shoji et al 1982, Yamahara et al 1995). The effect of gingerol seems to be rather specific to SR  $\text{Ca}^{2+}$ -ATPase activity (Kobayashi et al 1987).

**Thermogenic**

Ginger helps to maintain body temperature and inhibit serotonin-induced hypothermia in vivo (Huang et al 1991, Kano et al 1991). However, the addition of a ginger-based sauce to a meal did not produce any significant effect on metabolic rate in humans (Henry & Piggott 1987).

**Hypotensive**

Aqueous ginger extract has been shown to lower blood pressure via stimulation of muscarinic receptors and blockade of  $\text{Ca}^{2+}$  channels in guinea pig atria (Ghayur et al 2005). The calcium channel blocking effect of ginger has been demonstrated in acetylcholine (ACh)-induced airway constriction of mouse lung tissue. Pretreatment with a 70% aqueous methanolic crude extract of ginger 30 minutes prior to ACh administration achieved significant reduction in airway contraction and  $\text{Ca}^{2+}$ . Similar results were achieved with verapamil, indicating comparable modes of action. Concomitant use of both ginger extract and verapamil achieved the same outcome as when each was used alone (Ghayur et al 2008).

**CLINICAL USE**

Although ginger is used in many forms, including fresh ginger used in cooking or chai (Indian spicy tea), pickled or glazed ginger, ethanol extracts and concentrated powdered extracts, preparations made with the root are used medicinally. Depending on the specific solvent used, the resultant preparation will contain different concentrations of the active constituents and may differ markedly from

crude ginger. The great majority of research refers specifically to the species *Zingiber officinale*; however, there is the potential for confusion with other species or even with other genera (Canter 2004). Furthermore, there are reported to be wide variations in the quality of commercial ginger supplements with concentrations of gingerols ranging from 0.0 to 9.43 mg/g. As such, the results of specific extracts cannot necessarily be extrapolated to different preparations (Schwertner et al 2006).

**Prevention of nausea and vomiting**

Many clinical studies have investigated the effects of ginger in the prevention and treatment of nausea and vomiting associated with different circumstances, including pregnancy (Fischer-Rasmussen et al 1990, Keating & Chez 2002, Portnoi et al 2003, Smith et al 2004, Sripramote & Lekhyananda 2003, Vutyavanich et al 2001, Willetts et al 2003), the postoperative period (Arfeen et al 1995, Bone et al 1990, Meyer et al 1995, Phillips et al 1993, Visalyaputra et al 1998), motion sickness (Grontved & Hentzer 1986, Lien et al 2003, Mowrey & Clayson 1982, Schmid et al 1994, Stewart et al 1991) and chemotherapy (Manusirivithaya et al 2004, Meyer et al 1995, Sontakke et al 2003, Ryan et al 2012).

A systematic review of 24 randomised controlled trials (RCTs) covering 1073 patients suggests that results for the treatment of nausea and vomiting in pregnancy are encouraging and generally supportive; however, results for postoperative nausea and vomiting and motion sickness are unclear and daily doses of up to 6 g of ginger seem to have few side effects (Betz et al 2005). More reviews provide further encouragement and suggest that ginger may indeed be effective in nausea associated with pregnancy (Boone & Shields 2005) and the postoperative period (Chaiyakunapruk et al 2006). Similarly a review of four well-controlled, double-blind, randomised clinical studies concluded there was convincing evidence for application of ginger in the treatment of nausea and vomiting of pregnancy (Bryer 2005).

**Nausea and vomiting in pregnancy**

There is supportive evidence from clinical studies that ginger preparations in pregnancy reduce the duration and severity of nausea and vomiting.

**Nausea of pregnancy**

There are many studies, including an observational study (Portnoi et al 2003) and at least seven RCTs (Fischer-Rasmussen et al 1990, Keating & Chez 2002, Portnoi et al 2003, Smith et al 2004, Sripramote & Lekhyananda 2003, Vutyavanich et al 2001, Willetts et al 2003), as well as multiple systematic reviews, including a Cochrane review (Matthews et al 2010), that suggest that ginger powder or extract may be safe and effective in treating nausea and vomiting of pregnancy (Boone & Shields 2005, Borrelli et al 2005, Bryer 2005, Dib & El-Saddik 2004, Ernst & Pittler 2000, Jewell 2003). A

subsequent review, considering four double-blind RCTs including 504 subjects, suggests that ginger is superior to placebo and as effective as vitamin B<sub>6</sub> in reducing the frequency and intensity of pregnancy-related nausea and vomiting and that there is an absence of significant side effects and adverse pregnancy outcomes; however, the review does mention uncertainty regarding the maximum safe dosage and the need for further research (Ding et al 2013).

In three double-blind, placebo-controlled, randomised trials of ginger for pregnancy-related nausea and vomiting, including one trial on hyperemesis gravidarum, 1 g ginger in divided doses was significantly more effective than placebo in reducing nausea and vomiting (Fischer-Rasmussen et al 1990, Keating & Chez 2002, Vutyavanich et al 2001). In a further double-blind trial of 120 women, 25 mg of the ginger extract EV.EXT 35 (equivalent to 1.5 g of dried ginger) four times daily was useful in patients experiencing nausea and retching, although no significant result was seen for vomiting (Willets et al 2003).

#### Comparative studies

A comparative double-blind randomised controlled trial of 170 pregnant women who attended an antenatal clinic with the symptoms of nausea and vomiting in pregnancy found one capsule of ginger (0.5 g ginger powder) twice daily was identical in efficacy to treatment with 50 mg dimenhydrinate twice daily. In addition, ginger treatment resulted in fewer side effects (Pongrojapaw et al 2007). Initial comparative randomised, double-blind controlled trials found ginger to be equivalent to vitamin B<sub>6</sub> in helping to reduce pregnancy-related nausea, dry retching and vomiting (Smith et al 2004, Sripramote & Lekhyananda 2003). However, ginger (650 mg qid) proved more effective than vitamin B<sub>6</sub> (25 mg qid) in a randomised double-blind controlled trial involving 126 pregnant women, with a gestational age of  $\leq 16$  weeks who had nausea and vomiting (Chittumma et al 2007). Investigations over a 3-month duration into the efficacy of ginger compared to vitamin B<sub>6</sub> of 70 pregnant women with nausea and a gestational age of  $\leq 17$  weeks were randomised to receive either ginger 1 g/day or vitamin B<sub>6</sub> 40 mg/day for 4 days. Treatment with ginger (1 g/day) was found to be more effective than vitamin B<sub>6</sub> (40 mg/day) for relieving the severity of nausea, as well as equally effective in decreasing the episodes of vomiting (Ensiyeh & Sakineh 2008). Another clinical trial suggests that ginger at a dose of 250 mg taken four times per day is as effective as the higher dose of B<sub>6</sub> 40 mg twice per day for reducing pregnancy-induced nausea (Haji Seid Javadi et al 2013).

#### Postoperative nausea

Ginger may be useful for the prevention of postoperative nausea; however, not all studies have produced positive results and as the ginger preparations used have not been standardised, it is difficult to

directly compare studies. A meta-analysis of five randomised trials ( $n = 363$ ) found that a fixed dose of at least 1 g of ginger was more effective than placebo for the prevention of postoperative nausea and vomiting (Chaiyakunapruk et al 2006).

Most of the studies on postoperative nausea and vomiting have been conducted on patients undergoing gynaecological surgery. Powdered ginger (2 g) was administered to 239 women undergoing elective caesarean section at term, in order to evaluate the effects on intra- and post-operative nausea and vomiting. Ginger reduced the number of episodes of intraoperative nausea compared to placebo, but had no effect on incidence of nausea, vomiting or pain during or after elective caesarean section (Kalava et al 2013). In two other double-blind RCTs, ginger significantly reduced the incidence of postoperative nausea and vomiting (Bone et al 1990, Phillips et al 1993), although two further studies failed to show any benefit with ginger (Arfeen et al 1995, Eberhart et al 2003). A fifth study of 80 women undergoing gynaecological laparoscopy found that 1 g of ginger taken 1 hour before surgery was significantly superior to placebo in reducing the incidence of nausea 2–4 hours afterwards; however, it failed to show statistical significance for an observed reduction in the incidence and frequency of vomiting (Pongrojapaw & Chiamchanya 2003).

A double-blind RCT of 120 patients who underwent major gynaecological surgery found that a pretreatment with ginger powder (0.5 g) as compared to placebo resulted in lower incidence and frequency of vomiting in the treatment group. Frequency of vomiting was evaluated at 0, 2, 6, 12 and 24 hours postoperatively with the most statistically significant differences between ginger and placebo occurring at the 2- and 6-hour time intervals (Nanthakomon & Pongrojapaw 2006). Similarly a randomised study of 60 inpatients who underwent laparoscopic operations for non-cancer gynaecological conditions found that pretreatment 1 hour prior to surgery with three capsules of ginger (0.5 g of ginger powder per capsule) when compared to placebo significantly prevented vomiting at 6 hours postoperation. The effect was not apparent at 2 hours postoperation (Apariman et al 2006).

Although other types of surgery have not been as extensively studied as gynaecological surgery, there is a report on 6 months of clinical anaesthetic experience that suggests that a nasocutaneously administered 5% solution of essential oil of ginger given pre-operatively, together with conventional therapies, to general anaesthesia patients at high risk for postoperative nausea and vomiting is a safe and cost-effective way of reducing nausea and vomiting post anaesthesia (Geiger 2005).

Another RCT recently showed that inhaled ginger essential oil produced significant benefits by reducing postoperative nausea. The study involving 303 subjects in an ambulatory post anaesthesia care unit were administered three deep inhalations of a gauze pad soaked with saline (placebo), alcohol,

ginger essential oil (EO) or a combination of ginger, spearmint, peppermint and cardamom. The ginger EO and the ginger blend showed significant beneficial effects over placebo for nausea severity and a significant reduction in postoperative antiemetic medication was required (Hunt et al 2013).

In the only double-blind, placebo-controlled study of postoperative nausea and vomiting in patients undergoing middle ear surgery, ginger was ineffective and the use of 1 g of ginger 1 hour before surgery was associated with significantly more postoperative nausea and vomiting than the use of ondansetron or placebo (Gulhas et al 2003).

### Motion sickness

Commission E approves the use of ginger root for the prevention of motion sickness (Blumenthal et al 2000) and several clinical studies have assessed its effects as either prophylaxis or treatment. An early double-blind, randomised, placebo-controlled study involving 80 naval cadets found that ginger was significantly superior to placebo in reducing symptoms of vomiting and cold sweats due to seasickness. Fewer symptoms of nausea and vertigo were also reported with ginger, but the difference was not statistically significant (Grontved & Hentzer 1986). In another randomised double-blind study of seasickness involving over 1700 tourists on a whale-watching safari 300 km north of the Arctic Circle, 500 mg ginger was found to be as effective for the treatment of motion sickness as several common antiemetic medications (cinnarizine, cyclizine, dimenhydrinate, domperidone, meclizine and scopolamine) with ginger preventing seasickness in 80% of the subjects during the 6-hour boat trip, although the incidence of severe vomiting did not differ significantly between treatment groups (Schmid et al 1994).

At least three studies have had mixed results from experimental models of motion sickness whereby subjects are seated in a rotating chair. The first study involving 28 volunteers found no significant protective effects for powdered ginger (500 mg or 1000 mg) or fresh ginger root (1000 mg) (Stewart et al 1991), whereas a second study involving 36 undergraduate men and women who reported very high susceptibility to motion sickness found that ginger was superior to dimenhydrinate (Mowrey & Clayson 1982). Another double-blind, randomised, placebo-controlled crossover study showed positive benefits with ginger pretreatment on prolonging time before nausea, shortening recovery time and effectively reducing nausea (Lien et al 2003). This study used pretreatment doses of 1000 mg and 2000 mg, which were also shown to reduce tachy-gastria and plasma vasopressin.

### Chemotherapy-induced nausea and vomiting (CINV)

A review of seven RCTs and crossover trials concluded that ginger may be useful as an adjuvant therapy; however, interpretation is difficult because

of mixed results due to methodological differences and the complex aetiology of chemotherapy-induced nausea and vomiting (CINV). Chemotherapy may affect both the central nervous system and the gastrointestinal tract which can influence their development of CINV. Patients may also be affected by sensory input (e.g. smell, sight) or 'anticipatory nausea' as a result of the individual's psychological condition (e.g. fear, anxiety) (Marx et al 2013).

One of the largest most recent placebo-controlled studies was conducted by Ryan et al (2012) which involved 576 cancer patients and showed that supplementation of 0.5, 1.0 and 1.5 g powdered ginger significantly reduced self-assessed acute nausea severity compared to placebo when administered for 3 days prior and 3 days after chemotherapy administration (Ryan et al 2012).

### Comparative studies

Powdered ginger root effectively reduced cyclophosphamide-induced nausea and vomiting in a randomised, prospective, crossover double-blind study, with the antiemetic effect of ginger being equal to metoclopramide (Sontakke et al 2003). Ginger was found to have similar efficacy to metoclopramide in reducing cisplatin-induced emesis in a randomised, double-blinded, crossover study of 48 gynaecological cancer patients receiving chemotherapy (Manusirivithaya et al 2004); however, the current clinical significance of this result is questionable, due to the fact that metoclopramide is no longer used as a stand-alone antiemetic treatment (Marx et al 2013).

### Use with other anti-nausea medication

A recent combination study found that 1.5 g/day ginger taken with granisetron plus dexamethasone was more effective at reducing CINV than granisetron plus dexamethasone alone. A significantly lower prevalence of nausea, vomiting and retching was observed in the 6–24 hour post-chemotherapy period (Panahi et al 2012). Another RCT compared ginger root powder capsules or placebo in addition to ondansetron and dexamethasone for chemotherapy-induced nausea and vomiting in children and young adults, undergoing 60 cycles of cisplatin/doxorubicin for bone sarcoma (Pillai et al 2011). Acute moderate to severe vomiting and delayed nausea were reduced by 37–47% in the ginger group compared to placebo, highlighting the potential for ginger to act as an effective add-on therapy.

### Nausea and vomiting with antiretroviral treatment

Ginger (500 mg twice daily) was effective in ameliorating antiretroviral-induced nausea and vomiting in a placebo-controlled RCT involving 102 HIV-positive patients (Dabaghzadeh et al 2014).

### Musculoskeletal disorders

Ginger is described in Ayurvedic (traditional Indian) and Tibb (traditional Arabian) systems of medicine

to be useful in inflammation and rheumatism and this traditional use is supported by modern studies demonstrating ginger's anti-inflammatory activity.

A highly purified and standardised ginger extract (EV.EXT 77) moderately reduced the symptoms of osteoarthritis (OA) of the knee in a double-blind, placebo-controlled, multicentre, parallel-group 6-week study of 261 patients (Altman & Marcussen 2001). Similarly, 250 mg of the ginger extract (Zintona EC) taken four times daily for 6 months was significantly more effective than placebo in reducing pain and disability in 29 OA patients in a double-blind, placebo-controlled, crossover study (Wigler et al 2003).

These studies are supported by an open retrospective study involving 56 patients (28 with RA, 18 with OA, 10 with muscular discomfort) that revealed more than three-quarters experienced varying degrees of relief of pain and swelling from the long-term use of powdered ginger (Srivastava & Mustafa 1992). Further support comes from studies comparing ginger to NSAIDs.

In one double-blind RCT involving 120 patients, 30 mg of an ethanolic ginger extract equivalent to 1 g of ginger and prepared from fresh ginger purchased from a local market in India was found to be significantly more effective than placebo and was as effective as 1.2 g of ibuprofen in the symptomatic treatment of OA (Haghighi et al 2005). In another double-blind crossover study, 170 mg of the ginger extract EV.EXT 33 with a standardised content of hydroxy-methoxy-phenyl compounds given twice daily was found to be significantly more effective than placebo but not as effective as ibuprofen in reducing pain and disability in 75 patients with OA before the crossover period, whereas no statistical difference was seen between ginger and placebo in the analysis after the crossover period. The authors commented that the washout period may have been insufficient to prevent carry-over effects, and that ginger might need to be administered for longer than 3 weeks, and possibly in a higher dosage, to be clinically effective (Bliddal et al 2000).

### Topical ginger preparation

In a small pilot study, 10 patients with osteoarthritis applied external ginger compresses over the kidneys for 7 days in a phenomenological approach and found benefits such as improved posture, more comfortable and flexible joint mobility and a positive shift in pain perception (Therkleson 2010).

### Post-exercise muscle pain

In a double blind, placebo-controlled clinical trial of healthy volunteers, daily consumption of 2 g of raw or heated ginger for 11 days was found to reduce eccentric exercise-induced muscle pain when compared to placebo (Black et al 2010). In this study, dried powdered ginger was placed in a sealed bottle with deionised water and heated in a water bath for 3 hours and 15 minutes at 100 degrees Celsius. No significant difference in pain reduction

effect was found with the heated versus raw ginger (Black et al 2010).

### Dysmenorrhoea

Ginger has been used orally to treat dysmenorrhoea and appears to be effective based on available evidence. Due to its ability to inhibit thromboxane synthetase and activate endorphin receptors, the use of ginger has been suggested in treatment of dysmenorrhoea (Backon 1991). A double-blind comparative clinical trial involving 150 participants demonstrated that ginger (250 mg ginger rhizome powder qid for 3 days from the start of their menstrual period) was just as effective as 250 mg mefenamic acid or 400 mg ibuprofen capsules in relieving pain in women with primary dysmenorrhoea (Ozgoli et al 2009). Significant benefits were also seen in a RCT of 120 participants with mild-moderate dysmenorrhoea. Treatment with 500 mg powdered ginger given three times per day for 3–5 days produced a significant improvement in intensity and duration of menstrual pain (Rahnama et al 2012).

### Dyspepsia

Ginger stimulates the flow of saliva, bile and gastric secretions and therefore is traditionally used to stimulate appetite, reduce flatulence and colic, gastrointestinal spasms and generally act as a digestive aid. Commission E approves the use of ginger root for the treatment of dyspepsia (Blumenthal et al 2000).

### Hyperlipidaemia

A double-blind controlled clinical trial of 85 volunteers with hyperlipidaemia showed ginger treatment (3 g/day) produced a significant lipid-lowering effect compared to controls. Measurement of lipid concentrations before and after 45 days of treatment showed significantly higher mean changes in triglyceride and cholesterol levels for ginger compared to control ( $P < 0.05$ ) as well as significant mean reduction in LDL level and increase in HDL levels compared to controls (Alizadeh-Navaei et al 2008). This initial study shows promising results; however, further controlled human trials are necessary to prove efficacy, a conclusion shared by a review of the pharmacological properties of ginger (Li et al 2012).

### Migraine

Ginger is used to prevent and treat migraine headache. Its ability to inhibit thromboxane  $A_2$  and exert antihistamine, anti-inflammatory and gastric actions makes it a theoretically attractive choice (Mustafa & Srivastava 1990). This use is supported by an open-label study of 30 migraine sufferers reporting that treatment with a sublingual ginger and feverfew preparation (GelStat MigraineO) in the initial phase of a migraine resulted in most patients being satisfied with the therapy and being pain-free or only having mild headache post-treatment (Cady et al 2005).

**IN COMBINATION**

In a follow-up randomised pilot study of 60 patients, 221 migraine episodes were treated with sublingual feverfew/ginger (LipiGesic) or placebo, resulting in significant reductions in migraine and headache pain when used as a first line suppressive treatment (Cady et al 2011). Due to the use of a combination product, it is difficult to determine which herb is clinically effective from this study.

**Pain**

A review of eight RCTs for the treatment of any type of pain raised methodological concerns regarding previous clinical trial designs. Specifically, it concluded that the form of ginger (powder or ethanolic extract) results in variation in active constituent profiles, and this in combination with different therapeutic dosages results in variable levels of efficacy. Administration of over 1 g ginger per day results in amelioration of pain in most trials, whereas less than 510 mg per day does not (Terry et al 2011).

**OTHER USES**

Ginger cream or compress is used externally for mastitis.

**Cognitive function**

As a follow-up trial to a successful animal study, a double-blind RCT was conducted which involved 60 healthy middle aged women who received 800 mg ginger per day for 1 month or placebo. When compared to placebo, active treatment resulted in statistically significant improvements in attention, cognitive processing and working memory, including speed of recall and quality of memory (Saenghong et al 2012).

**Diabetes**

A randomised, double-blind placebo-controlled trial of 88 diabetic participants recently found that 1 g ginger capsules taken three times daily for 8 weeks significantly improved fasting blood sugar, fasting insulin and insulin sensitivity (Mozaffari-Khosravi et al 2014). Animal studies have also shown that ginger may have potential benefits in the treatment of diabetes, indicating that ginger improves insulin sensitivity and reduces serum glucose levels. Further clinical trials are required to confirm the significance of these findings in humans.

**Weight loss**

Further investigations in animal models and mixed-herbal clinical trials suggest a potential role for ginger in weight loss (Hasani-Ranjbar et al 2009). A significant reduction in body weight and parametrial adipose tissue following oral administration of zingerone in ovariectomised rats indicated that by increasing noradrenaline-induced lipolysis in adipocytes, zingerone may prevent fat storage (Han et al 2008). The anti-obesity action of ginger may be a result of slowed intestinal absorption of dietary fat (Han et al 2008).

**Asthma**

A possible therapeutic role for gingerol in the treatment of asthma has been indicated through a recent animal model. An aqueous ginger extract enriched in *n*-gingerols was investigated in Th2-mediated pulmonary inflammation where gingerols were found to decrease recruitment of eosinophils to the lungs and suppress Th2 cell response to allergen. Serum IL-4, IL-5 and IgE titres were diminished in ginger-treated mice relative to controls (Ahui et al 2008).

**Ulcerative colitis**

Recent research has identified a potential role for ginger in attenuating inflammatory bowel disease. In an *in vitro* study involving ulcerated male Wistar rats, ginger extract was found to be comparable to sulfasalazine in attenuating colonic mucosal injury. The effect of ginger against acetic acid-induced ulcerative colitis has been attributed to its anti-inflammatory and antioxidant properties (El-Abhar et al 2008). Clinical trials are required to determine the significance of this effect in humans.

**DOSAGE RANGE**

The recommended dose ranges widely from 500 mg to 9 g/day dried root or equivalent; however, a safe maximal dose is 4 g/day. As there are wide variations in the gingerol concentrations in commercial ginger supplements (Schwertner et al 2006), the effective dosage will depend on the preparation and the indication for use.

- Liquid extract (1:2): 0.7–4.0 mL/day.
- Dried root: 1–3 g daily in divided doses.
- Infusion: 4–6 slices of fresh ginger steeped in boiling water for 30 minutes.

**According to clinical studies**

- Dysmenorrhoea: 250 mg ginger rhizome powder taken four times daily for 3 days from the start of the menstrual period.
- Hyperlipidaemia: 3 g/day.
- Nausea and vomiting of pregnancy: 1–2 g taken daily in divided doses.
- Motion sickness: powdered ginger (500 mg or 1000 mg) or fresh ginger root (1000 mg) up to 2000 mg.
- Osteoarthritis: 250 mg of the ginger extract (Zintona EC) four times daily.
- Prevention of postoperative nausea: 1 g 1 hour prior to surgery.
- Rheumatoid arthritis: 1–2 g/day of powdered ginger.

**ADVERSE REACTIONS**

Gastric irritation, heartburn and bloating have been reported in clinical trials (Arfeen et al 1995). Contact dermatitis of the fingertips has also been reported (Seetharam & Pasricha 1987) with topical use.

## SIGNIFICANT INTERACTIONS

Controlled studies are not available for many interactions; therefore they are based on evidence of activity and are largely theoretical and speculative.

### Antibiotics

According to a recent review, ginger may enhance the absorption of antibiotics such as azithromycin, erythromycin and cephalexin when used in doses of between 10 and 30 mg/kg due to the herb's modulating effect on the gastric mucosa; however, the clinical significance of this effect is untested (Kesarwani & Gupta 2013).

### Warfarin

Due to the herb's antiplatelet effects there is a theoretical risk of increased bleeding at high doses (>10 g), although this is not evident clinically. There is no evidence of an interaction with warfarin at the usual dietary and therapeutic intakes (Jiang et al 2005, Stenton et al 2001, Vaes & Chyka 2000), and ginger has been shown not to alter prothrombin times in pooled human plasma collected from male volunteers between the ages of 18 and 57 years (Jones et al 2001). A standardised ginger extract, EV.EXT 33, has demonstrated no significant effect on coagulation parameters or on warfarin-induced changes in blood coagulation in rats (Weidner & Sigwart 2000) and three ginger capsules (each containing an extract equivalent to 400 mg of ginger rhizome powder) taken three times daily for 2 weeks had no effect on the pharmacokinetics or pharmacodynamics of a single 25-mg dose of warfarin taken on day 7. Moreover, ginger alone did not affect the International Normalised Ratio (INR), platelet aggregation or the pharmacokinetics or pharmacodynamics of warfarin in healthy human subjects (Jiang et al 2005).

### Antiplatelet drugs

Theoretically, increased antiplatelet and anti-inflammatory effects may occur with high-dose ginger preparations, but the clinical significance of this is unknown. Caution should be exercised with doses > 10 g — possible beneficial effect.

### PREGNANCY USE

Although Commission E suggests that ginger is contraindicated in pregnancy, more recent research suggests that ginger is not contraindicated in pregnancy — doses up to 2 g/day of dried ginger root have been used safely.

No adverse effects on pregnancy were observed in multiple studies of ginger for nausea and vomiting (Boone & Shields 2005, Borrelli et al 2005, Bryer 2005, Dib & El-Saddik 2004, Ernst & Pittler 2000, Jewell & Young 2002).

### Cisplatin

Pretreatment has restored testicular antioxidant parameters and sperm motility in cisplatin-induced damage in an animal model (Amin & Hamza 2006). Clinical implications are uncertain; however, potential benefits may be found upon further testing.

### CONTRAINDICATIONS AND PRECAUTIONS

Ginger in high doses is not recommended for children under 6 years of age due to the pungent nature of ginger. However, if the benefits of ginger treatment outweigh the potential for gastric irritation, then it can be used. Alternatively, ginger lollies or ginger ale is sometimes used and a dose of 250 mg every 4 hours for motion sickness is safe.

Commission E suggests that people with gallstones consult with their doctor before using ginger. People with gastric ulcers or reflux should use this herb with caution. Suspend use of high-dose supplements (>10 g) 1 week before major surgery.

### Practice points/Patient counselling

- Ginger is most often used for its antiemetic, anti-inflammatory and gastrointestinal effects.
- There is good clinical support for the use of ginger in the treatment of nausea and vomiting associated with pregnancy and some evidence for its use in motion sickness, the postoperative period and chemotherapy although this is less consistent.
- Ginger is traditionally used for gastrointestinal disorders, including dyspepsia, poor appetite, flatulence, colic, vomiting, diarrhoea and spasms, as well as a diaphoretic in the treatment of the common cold and influenza.
- Ginger is also used as an anti-inflammatory agent for arthritis, although large controlled studies have yet to produce strong support for this use.
- Although antiplatelet effects have been reported, these require very large doses and are not likely to be significant in normal therapeutic doses or dietary intake levels.
- A study of 24 subjects found that ginger did not significantly affect clotting status or pharmacokinetics of warfarin in healthy subjects (Jiang et al 2006).
- Due to the potential seriousness of the proposed interaction, people taking warfarin should use high-dose supplements (>10 g/day) with caution.

### PATIENTS' FAQs

#### *What will this herb do for me?*

Ginger is a useful treatment for nausea and vomiting associated with pregnancy and may also be of benefit

in motion sickness, postoperative nausea and seasickness. It is also useful for treating symptoms of dyspepsia and may have symptom-relieving effects in arthritis, although this is less certain.

#### **When will it start to work?**

In the case of dyspepsia and motion sickness prevention, ginger will have an almost immediate effect, with improvement reported within 30 minutes. For motion sickness, 0.5–1.0 g ginger should be taken 30 minutes before travel and repeated 4-hourly. For nausea of pregnancy it should be taken for at least 4 days; however, symptoms should start to reduce within 1 hour of administration.

#### **Are there any safety issues?**

Ginger is well tolerated, although it should be used with caution by people with gallstones, gastric ulcers or reflux.

## Ginkgo biloba

**HISTORICAL NOTE** *Ginkgo biloba* is one of the world's oldest living tree species, earning it the name 'living fossil'. Its existence can be traced back more than 200 million years and it was commonly found in North America and Europe before the Ice Age. Its place of origin is believed to be remote mountainous valleys of Zhejiang province of eastern China and, up to 350 years ago, knowledge about this plant was restricted to China (Singh et al 2008). Ginkgo was first introduced into Europe in 1690 by the botanist Engelbert Kaempfer, who described it as the 'tree with duck feet'. Ginkgo has been used medicinally for decades and is now one of the most popular therapeutic agents prescribed in Europe by medical doctors. It has been estimated that, in Germany and France, prescriptions for ginkgo make up 1% and 1.3%, respectively, of total prescription sales (Pizzorno & Murray 2006). Also popular in the United States, it was the top-selling herbal medicine in 1999, with sales of US\$148 million. Current estimates

indicate that the use of *G. biloba* has been growing at a very rapid rate worldwide, at 25% per year in the open-world commercial market (Singh et al 2008). Germany, Switzerland and France have respectively 31%, 8% and 5% of the world commercial market. To meet the demand for ginkgo products, 50 million *G. biloba* trees are grown, especially in China, France and South Carolina, United States, producing 8000 tons of dried leaves each year.

## COMMON NAME

Ginkgo

In England, it is known as 'maidenhair tree' based on its resemblance to the foliage of the 'maidenhair fern' (*Adiantum*). In Japan, it is known as 'ginkyo' and in France, 'l'arbre aux quarante écus' and 'noyer du Japon' (Singh et al 2008).

## OTHER NAMES

Adiantifolia, arbre aux quarante écus, bai guo ye, duck foot tree, fossil tree, gin-nan, icho, Japanese silver apricot, kew tree, maidenhair tree, salisburia, silver apricot, tempeltrae, temple balm, yinhsing

## BOTANICAL NAME/FAMILY

*Ginkgo biloba* (family Ginkgoaceae)

## PLANT PARTS USED

In modern times only the leaf is used, but traditionally the nut was also used.

## CHEMICAL COMPONENTS

Important constituents present in the leaves are the terpene trilactones (i.e. ginkgolides A, B, C and J and bilobalide), many flavonol glycosides (mostly derivatives of quercetin and kaempferol) (Hibatallah et al 1999), biflavones, proanthocyanidins, alkylphenols, simple phenolic acids, 6-hydroxykynurenic acid, 4-O-methylpyridoxine and polyprenols (van Beek 2002). *G. biloba* contains more than 30 genuine flavonoids, of which the flavonol glycosides are the most abundant (Singh et al 2008).

There has been some interest in ginkgo alkylphenols (ginkgolic acids) because of their allergenic properties, so most manufacturers limit the concentration of alkylphenols to 5 ppm.

## MAIN ACTIONS

The many and varied pharmacological actions of ginkgo preparations are related to the presence of several classes of active constituents. Research has mainly been conducted with a standardised ginkgo biloba extract (GBE) and also several of its key constituents, such as ginkgetin. Various preparations have also been tested, including oral, injectable and topical preparations.

### Antioxidant

GBE and several of its individual constituents, such as quercetin and kaempferol, have demonstrated significant antioxidant properties in vitro (Hibatallah et al 1999, Sloley et al 2000). Antioxidant activity has further been demonstrated in several different animal models.

Experimental models investigating the effects of ginkgo on reducing ischaemic injury in various

### Clinical note — Ginkgo extract used in practice

The standardised ginkgo extract is made from dried ginkgo leaves extracted in 60% acetone. Only a fraction of the leaf matter is extracted; 98% is not extracted. Of the 2% extracted, the flavones account for 25%, the ginkgolides 3% and the bilobalide 3%. The remaining 69% is not specified. The drug ratio may vary from 35:1 to 67:1 (average ratio 50:1). This means that, on average, it takes 50 kg dried leaf to produce 1 kg of extract. Standardised ginkgo extract (e.g. EGb 761) must be standardised to 22–27% flavone glycosides, 5–7% terpene lactones (2.8–3.4% ginkgolides A, B and C, and 2.6–3.2% bilobalide). The content of ginkgolic acids must be less than 5 ppm (Blumenthal et al 2000). Although the standardisation is very specific, the compounds are considered to be marker compounds, as the active constituents of *G. biloba* have not been fully identified (unpublished data: Keller K, Chair of the Herbal Medicinal Products Working Group, European Medicines Evaluation Agency, Quality Assurance of Herbal Medicines, March 2001).

tissues have shown positive results, indicating that ginkgo reduces the damage caused by oxidative stress during reperfusion (Liu et al 2007, Schneider et al 2008).

Hepatoprotective effects, via an antioxidant action, have also been seen in an animal study in the treatment of non-alcoholic steatohepatitis (Zhou et al 2010).

A novel study has investigated the effect of *G. biloba* on mobile phone-induced oxidative damage in brain tissue of rats (Ilhan et al 2004). Rats were exposed to the same amount of mobile phone-induced radiation for 7 days, with some also pre-treated with *G. biloba*. After exposure, oxidative damage was evident by the: (1) increase in malondialdehyde and nitric oxide (NO) levels in brain tissue; (2) decrease in brain superoxide dismutase and glutathione peroxidase activities; and (3) increase in brain xanthine oxidase and adenosine deaminase activities. *Ginkgo biloba* prevented these alterations and the mobile phone-induced cellular injury in brain tissue histopathologically.

Initial research on apoptosis of human lens epithelial cells when exposed to high glucose suggests that GBE has a protective effect inhibiting this oxidative stress (Wu et al 2008b).

*G. biloba's* antioxidant action and prevention of mitochondrial degeneration may have some effect on protecting Sertoli and spermatid cells in a rat model with testicular torsion (Kanter 2011).

Topical antioxidant effects have also been investigated. *G. biloba* has been shown to reduce the effects of ultraviolet radiation on skin (Aricioglu et al 2001, Hibatallah et al 1999, Kim 2001, Lin & Chang 1997). When applied topically, ginkgo increases the activity of superoxide dismutase within skin, thereby enhancing the skin's natural defences.

### Cardioprotective

Ginkgo reduces the damage caused by oxidative stress during reperfusion according to research with various preclinical models.

One study using a model of myocardial infarction found that pretreatment with GBE EGb 761 reduced ischaemic myocardial injury compared to untreated controls (Schneider et al 2008) and another showed *G. biloba* may provide cardioprotection in preventing diabetic complications of cardiovascular autonomic neuropathy, as seen in diabetes-induced myocardial nervous damage (Schneider et al 2010). Another animal study demonstrated that *G. biloba* phytosomes conferred significant cardiac protection with antioxidant activity and decreased lipid peroxidation (Panda & N 2009).

EGb 761 may have a role in reducing cardiotoxic effects of the antineoplastic drug, Adriamycin, as pretreatment for 10 days prior to drug use resulted in normalisation of cardiac enzymes (having an effect on cardiac malondialdehyde, total antioxidant capacity, tumour necrosis factor- $\alpha$  [TNF- $\alpha$ ] and NO levels) (El-Boghdady 2013b). A recent rat study revealed cardioprotective effects reducing ischaemic free radical damage to the heart mitochondria (Bernatoniene et al 2011). These cardiac benefits found in animal studies did not translate to show a clinical effect in the Ginkgo Evaluation of Memory study assessing *G. biloba*'s effect on cardiovascular disease. This enormous double-blind trial randomised 3069 participants over 75 years (120 mg of *G. biloba* EGb 761 twice daily) with follow-up over 6.1 years; no reduction was found in cardiovascular disease events or mortality (Kuller et al 2010).

### Anti-inflammatory

The anti-inflammatory activity of ginkgo has been investigated for the whole extract and an isolated biflavonoid component known as ginkgetin, with both forms demonstrating significant anti-inflammatory activity.

### Ginkgo extract

Intravenously administered ginkgo extract produced an anti-inflammatory effect that was as strong as the same dose of prednisolone (i.e. 1 mg GBE = 1 mg prednisolone) in an experimental model. Ginkgo extract was also found to significantly reduce the concentration of prostaglandin E<sub>2</sub>, TNF- $\alpha$  and NO production in vitro (Ilieva et al 2004). Studies with subcutaneously administered GBE in experimental models have further confirmed significant anti-inflammatory activity, with the addition of antinociceptive effects (Abdel-Salam et al 2004).

Investigation with an animal model of colitis revealed that *G. biloba* (EGb 761) extract reduces markers of inflammation (inducible nitric oxide synthase [iNOS], cyclooxygenase-2 [COX-2] and TNF- $\alpha$ ) and inflammatory stress (p53 and p53-phosphoserine 15) (Kotakadi et al 2008). In the case of ischaemia-reperfusion injury in a rat model, *G. biloba* was found to inhibit inflammatory cytokines (interleukin-6 [IL-6]) and promote anti-inflammatory cytokines (IL-4) (Bao et al 2010).

### Ginkgetin

Ginkgetin showed a stronger anti-inflammatory activity than prednisolone when administered by intraperitoneal injection in an animal model of arthritis. Histological examination of the knee joints confirmed the effect (Kim et al 1999). When used topically in an animal model of chronic skin inflammation and proinflammatory gene expression, it was found to inhibit ear oedema by approximately 26% and prostaglandin E<sub>2</sub> production by 30% (Lim et al 2006). Histological comparisons revealed that ginkgetin reduced epidermal hyperplasia, inhibited phospholipase A<sub>2</sub> and suppressed COX-2 and iNOS expression (Lim et al 2006).

### Vascular effects

#### Vasodilation

Ginkgo promotes vasodilation and improves blood flow through arteries, veins and capillaries. Increases in microcirculatory blood flow occur rapidly and have been confirmed under randomised crossover test conditions 1 h after administration (Jung et al 1990).

Several mechanisms of action are responsible. Currently, these are considered to be: inhibition of NO release, activation of Ca<sup>2+</sup>-activated K<sup>+</sup> channels, increased prostacyclin release and an antioxidant and anti-inflammatory effect (Chen et al 1997, 2011a, Koltermann et al 2007, Nishida & Satoh 2003). In 2008, a clinical study by Wu et al investigated the effects of GBE on the distal left anterior descending coronary artery (LAD) blood flow and plasma NO and endothelin-1 (ET-1) levels (Wu et al 2008c). The randomised controlled trial (RCT) of 80 volunteers with coronary artery disease (CAD) used Doppler echocardiography to determine blood flow, which was measured at baseline and after 2 weeks of treatment. A significant improvement in maximal diastolic peak velocity, maximal systolic peak velocity and diastolic time velocity integral was observed for the group treated with GBE compared with controls ( $P < 0.01$ ). Additionally, a significant increase in NO and decrease in ET-1 was observed, suggesting that the observed increase of LAD blood flow might be related to restoration of the delicate equilibrium between NO and ET-1.

#### Reduces oedema

Various flavonoids, including anthocyanosides and GBE, have been shown to be effective against

experimentally induced capillary hyperfiltration (Cohen-Boulakia et al 2000).

### Antiplatelet and anticoagulant — no significant effect

Standardised *G. biloba* therapy is not associated with a higher bleeding risk, according to a 2011 meta-analysis of 18 RCTs (Kellermann & Kloft 2011). This level 1 evidence overrides previous speculation based on several case reports suggesting ginkgo biloba can cause bleeding and some evidence that one of its components, ginkgolide B, is a platelet-activating factor antagonist (Smith et al 1996).

Controlled studies have included young healthy volunteers, older adults, people with multiple sclerosis (MS) and people using warfarin or aspirin at the same time as *G. biloba* (Aruna & Naidu 2007, Bal Dit et al 2003, Beckert et al 2007, Carlson et al 2007, Engelsens et al 2003, Gardner et al 2007, Jiang et al 2005, Kohler et al 2004, Lovera et al 2007, Wolf 2006). An escalating-dose study found that 120 mg, 240 mg or 480 mg given daily for 14 days did not alter platelet function or coagulation (Bal Dit et al 2003).

Only one study could be located which demonstrated that EGb 761 (80 mg/day) produced a significant reduction in blood viscosity after 30 days' treatment (Galduroz et al 2007). When measured again 90 days after commencement of EGb 761 treatment, a further reduction was observed which appeared to stabilise, as no further reduction was observed after 180 days of use.

### Alters neurotransmitters

#### Monoamine oxidase (MAO) inhibition — not in vivo

In vitro tests in rat brains suggest that EGb 761 may exert MAO-A and MAO-B inhibitor activity (Wu & Zhu 1999). Tests with isolated constituents, kaempferol, apigenin and chrysin, have demonstrated these to be potent MAO inhibitors, with greater effect on MAO-A than MAO-B (Sloley et al 2000). A recent rat model showed MAO activity was not affected by EGb 761, suggesting the effect is not significant in vivo (Fehske et al 2009). The lack of significant in vivo MAO-inhibitory activity was confirmed in a human study using positron emission tomography, which found that treatment with *G. biloba* (EGb 761: 120 mg/day) for 1 month did not produce significant changes in brain MAO-A or MAO-B in the 10 participating volunteers (Fowler et al 2000).

#### Serotonin

An in vitro study found that oral EGb 761 significantly increases the uptake of serotonin, but not dopamine, in cerebral cortex samples from mice (Ramassamy et al 1992) and a later in vivo study identified an antiaggressive effect mediated by 5-HT<sub>2A</sub> receptors (Shih et al 2000). In contrast, an animal study suggests no change in 5-HT uptake

after 14 days of oral treatment with EGb 761 (Fehske et al 2009).

### Cholinergic effects

Considering that *G. biloba* appears to be as effective as anticholinesterase drugs, several researchers have investigated whether it exerts cholinergic effects. Evidence from behavioural, in vitro and ex vivo tests with *G. biloba* has shown both direct and indirect cholinergic activities (Das et al 2002, Nathan 2000). The extract appears to increase the rate of acetylcholine turnover and stimulate the binding activity of ligands to muscarinic receptors in the hippocampus (Muller 1989).

### Gamma-aminobutyric acid (GABA) receptors

Bilobalide in *G. biloba* is a competitive antagonist for GABA-A receptors according to in vitro tests (Huang et al 2003). The effect is almost as potent as bicuculline and picrotoxin.

### Corticosterone

In vivo tests have found that EGb 761 has stress-alleviating properties mediated through its moderation of corticosterone levels (Puebla-Perez et al 2003).

### Dopamine

Chronic, but not acute, treatment with *G. biloba* (EGb 761) significantly increases extracellular dopamine in vivo, which may be one of the mechanisms in improving cognitive function (Yoshitake et al 2010). *G. biloba* (EGb 761) affects the dopaminergic system, which was observed as a reduction in serum prolactin levels in male rats (Yeh et al 2008) and an increase in dopamine and acetylcholine levels in the prefrontal cortex (Kehr et al 2012). *G. biloba*'s dopamine-enhancing effect may be explained by its ability to decrease the uptake of noradrenaline as dopamine clearance in the frontal cortex is mediated by noradrenaline (Fehske et al 2009).

### Neuroprotection

*G. biloba* leaf extract (EGb 761) has demonstrated neuroprotective effects in a variety of studies ranging from molecular and cellular, to animal and human; however not all the cellular and molecular mechanisms have been elucidated (Ao et al 2006, Kaur et al 2013, Smith et al 2002). Of the constituents studied, it appears that the bilobalide constituent is chiefly responsible for this activity, although others are also involved (DeFeudis & Drieu 2000).

Until recently, it was believed that the antioxidant, membrane-stabilising and platelet-activating factor antagonist effects were chiefly responsible for neuroprotection, but effects at the mitochondria may also be important contributing mechanisms. Recent research suggests that *G. biloba* (EGb 761) exerts a multifunctional neuroprotective role associated with activation of the haem oxygenase 1 (HO1) and nuclear factor erythroid 2-related factor 2 (Nrf2), upregulation of vascular endothelial growth

factor (VEGF) and downregulation of inflammatory mediators (Tulsulkar & Shah 2012). Another in vivo animal study suggests the neuroprotection may also be a result of antiapoptotic activity and effects on energy metabolism (Mahdy et al 2011).

### Beta-amyloid

GBE EGb 761 protects cells against toxicity induced by beta-amyloid in a concentration-dependent manner, according to in vitro tests (Bastianetto & Quirion 2002a, 2002b, Bastianetto et al 2000). In vivo studies have confirmed that ginkgo extract has an anti-amyloid aggregation effect (Luo 2006). It appears that ginkgo increases transthyretin RNA levels in mouse hippocampus, which is noteworthy because transthyretin is involved in the transport of beta-amyloid and may provide a mechanism to reduce amyloid deposition in brain (Watanabe et al 2001). There is also evidence that *G. biloba* modulates alpha-secretase, the enzyme that cuts the amyloid precursor protein and prevents amyloidogenic fragments from being produced (Colciaghi et al 2004).

### Cerebral ischaemia

There is evidence from experimental and clinical studies that GBE protects cerebral tissues from ischaemia/reperfusion damage and, while the effect has been reported for prophylactic use (Janssens et al 2000, Kaur et al 2013, Peng et al 2003), some research also suggests *G. biloba* exerts significant neuroprotective effects after acute ischaemic stroke (Ma et al 2012, Nada & Shah 2012, Zhang et al 2012b). This was confirmed most recently in a 2013 placebo-controlled RCT of 102 consecutive patients with acute ischaemic stroke which found that treatment with GBE for 4 months produced a significant reduction in poststroke National Institutes of Health Stroke Scale (NIHSS) score compared to placebo, showing improved function (Oskouei et al 2013). The treatment used was *G. biloba* tablets (Gol-Darou, Isfahan, Iran) with a total dose of 120 mg/day (40 mg three times/day),

*G. biloba* crosses the blood-brain barrier and reaches extracellular concentrations in the brain, allowing efficient interaction with target molecules. The availability of ginkgo in cerebral tissue is high when given before ischaemia, but severely limited after the occurrence of ischaemia, which may explain the greater success seen in animal model research when used prophylactically and mean higher doses are required poststroke (Oskouei et al 2013).

### Stabilisation and protection of mitochondrial function

Several in vitro tests have demonstrated that EGb 761 stabilises and protects mitochondrial function (Eckert et al 2005, Janssens et al 2000). These observations are gaining the attention of researchers interested in neurodegenerative diseases, as it is suspected that the mitochondria and the phenomenon

of mitochondrial permeability transition play a key role in neuronal cell death and the development of such diseases (Beal 2003, Shevtsova et al 2005). Animal studies are confirming these in vitro findings and it may be that both the ginkgolides and the bilobalide compounds have this mitochondrial protective action on neural function (Eckert 2012).

### Immunostimulant

Immunostimulatory activity has been demonstrated in several experimental models (Puebla-Perez et al 2003, Tian et al 2003, Villasenor-Garcia et al 2004).

The beneficial effects of EGb 761 on immune function are based on its antioxidant properties, as well as the cell proliferation-stimulating effect. An in vitro animal study has suggested that nebulised total ginkgo flavone glycosides have a therapeutic effect for asthmatic mice, perhaps through regulating Th1/Th2 imbalance (Chen et al 2008).

### Anticancer

Studies conducted with various molecular, cellular and whole-animal models have revealed that leaf extracts of *G. biloba* may have anticancer (chemopreventive) properties that are related to its antioxidant, antiangiogenic and gene-regulatory actions (DeFeudis et al 2003). Both the flavonoid and terpenoid constituents are thought to be responsible for many of these mechanisms, meaning that the whole extract is required for activity. In vitro and in vivo studies have shown GBE inhibits the growth and proliferation of several types of tumour, including colon cancer cells (Chen et al 2011b), gastric precancerous lesions (Jiang et al 2009), pancreatic cancer cells (Zhang et al 2008), liver cancer cells (Hao et al 2009, Wang et al 2011), breast cancer cells (Jiang et al 2011, Park et al 2013) and ovarian cancer BRCA1 gene mutation cells (Jiang et al 2011) and provides protection from cigarette smoke in human lung cells (Hsu et al 2009). An in vitro study identified the kaempferol and quercetin constituents of *G. biloba* as key components inducing apoptosis in oral-cavity cancer cells (Kang et al 2010). Studies in humans have found that ginkgo extracts inhibit the formation of radiation-induced (chromosome-damaging) clastogenic factors and ultraviolet-induced oxidative stress, both effects that may contribute to the overall chemopreventive activity. As a result of these observations, there has been a call by some academics for ginkgo to be more widely investigated and used in the prevention and treatment of cancer (Eli & Fasciano 2006).

## OTHER ACTIONS

### Antiatherosclerotic

Animal models have found *G. biloba* to be effective against atherosclerosis (Chen et al 2011a, Lim et al 2011, Pierre et al 2008). An in vitro study suggests an antiatherosclerotic effect via downregulation of VEGF (Liu et al 2009) and an in vivo study suggests that *G. biloba* may have a cholesterol-lowering effect

via HMG-CoA reductase activity and decreasing cholesterol influx (Xie et al 2009). Another animal model found *G. biloba*'s antiatherosclerotic action was through lipid modulation, reducing vascular lesions and modulation of connexin 43 protein (Wei et al 2013).

### Antiviral

Ginkgolic acid inhibits HIV protease activity and HIV infection in vitro (Lu et al 2012). In vitro research also identified anti-influenza action with GBE, but only with pretreatment before cell exposure, suggesting it interferes with the interaction between the virus and erythrocytes (Haruyama & Nagata 2013).

### Glycaemia

Some in vitro and animal research has suggested that *G. biloba* may have a beneficial effect on reducing insulin resistance (Cong et al 2011, Zhou et al 2011).

### Antiosteoporotic

*G. biloba* treatment produced a significant reversal in bone loss of the mandible and femur in a glucocorticoid-induced osteoporosis model (Lucinda et al 2010).

### Activity on cytochromes and P-glycoprotein

Several studies have investigated *G. biloba* for effects on different cytochromes in test tube and animal models and, more recently, human studies. While early in vitro tests demonstrated that *G. biloba* inhibits CYP 3A4, clinical studies have found no such effect (Budzinski et al 2000, Gurley et al 2002, 2005, 2012, Markowitz et al 2003). In vitro tests have suggested that the effect on cytochromes is biphasic, with low doses of ginkgo extract inducing CYP 1A2 and inhibiting 2D6 and higher doses exhibiting the opposite effect (Hellum et al 2007). Studies investigating ginkgo extract and its various constituents in animal models have identified induction of CYP 3A1, 1A1, 1A2, 2E1, 2B12 for ginkgo, which appears to be largely mediated by the bilobalide constituent, whereas no effect on CYP 2D6, 2C11 or 2C7 has been demonstrated (Deng et al 2008, Ribonnet et al 2011, Taki et al 2009, Tang et al 2007a, Zhao et al 2006).

The question arises of clinical significance and whether the effects observed in animal models also occur in humans to an appreciable degree. To this end, clinical studies have been conducted clarifying the issue (Duche et al 1989, Gurley et al 2002, 2005, Kim et al 2010, Markowitz et al 2003, Tang et al 2007a, Zadayan et al 2012, Zuo et al 2010). Tests with human volunteers have found no significant effect on CYP 3A4, 2D6 or 1A2 with GBE. Gurley et al (2012) report that 29 drugs mediated by various cytochromes have been evaluated and conclude that there is little risk of herb-drug interactions with *G. biloba* at doses of 240 mg/day or less.

Less is known about the effects of ginkgo on the drug transporter molecule P-glycoprotein (P-gp, also known as ABCB1). In vitro studies have identified induction of P-gp with ginkgo (Hellum & Nilsen 2008, Yeung et al 2008). A human study found no effects on P-gp after a single ginkgo dose (120 mg); however use of 120 mg three times daily (360 mg/day) for 14 days did show significant P-gp inhibition for *G. biloba* (Fan et al 2009). The most common therapeutic dose used is 240 mg daily, suggesting some minor effects are possible clinically. More clinical trials are needed to confirm this finding.

### Antiasthmatic

In an asthma mouse study ginkgolide B exhibited a significant effect on regulating the kinase/MAPK pathway and a significant decrease in eosinophil count in bronchoalveolar lavage fluid after treatment (Chu et al 2011). Emerging research demonstrates how GBE may be useful in asthma treatment and acute lung injury by its action of suppressing NF- $\kappa$ B gene expression (Huang et al 2013, Li et al 2008).

## CLINICAL USE

*G. biloba* is a complex herb that contains many different active constituents and works by means of multiple mechanisms. In practice, its therapeutic effect is a result of interactions between constituents and mechanisms, giving it applications in many varied conditions. To date, most of the research conducted in Europe has used a standardised preparation known as EGb 761.

### Dementia, memory impairment

*G. biloba* has been used and studied as a cognitive activator in a variety of populations, such as cognitively intact people and those with cerebral insufficiency, age-related memory impairment, Alzheimer's dementia or multi-infarct dementia and dementia with neuropsychiatric features. It has also been tested in healthy adults with poor memory and others with no cognitive deficits to determine whether treatment can further improve memory. Overall, the evidence suggests that oral ginkgo extract improves cognitive function in people with mild to moderate cognitive impairment when used long-term and it also provides benefits for people with dementia and neuropsychiatric symptoms when used long-term (approximately 6 months). Some benefits may also be possible for various aspects of cognitive function in older adults, such as retrieval of learned material, but results are inconsistent for cognitive function overall. In regard to younger healthy adults, acute dosing appears more successful than chronic use.

While ginkgo biloba demonstrates neuroprotective effects in experimental models, the current evidence indicates long-term use does not protect against the development of dementia.

**Clinical note — What is cerebral insufficiency?**

Cerebral insufficiency is a syndrome characterised by a collection of symptoms, although it is not associated with any clear pathological changes. The 12 symptoms associated with this condition are: (1) difficulties of memory; (2) difficulties of concentration; (3) being absent-minded; (4) confusion; (5) lack of energy; (6) tiredness; (7) decreased physical performance; (8) depressive mood; (9) anxiety; (10) dizziness; (11) tinnitus; and (12) headaches (Kleijnen & Knipschild 1992). Some of these symptoms are also described as early symptoms of dementia and appear to be associated with decreased cerebral blood flow, although frequently no explanation is found.

A 2013 systematic review and meta-analysis of eight RCTs involving people with dementia reported significant, although modest, improvements in both cognitive function and daily activities. All studies used the GBE EGb 761 and two of the studies compared the extract to the drug donepezil and found no significant difference between the two treatments when treating mild to moderate dementia (Brondino et al 2013). Two of the studies included in the Brondino review focused on outpatients ( $n = 410$ ) with mild to moderate dementia and neuropsychiatric symptoms who were treated with *G. biloba* (240 mg daily EGb 761) for 24 weeks; a significant improvement was produced in apathy, sleep, irritability, depression and aberrant motor behaviour and improved wellbeing of their caregivers (Bachinskaya et al 2011, Herrschaft et al 2012). Another trial in the 2013 review was a double-blind RCT of 400 subjects with mild to moderate dementia (Alzheimer's disease or vascular dementia) with neuropsychiatric features testing EGb 761 extract over 22 weeks (Napryeyenko & Borzenko 2007). Active treatment produced a mean  $-3.2$ -point improvement in the Specialty Knowledge Test (SKT) with an average deterioration by  $+1.3$  points on placebo ( $P < 0.001$ ). EGb 761 was significantly superior to placebo on all secondary outcome measures, including the Neuropsychiatric Inventory (NPI), and an activities-of-daily-living scale. Treatment results were essentially similar for Alzheimer's disease or vascular dementia subgroups. The drug was well tolerated and adverse events were similar for ginkgo and placebo treatment. A secondary analysis of this Napryeyenko RCT found *G. biloba* (EGb 761 240 mg/day) to be effective for both Alzheimer's disease and vascular dementia for neuropsychiatric symptoms (Napryeyenko et al 2009).

A 2009 Cochrane systematic review of 36 RCTs for ginkgo (any dose) in the treatment of dementia and cognitive decline (any severity) concluded that the results were inconsistent and unreliable but

explained that the studies were mainly small, often poorly designed and of less than 3 months' duration, which may explain the inconsistency. All but one study used the EGb 761 extract (dose ranging from 80 to 600 mg/day, with most less than 200 mg daily). The authors reported that, although earlier studies found significant benefits, later studies were inconsistent and they found no difference between the 120 mg and 240 mg standard dosing (Birks & Grimley Evans 2009). This inconsistency may be in part due to reviewers pooling all studies regardless of patient diagnoses, the myriad of different scales and measures used and the fact that some studies are over 20 years old and randomisation and blinding techniques have changed in recent years. As a result, the findings are not straightforward and deserve more detailed description to be better understood. A literature review in 2012 suggested that the evidence for the use of *G. biloba* for cognitive impairment and dementia was not convincing (Roland & Nergard 2012).

However, other meta-analyses, with well-defined parameters, have found *G. biloba* to be clinically effective. One review and meta-analysis included nine well-designed studies between 12 and 52 weeks ( $n = 2372$ ), all using the standardised extract EGb 761 (once-a-day dose of 240 mg) and found *G. biloba* to be more effective than placebo; with the Alzheimer's disease subgroup experiencing a larger cognitive benefit (Weinmann et al 2010). Another meta-analysis of six RCTs took a bivariate random approach considering the influence of baseline risk and found *G. biloba* to be effective for cognitive function in dementia with 6 months of treatment (Wang et al 2010). Kaschel undertook a literature review in 2009, aiming to discover the differential effects in neuropsychological improvement with *G. biloba* use, hypothesising that there may be certain parts of our memory that improve with this herb. Results from 29 RCTs were analysed, giving psychometric scores in different cognitive domains and 14 cognitive subfunctions. This reviewer suggested there is consistent evidence for long-term use of *G. biloba* in providing benefits for selective attention, fluid intelligence and long-term memory for both verbal and non-verbal material. It does not seem to have much effect on pure speed or on the less age-sensitive area of short-term memory (Kaschel 2009). This selective testing has provided a credible explanation for why there may be inconsistent study results and is perhaps the best way forward for future studies.

Two trials were not included in the recent reviews: the first was a double-blind, parallel-group RCT of 176 subjects with mild to moderate dementia which used low-dose standardised extract of *G. biloba* (120 mg daily) over 6 months, finding no benefits beyond placebo (McCamey et al 2008). The second trial was a larger double-blind RCT of 400 patients with dementia associated with neuropsychiatric features, testing a higher dose of EGb 761 extract (240 mg/day) (Scripnikov et al 2007).

The study population included people with probable or possible Alzheimer's disease with cerebrovascular disease or vascular dementia. At this dose, EGb 761 was significantly superior to placebo with respect to the primary outcome (SKT battery) and all secondary outcome variables. While herbal treatment improved outcomes, the placebo group showed evidence of deterioration as measured by the mean composite score (frequency  $\times$  severity) and the mean caregiver distress score ( $P < 0.001$ ). The largest effects for EGb 761 were found for apathy/indifference, anxiety, irritability/lability, depression/dysphoria and sleep/nighttime behaviour.

Some smaller recent trials report benefit in treating mild cognitive impairment (Dong et al 2012) and one group found that episodic memory of patients with mild cognitive impairment improved (Zhao et al 2012).

Several recent reviews have focused on the role of ginkgo in Alzheimer's disease, producing inconsistent conclusions, which may be due to differences in exclusion criteria and the heterogeneity of the studies making data analysis difficult. A Cochrane systematic review in 2009 found 925 patients from nine Alzheimer's disease and ginkgo trials and suggested no consistent pattern of benefit (Birks & Grimley Evans 2009) and another systematic review suggested results were inconclusive (Fu & Li 2011). However, in 2010, a systematic review of the use of *G. biloba* in Alzheimer's disease found evidence of high-dose *G. biloba* (240 mg/day EGb 761) improving daily living, mood and cognition; the results were statistically significant in three of the four studies within the subgroup analysis. The complete meta-analysis included six quality studies of at least 16 weeks' duration and, although benefit for *G. biloba* was reported, the authors found that no potential effect size could be estimated because of the heterogeneous results and recommend future research focusing on subgroups of Alzheimer's disease. No evidence of harm was found in any of the studies (Janssen et al 2010).

#### Alzheimer's disease or vascular dementia with neuropsychiatric features

A 2013 review of four RCTs testing EGb 761 in elderly patients ( $n = 1294$ ) with a total score of 9–23 in the SKT cognitive test battery (cognitive domain) and with a composite score of 6 and greater in the NPI (behavioural domain) concluded that active treatment with ginkgo was safe, effective and well tolerated (Ihl 2013). Patients treated with EGb 761 showed improvements of cognitive performance and behavioural symptoms that were associated with advances in activities of daily living and a reduced burden to caregivers, whereas the placebo groups showed only minimal improvements or signs of disease progression. EGb 761 was significantly superior to placebo groups in all mentioned domains ( $P < 0.01$ ) and had similar effects to donepezil. The RCTs compared a dose of EGb 761 2 capsules of

120 mg/day or one capsule of 240 mg/day to placebo while one RCT used donepezil as an active control. The duration of treatment was 22 or 24 weeks.

#### Use in healthy subjects

Many double-blind studies have investigated the effects of *G. biloba* (120–600 mg/day) on cognitive function in younger and older healthy subjects. Some studies have evaluated the effects of a single dose, whereas others are long-term studies (2 days–13 weeks).

A 2012 meta-analysis of *G. biloba* as a cognitive enhancer in healthy individuals identified 10 RCTs (with 13 data sets) and concluded that, on measures of memory, executive function and attention, there was no significant effect on cognitive function. In the analysis the authors reported all effect sizes as non-significant and found no difference with age of participants, dose, time of trial or type of GBE. In the 13 studies assessing memory, not one of the studies found a significant effect (Laws et al 2012).

Previously, a systematic review of placebo-controlled trials, published in 2007, investigated whether *G. biloba* enhances cognitive function in healthy subjects aged under 60 years (Canter & Ernst 2007). A number of the acute studies included in the analysis used multiple outcomes and reported positive effects on one or more of these at particular time points with particular doses, but these findings were either not replicated or contradicted by other studies. The evidence from long-term studies is largely negative. Of those studies that measured subjective effects, only one of five acute studies and one of six long-term studies reported any significant positive results.

More recently, a benefit was found in 188 healthy middle-aged volunteers who were given placebo or ginkgo 240 mg once daily (EGb 761) for 6 weeks. There was significant improvement on the demanding standardised free-recall test but no benefit in another memory test on recalling a driving route. This confirms previous evidence suggesting a role for *G. biloba* in retrieval of learned material, which is known to be sensitive to ageing (Kaschel 2011).

Overall, tests with younger subjects taking *G. biloba* long-term have failed to show positive effects on memory; however, short-term benefits after acute dosing may be possible for some aspects of memory. Healthy older adults with poorer cognitive performance appear to experience greater benefit than those with higher cognitive function levels. This was confirmed in a 2011 RCT which found a more pronounced and consistent improvement in cognition in subjects with a lower memory function at baseline in mild cognitive impairment ( $n = 300$ ) who were taking *G. biloba* (240 mg/daily EGb 761) for 12 weeks (Grass-Kapanke et al 2011).

Tests with younger (18–43 years) and older volunteers (55–79 years) produced different results in a 12-week, double-blind, placebo-controlled study

(Burns et al 2006). The effects of ginkgo (120 mg/day) were assessed for both groups on a wide range of cognitive abilities, executive function, attention and mood. The older group responded to treatment as long-term memory assessed by associational learning tasks showed significant improvement with ginkgo; however, no other significant differences were found on any other measure. The young adult group ( $n = 104$ ) failed to respond on any measure, as no significant differences were observed for the treatment or placebo groups. Similarly, no significant effects on mood or any of the cognitive tests employed by Elsabagh et al (2005a) were found for ginkgo (120 mg/day) taken over 6 weeks in a placebo-controlled study of 52 young adults. In contrast, acute treatment of younger subjects with ginkgo (120 mg) significantly improved performance on the sustained-attention task and pattern recognition memory task according to a randomised, double-blind study (Elsabagh et al 2005a). The study of 52 students found no further effects for ginkgo on working memory, planning, mental flexibility or mood.

Kennedy et al (2007b) reported on a re-analysis of data from three methodologically identical, double-blind, crossover studies that each included a treatment of 120 mg ginkgo extract and matched placebo. The analysis found that 120 mg of ginkgo conferred a significant improvement on the 'quality of memory' factor and was most evident at 1 and 4 hours after single-dose treatment, but had a negative effect on performance on the 'speed of attention' factor, which was most evident at 1 and 6 hours after treatment.

### Vascular cognitive impairment

One study of 80 patients diagnosed with vascular cognitive impairment compared conventional treatment with antiplatelet medication to treatment with adjunctive *G. biloba* and the antiplatelet medication. The 3-month trial found addition of ginkgo improved the therapeutic effect, with increases in cerebral blood flow and cognitive enhancement observed (Zhang & Xue 2012).

### Ginkgo complexed with phospholipids

Some recent data suggest that the complexation of standardised GBE with soy-derived phospholipids may enhance the bioavailability of active components, thereby producing better results. Kennedy et al (2007a) tested two different ginkgo products complexed with either phosphatidylserine or phosphatidylcholine in a placebo-controlled study of younger volunteers. Test subjects were given an acute dose of ginkgo, one of the ginkgo combinations or placebo on separate days (7 days apart). Confirming earlier results, *G. biloba* (120 mg) as sole treatment was not associated with markedly improved performance on the primary outcomes in this younger population; however, administration of GBE complexed with phosphatidylserine resulted in improved secondary memory performance and

significantly increased speed of memory task performance across all of the postdose testing sessions. Interestingly, all three herbal treatments were associated with improved calmness. Whether the superior effect obtained for this combination is due to the complexation of the extracts, their mere combination or the separate psychopharmacological actions of the two extracts remains to be tested.

### Cognitive effects in postmenopausal women

A systematic review of herbal and dietary supplements and their use in menopause for cognitive function included two *G. biloba* studies, both using a low dose of 120 mg/day (Clement et al 2011). In one RCT, 57 postmenopausal women were given a combination of ginkgo at 120 mg and ginseng at 200 mg (Gincosan) over 12 weeks. No significant effects were found in any of the symptoms measured of anxiety and mood and cognitive measures of attention and memory (Hartley et al 2004). The second was a double-blind RCT of 87 postmenopausal women; it was found that 1 week's treatment with ginkgo (120 mg/day) significantly improved mental flexibility in older (mean age 61 years) postmenopausal women beyond placebo. However no significant benefits were seen for younger women with better cognitive performance at baseline and no benefit for any of the women for the cognitive function of memory and sustained attention (Elsabagh et al 2005b). The study tested ginkgo extract (LI 1370, Lichtwer Pharma, Marlow, UK) over 6 weeks (Elsabagh et al 2005b).

### Comparisons with anticholinesterase drugs

The type of central nervous system effects produced by EGb 761 in elderly dementia patients is similar to those induced in tacrine responders and those seen after the administration of other 'cognitive activators', according to a small randomised study involving 18 elderly people diagnosed with mild to moderate dementia (possible or probable Alzheimer's disease) (Itil et al 1998). The results also demonstrated that 240 mg EGb produced typical cognitive activator electrocardiogram profiles (responders) in more subjects (8 of 18) than 40 mg tacrine (3 of 18 subjects). Later reviews concluded that ginkgo extract and second-generation cholinesterase inhibitors (donepezil, rivastigmine, metrifonate) should be considered equally effective in the treatment of mild to moderate Alzheimer's dementia (Kasper & Schubert 2009, Wettstein 2000). One double-blind exploratory RCT with 96 outpatients compared *G. biloba*, donepezil or combined treatment over 22 weeks and found no significant differences between them and only superior benefits when they were combined (Yancheva et al 2009).

Commission E approves the use of standardised ginkgo extract in dementia syndromes, including vascular, primary degenerative and mixed types (Blumenthal et al 2000).

## Dementia prevention

The many mechanisms attributed to ginkgo make it an ideal candidate for the long-term prevention of many age-related diseases such as dementia. Two clinical trials were published in 2008, which investigated whether treatment with *G. biloba* could significantly reduce the incidence of dementia and, more recently, a large RCT released results in 2012. Overall, the current body of evidence indicates that ginkgo treatment does not protect against the development of dementia or Alzheimer's disease when taken by people over 70 years (DeKosky et al 2008, Dodge et al 2008, Vellas et al 2012).

DeKosky et al (2008) compared the effectiveness of *G. biloba* to placebo in reducing the incidence of all-cause dementia and Alzheimer's disease in elderly individuals with normal cognition and those with mild cognitive impairment. The large randomised, double-blind, placebo-controlled clinical trial involved 3069 community-dwelling subjects aged 75 years or older with normal cognition ( $n = 2587$ ) or mild cognitive impairment ( $n = 482$ ). It was conducted at five academic medical centres in the United States between 2000 and 2008, with a median follow-up of 6.1 years. Treatment consisted of a twice-daily dose of 120 mg extract of *G. biloba* and was not shown to reduce the overall incidence rate of either dementia or Alzheimer's disease incidence in elderly individuals. Treatment was well tolerated by this population, as the incidence of side effects was similar for both groups.

In the same year, Dodge et al (2008) published the results of a double-blind study involving 118 cognitively intact older subjects (85 years or older). In the intention-to-treat analysis, there was no reduced risk of progression to clinical dementia among the GBE group; however, in the secondary analysis, where medication adherence level was controlled, the GBE group had a significantly lower risk of progression and a smaller decline in memory scores. Importantly, more stroke and transient ischaemic attack cases were observed among the GBE group; further investigation is required to confirm this finding.

A 5-year double-blind RCT (GuidAge) released results in 2012. This large clinical trial recruited participants aged over 70 years who had consulted their primary care doctor for memory problems; 1404 patients were prescribed a dose of 120 mg twice daily (EGb 761) and 1414 were given placebo. The findings were negative and *G. biloba* did not reduce the incidence of Alzheimer's disease in elderly patients with memory complaints (Vellas et al 2012).

## Acute ischaemic stroke

GBE is widely used in the treatment of acute ischaemic stroke in China.

A 2005 Cochrane systematic review identified 14 trials, of which 10 (792 patients) were included (Zeng et al 2005). In those 10 trials, follow-up was performed at 14–35 days after stroke and, in all

studies, neurological outcome was assessed, but none of them reported on disability (activities of daily living function) or quality of life and only three trials reported adverse events. Nine of the trials were considered to be of inferior quality. Overall, results from the 10 studies found that GBE was associated with a significant increase in the number of improved patients. Of note, one placebo-controlled trial, assessed to be of good quality, failed to show an improvement in neurological deficit at the end of treatment. A recent review of *G. biloba* confirmed previous Cochrane reviews and concluded that there was no convincing evidence of ginkgo being effective for acute ischaemic stroke (Roland & Nergard 2012).

However, the story is not yet complete, as two more recent studies have shown benefits for ginkgo treatment in ischaemic stroke. A double-blind RCT of 31 patients after an acute ischaemic stroke or a cerebrovascular accident were administered standard pharmacotherapy or standard treatment with the addition of *G. biloba* (1500 mg/day) for 30 days. Blood samples before and after the treatment showed greater antioxidant status and lower inflammatory markers, such as C-reactive protein, which may assist in neuroprotection after a stroke (Thanoon et al 2012). Of more interest is a 2013 placebo-controlled RCT of 102 consecutive patients with acute ischaemic stroke which tested treatment with *G. biloba* tablets (Gol-Darou, Isfahan, Iran) with a total dose of 120 mg/day (40 mg three times/day) over 4 months (Oskouei et al 2013). The primary outcome was a 50% reduction in the 4-month NIHSS, which was used to measure functional outcome. Treatment with ginkgo was significantly superior to placebo and the risk ratio and number needed to treat were 3.16 and 2.50, respectively. In addition, multivariate regression adjusted for age and sex revealed a significant NIHSS decline in the *G. biloba* group compared to the placebo group ( $P < 0.05$ ).

## Depression

Although studies have investigated the effects of *G. biloba* in cerebral insufficiency, a syndrome that is often characterised by depression and dementia with neuropsychiatric features, no clinical studies are available that have specifically investigated its use in clinical depression.

One randomised, double-blind, placebo-controlled study has investigated its effects in seasonal affective disorder (SAD). GBE PN246, in tablet form (Bio-Biloba), was tested in 27 patients with SAD over 10 weeks or until they developed symptoms, starting in a symptom-free phase about 1 month before symptoms were expected. In this trial, *G. biloba* failed to prevent the development of SAD (Lingaerde et al 1999).

Cieza et al (2003) tested EGb 761 (240 mg/day) on the subjective emotional wellbeing of healthy older subjects (50–65 years) in a randomised, double-blind study. Ginkgo treatment produced a

statistically significant difference for the visual analogue scale on mental health and for quality of life, as well as for the Subjective Intensity Scale: Mood score in week 2 compared with placebo. At the end of the study, statistically significant improvement in the EGb 761 group was observed for the variables of depression, fatigue and anger. Several more-recent studies investigating the effects of ginkgo on memory have also measured effects on mood. The double-blind studies found no significant effects for healthy older or younger volunteers (Burns et al 2006, Carlson et al 2007, Elsabagh et al 2005a). Whether ginkgo may have a mood-enhancing effect in a population with diagnosed depression remains to be tested.

### Generalised anxiety disorder (GAD)

EGb 761 has demonstrated stress-alleviating and anxiolytic-like activity in preclinical studies, and in a randomised study of 107 patients with GAD ( $n = 82$ ) or adjustment disorder with anxious mood ( $n = 25$ ) (Woelk et al 2007). *G. biloba* was tested in two different doses (480 mg/day and 240 mg/day) against placebo over 4 weeks and found to be significantly superior, with a dose-response trend being identified. Beneficial effects were observed after 4 days of treatment. Additionally, ginkgo treatment was safe and well-tolerated. A review of controlled studies of the use of medicinal plants for GAD found only a small number of studies on *G. biloba* but in those studies ginkgo showed an effect similar to or better than anxiolytic drugs (Faustino et al 2010).

### Peripheral vascular diseases

Ginkgo has been used in the treatment of intermittent claudication, Raynaud's syndrome and chilblains (Mouren et al 1994, Pittler & Ernst 2000). This is often based on the known pharmacological actions of ginkgo in improving peripheral circulation and exerting antioxidant and anti-inflammatory activities. While clinical trials have produced inconsistent results, the lack of non-surgical and safe pharmaceutical treatment options means ginkgo biloba is worthy of consideration in practice as a 3-month trial to determine individual response.

#### Intermittent claudication

A 2013 Cochrane database systematic review included 14 trials with 739 patients and found a non-significant increase of only 64.5 m on a flat treadmill being the absolute claudication distance (ACD) and concluded no significant benefit for patients with peripheral arterial disease. In the 24 weeks subgroup, authors found a significant improvement in ACD with an increase of 85.3 m. Nine trials compared 120–160 mg *G. biloba* daily with placebo and three of the trials used larger doses of 240 mg (Wang et al 2007), 300 mg (Gardner et al 2008) and 320 mg (Mouren et al 1994), with the majority of the trials lasting 12–24 weeks. The authors suggest that a publication bias and exclusion

of some 'negative' trials in earlier reviews skewed the results and also suggested that exercise therapy alone has shown a 5–10 times greater benefit than GBE (Nicolai et al 2013).

The earlier trials referred to included a 2004 meta-analysis reporting that ginkgo was more effective than placebo in intermittent claudication (Horsch & Walther 2004). Nine double-blind studies of EGb 761 for intermittent claudication were assessed in a total of 619 patients. A sensitivity analysis of a homogeneous sample in terms of design, treatment duration, inclusion and exclusion criteria and methods of measurement confirms these findings. Most studies have used a dose of 120 mg/day taken in divided doses, although one trial found that 240 mg/day gave better results. It should be recommended as long-term therapy and as an adjunct to exercise for the best results. An earlier randomised study measuring transcutaneous partial pressure of oxygen during exercise showed that a dose of 320 mg/day EGb 761 taken for 4 weeks significantly decreased the amount of ischaemic area by 38%, compared with no change with placebo (Mouren et al 1994).

Commission E approved the use of standardised ginkgo extract for intermittent claudication (Blumenthal et al 2000).

#### Clinical note — Peripheral arterial disease

Peripheral arterial disease is the chronic obstruction of the arteries supplying the lower extremities. The most frequent symptom is intermittent claudication, which results from poor oxygenation of the muscles of the lower extremities and is experienced typically as an aching pain, cramping or numbness in the calf, buttock, hip, thigh or arch of the foot. Symptoms are induced by walking or exercise and are relieved by rest. Presently, medical treatment revolves around lifestyle changes, such as increased exercise, and surgery as a final option.

#### Raynaud's syndrome

Whether ginkgo is an effective treatment in Raynaud's syndrome is difficult to ascertain. A review and meta-analysis of complementary medicine and Raynaud's syndrome (Malenfant et al 2009) included only one study on *G. biloba* by Muir et al (2002), which found a non-significant change in duration and severity of symptoms ( $P = 0.75$  and  $0.23$ , respectively). This study used a standardised GBE (Seredrin 360 mg daily) taken over a 10-week period which significantly reduced the number of attacks per week (from 13.2 to 5.8) compared with placebo (Muir et al 2002).

Several later studies were published, including an RCT conducted over 8 weeks, with 93 patients, which compared the use of the calcium channel blocker nifedipine with *G. biloba* and found a 50% improvement in the drug group versus a 31%

improvement in the ginkgo group (Choi et al 2009). Another RCT conducted during the coldest part of the year involved 41 participants and found no significant differences between EGb 761 (240 mg/day) and placebo after 10 weeks (Bredie & Jong 2012). Whether participants in these last two studies had more severe symptoms than in the previous positive study is unknown

### **Vertigo, tinnitus, labyrinthitis and sudden deafness**

Ginkgo is used to treat these and other symptoms of vestibulocochlear disorders.

#### **Tinnitus**

A recent Cochrane review included only four quality trials ( $n = 1543$ ) and they found no evidence to suggest that *G. biloba* was effective in patients whose primary issue was tinnitus, although they did report a small, statistically significant reduction in tinnitus in patients with vascular dementia and Alzheimer's disease (Hilton et al 2013). Two double-blind studies included in the recent Cochrane review have shifted the evidence against the use of *G. biloba* in tinnitus. The first was a large, double-blind, placebo-controlled study involving 1121 people aged between 18 and 70 years with tinnitus and 978 matched controls, which found that 12 weeks of treatment with ginkgo extract, LI 1370 (Lichtwer Pharma, Berlin, Germany), 50 mg three times daily resulted in no significant differences when subjects assessed their tinnitus in terms of loudness and how troublesome it was (Drew & Davies 2001). The second RCT of 66 subjects with tinnitus failed to show benefits with active treatment using a dose of 120 mg extract daily over 12 weeks (Rejali et al 2004). The primary outcome measures used were the Tinnitus Handicap Inventory, the Glasgow Health Status Inventory and the average hearing threshold at 0.5, 1, 2 and 4 kHz. In 2004, Rejali et al conducted a meta-analysis of clinical trials and found that 21.6% of patients with tinnitus reported benefit from *G. biloba* versus 18.4% of patients who reported benefit from a placebo.

Importantly, a 2011 systematic review which looked at the quality of plant extract and dosage levels included results of eight trials (all with EGb 761 with 120–240 mg/day) and excluded trials such as the Rejali study that did not specify the ginkgo preparation and which had a large drop-out rate due to illness. This review found that GBE EGb 761 was superior to placebo and was an effective treatment option for tinnitus. The authors suggest that trials with other GBEs were often of poor methodological quality (von Boetticher 2011).

#### **Salicylate-induced tinnitus**

One in vivo study investigating the effects of ginkgo in salicylate-induced tinnitus found a statistically significant decrease in the behavioural manifestation of tinnitus for ginkgo in doses of 25, 50 and 100 mg/day (Jastreboff et al 1997).

#### **Vertigo**

Despite being a common disease, there is no effective and side effect-free pharmaceutical agent that has shown efficacy for vertigo, creating interest in well-tolerated treatments such as ginkgo biloba, which displays mechanisms of action which may be relevant, such as antioxidant, neuroprotective, cognitive enhancing, improved perfusion and possibly vigilance enhancing. Research with animal models further indicates EGb 761 has an effect on the vestibular system and vestibular compensation (Hamann 2007).

In 2013, the REVERT registry collected data from 4294 patients with vertigo in 13 countries over 28 months and found that, in real-life medical practice, the most common treatments prescribed were betahistine followed by piracetam, ginkgo biloba and diuretics, and the greatest improvements were seen in the more severely ill, and those with benign paroxysmal positional vertigo or 'other vertigo of peripheral origin' (Agus et al 2013). Although the registry reported that 93% of patients had some improvement in the 6-month follow-up, there were no specific data on the ginkgo subsection.

A systematic review of preclinical studies and five double-blind RCTs investigating the effects of EGb 761 in vestibular and non-vestibular vertigo concluded that ginkgo has benefits in vertiginous syndromes (Hamann 2007). The RCTs used a daily dose between 120 and 160 mg which was taken for 3 months.

#### **Labyrinthitis**

A novel guinea pig model has shown that *G. biloba* can minimise cochlear damage on otitis media-induced labyrinthitis (Jang et al 2011). Clinical trials are needed to confirm if this has any clinical relevance.

#### **Sudden deafness**

Ginkgo extract was as effective as pentoxifylline in the treatment of sudden deafness, according to one randomised, double-blind study (Reisser & Weidauer 2001). Both treatments equally reduced associated symptoms of tinnitus and produced the same effects on the return to normal of speech discrimination. Subjective assessment suggested that GBE was more beneficial than pentoxifylline. EGb 761 (240 mg/day) has also been shown to accelerate and secure recovery of acute idiopathic sudden sensorineural hearing loss, observable within 1 week of treatment under randomised double-blind test conditions (Burschka et al 2001).

Commission E approves the use of standardised ginkgo extract in these conditions when of vascular origin (Blumenthal et al 2000).

#### **Macular degeneration, glaucoma and retinopathy**

With regard to these ophthalmological conditions, ginkgo has numerous properties that should

theoretically make it a useful treatment, such as increasing ocular blood flow, antioxidant and platelet-activating factor inhibitor activity, NO inhibition, protecting retinal ganglion cells against apoptosis (Wang et al 2012) and neuroprotective abilities.

### Macular degeneration

Although some positive evidence exists, a 2013 Cochrane review has suggested that, overall, there is insufficient evidence currently available to conclude that *G. biloba* treatment is effective in macular degeneration, with further testing required (Evans 2013). Based on its known mechanisms of action, it is a worthy candidate for further research.

### Glaucoma

With regard to glaucoma, the little research conducted so far appears promising. Researchers using colour Doppler imaging have observed significantly increased end-diastolic velocity in the ophthalmic artery after treatment with EGb (120 mg/day) in a placebo-controlled, randomised, crossover study (Chung et al 1999).

A randomised, double-blind, crossover study found that EGb 761 (120 mg/day) taken for 4 weeks produces positive effects in normal-tension glaucoma (Quaranta et al 2003). Furthermore, ginkgo treatment did not significantly alter intraocular pressure, blood pressure or heart rate and was well tolerated.

Other more recent studies have confirmed a benefit for normal-tension glaucoma. One RCT of 30 patients, administered 80 mg GBE twice a day over 4 weeks, found that retinal blood flow increased significantly in these normal-tension glaucoma patients (Park et al 2011). A retrospective study of 42 patients with a mean follow-up time of 12.3 years showed that 80 mg GBE twice daily slowed visual field defect damage (Lee et al 2013). These findings were also confirmed in a retrospective study with 332 patients who were compared to controls ( $n = 97$ ); of the cohort, 132 patients were given bilberry anthocyanins and 103 patients received *G. biloba* (ginkgo leaf extract from SK Chemicals, Gyeonggi-do, Korea) at a dose of one 80-mg tablet twice a day. Both treatments were found to improve visual function in some patients with normal-tension glaucoma (Shim et al 2012).

### Chloroquine retinopathy

In vivo tests using electroretinography have identified protective effects against the development of chloroquine-induced retinopathy using *G. biloba* (Droy-Lefaix et al 1992). This has been observed in both acute and chronic chloroquine toxicity of the retina (Droy-Lefaix et al 1995).

### Prevention of altitude sickness/acute mountain sickness

Acetazolamide and ginkgo biloba are the two most investigated drugs for the prevention of acute

mountain sickness (AMS) (Ke et al 2013). In general, research indicates that ginkgo may be useful as a prophylactic treatment when started 4–5 days prior to ascent to reduce the incidence of AMS (van Patot et al 2009). Considering its excellent safety profile, it is a treatment worthy of consideration.

While many studies have shown that pretreatment with ginkgo extract reduces the incidence of developing AMS, not all studies are positive when compared to placebo. This was most clearly seen in a study which consisted of two RCTs, one of which showed significant results (standardised *Ginkgo biloba* produced by Spectrum Chemical and Laboratory Products, Gardena, CA, United States) and the other did not (*Ginkgo biloba* 24/6/5 from Technical Sourcing International, TSI, Missoula, MT, United States) (Leadbetter et al 2009). The positive study used a dose of 120 mg twice daily starting 4 days before ascent to 4300 m and the other used prophylaxis at the same dose for 3 days.

In the positive study, treatment with 120 mg GBE twice daily significantly reduced both the incidence and the severity of AMS in participants rapidly exposed to high altitude; 68% of participants had AMS in the placebo group, compared to 33% in the GBE group and the number needed to treat was 3. In contrast, no significant effects on AMS incidence or severity were seen with the other ginkgo treatment and AMS developed in 45% of the placebo group compared to 27% taking ginkgo. Of note, the incidence of AMS in both ginkgo groups was still lower than placebo; however, the higher rate of AMS in the placebo group in the positive study may have been responsible for the discrepant results. The authors noted that the studies were underpowered to confirm these suspicions; however, the rates of AMS observed with placebo reflected the rates reported in the literature (50–75%).

A 2012 systematic shortcut review of literature (Seupaul et al 2012) on prophylaxis for AMS suggested that *G. biloba* was not effective; however, this review only included one study with *G. biloba* which was negative and involved 487 healthy Western hikers (Gertsch et al 2004). While the study by Gertsch et al is considered to be the only adequately powered GBE and AMS study published, treatment was not administered until participants reached approximately 4300 m without evidence of AMS, thus skewing the population towards those who are less susceptible to the condition and not being a proper trial design to test prophylaxis (Leadbetter et al 2009).

Numerous other studies not reported in the 2012 systematic review by Seupaul et al have been conducted, with research commencing in the 1990s and generally showing some benefits with ginkgo biloba pretreatment. Roncin et al (1996) involved 44 subjects and found that a dose of 160 mg/day taken for 5 days as prophylactic treatment resulted in 0% of subjects developing the cerebral symptoms of AMS versus 41% of subjects in the placebo group, whereas

only 3 subjects (13.6%) in the EGb 761 group developed respiratory symptoms of AMS; 18 (81.8%) in the placebo group developed these symptoms. Besides effectively preventing AMS for moderate altitude (5400 m), the treatment also decreased vasomotor disorders of the extremities. In 2001, [Maakestad et al](#) reported on a randomised, double-blind trial of *G. biloba* (120 mg twice daily starting 5 days before ascent) compared to placebo for the prevention of AMS in 40 college students who underwent rapid ascent from 1400 to 4300 m. Using the Lake Louise Symptoms score and Environmental Symptoms Questionnaire as outcomes, *G. biloba* was shown to significantly reduce the incidence of AMS compared to placebo.

In subsequent years, some researchers compared ginkgo to acetazolamide. In 2003, two studies produced conflicting results. The study by [Moraga et al \(2003\)](#) compared prophylaxis with *G. biloba* (80 mg twice daily) versus acetazolamide (250 mg twice daily) versus placebo, which was started 24 hours before rapid ascent to 3700 m. Of 32 subjects enrolled, none of those in the *G. biloba* group developed AMS, compared with 35% of those in the acetazolamide group and 54% of those receiving placebo. Alternatively, ginkgo (120 mg twice daily) started 3 days before ascent produced no significant effects when compared to placebo or acetazolamide in a randomised, double-blind study by [Leadbetter and Hackett \(2003\)](#). The study involved 59 subjects who experienced a rapid ascent to 4300 m. Negative results were also obtained by [Chow et al \(2005\)](#) in a small RCT, showing no benefits over placebo and superiority of acetazolamide.

A study published in 2007 tested a different type of treatment regimen that produced significant benefits. The placebo-controlled study of 36 people found that pretreatment followed by continued treatment with *G. biloba* prevented AMS and was significantly more effective than acetazolamide ([Moraga et al 2007](#)). Volunteers were given placebo, acetazolamide (250 mg per dose) or ginkgo (80 mg per dose) every 12 hours starting 24 hours before ascending and continuing throughout the 3-day stay at high altitude. Not a single person treated with ginkgo experienced AMS, compared with 36% taking acetazolamide and 54% taking placebo. While ginkgo did not alter arterial oxygen saturation compared to acetazolamide, a marked increased saturation in arterial oxygen was seen in comparison with the placebo group.

### Premenstrual syndrome (PMS)

A double-blind RCT evaluating the effects of EGb 761 in treating congestive symptoms of PMS in a group of 165 women found that treatment over two menstrual cycles (from day 16 until day 5 of the next cycle) was successful. Treatment was particularly effective in reducing breast symptoms, although neuropsychological symptoms were also alleviated ([Tamborini & Taurelle 1993](#)). A more recent placebo-controlled RCT with 85 participants has

confirmed that *G. biloba* can significantly reduce the severity of PMS symptoms when given at a dose of 40 mg ginkgo extract three times a day from day 16 of the menstrual cycle to day 5 of the next menstrual cycle ([Ozgoali et al 2009](#)).

### Vitiligo

A dose of 120 mg/day ginkgo extract significantly stopped active progression of depigmentation in slow-spreading vitiligo and induced repigmentation in some treated patients under double-blind, placebo-controlled study conditions ([Parsad et al 2003](#)). Although the mechanism of action responsible is unknown, antioxidant activity is thought to be important. An open-label trial of just 12 participants also reported repigmentation with *G. biloba* 120 mg/day given over 12 weeks ([Szczerko et al 2011](#)).

### Sexual dysfunction/sexual function

Due to its vasodilatory effects, ginkgo has been used in the management of sexual dysfunction in cases where compromised circulation is suspected. One open study has been conducted with subjects experiencing sexual dysfunction associated with antidepressant use ([Cohen & Bartlik 1998](#)). Ginkgo extract (average dose 209 mg/day) was found to be 84% effective in treating antidepressant-induced sexual dysfunction, predominantly caused by selective serotonin reuptake inhibitor, in a study of 63 subjects. A relative success rate of 91% was observed for women, compared with 76% for men, and a positive effect was reported on all four phases of the sexual response cycle: desire, excitement (erection and lubrication), orgasm and resolution. Although this was an open trial, the results are encouraging when one considers that the placebo effect is about 25% from past randomised trials of US Federal Drug Administration-approved medications for erectile dysfunction ([Moyad 2002](#)).

More recently, a small, triple-blind (investigator, patient, statistician), randomised, placebo-controlled trial of *G. biloba* (240 mg/day for 12 weeks) was undertaken with 24 subjects experiencing sexual impairment caused by antidepressant drugs ([Wheatley 2004](#)). The authors report some spectacular individual responses in both groups, but no statistically significant differences, and no differences in side effects.

[Meston et al \(2008\)](#) conducted two studies of women with sexual dysfunction. The first was a single-dose, placebo-controlled study using 300 mg ginkgo extract, which produced a small but significant facilitatory effect on physiological, but not subjective, sexual arousal in 99 sexually dysfunctional women. The second study investigated long-term use of ginkgo (300 mg/day) over 8 weeks, and found that herbal treatment combined with sex therapy significantly increased sexual desire and contentment compared to placebo or ginkgo as sole treatment. A newer study looking at the effect of *G. biloba* on menopausal women's sexual function

reported significant improvement in sexual desire, sexual pleasure, orgasm and importance of sex in comparison to previous years. The triple-blind, randomised, placebo-controlled trial included 80 healthy women aged 50–60 years who were given a dose of 120–240 mg *G. biloba* daily (Taavoni et al 2012).

## OTHER USES

*G. biloba* is used for many other indications, including improving connective tissue conditions such as haemorrhoids, common allergies, reducing the effects of exposure to radiation and to prevent some of the complications associated with diabetes. In the United Kingdom and other European countries, the cardioprotective effects of EGb 761 in myocardial ischaemia and reperfusion are currently being investigated in preclinical studies.

### Attention-deficit hyperactivity disorder and autism — no effect

A clinical trial in children with attention-deficit hyperactivity disorder (ADHD) found *G. biloba* to be less effective than the drug methylphenidate (Salehi et al 2010). A systematic review of herbal and nutritional products for treating ADHD confirmed no evidence of benefit with ginkgo (Sarris et al 2011). Additionally, *G. biloba* provided no benefits when used as add-on therapy in autism, according to a double-blind clinical trial adding the herb to risperidone therapy (Hasanzadeh et al 2012).

### Addiction — no effect

A pilot study for the treatment of cocaine dependence found no benefit to *G. biloba*. In the RCT 10-week trial 44 participants dependent on cocaine took piracetam (4.8 g/day) or ginkgo (120 mg/day) or placebo. The results found that piracetam was associated with more cocaine use and that ginkgo was not superior to placebo (Kampman et al 2003).

### Allergic conjunctivitis

An RCT of 60 patients with symptomatic allergic conjunctivitis using a topical GBE with hyaluronic acid ophthalmic solution (Trium) or hyaluronic acid alone found that additional *G. biloba* produced a significant decrease in symptoms of conjunctival hyperaemia, conjunctival discharge and chemosis (Russo et al 2009).

### Adjunct in cancer treatment

As a herb with significant antioxidant and neuro-protective activities, ginkgo has been used to reduce the toxic side effects of some chemotherapeutic drugs. Evidence from in vivo studies demonstrates protective effects against nephrotoxicity induced by cisplatin, cardiotoxicity induced by doxorubicin (El Boghdady 2013a, Naidu et al 2002, Ozturk et al 2004), cisplatin-induced ototoxicity (Huang et al 2007), Adriamycin-induced hyperlipidaemic nephrotoxicity (Abd-Ellah & Mariee 2007) and protective effects for testicular tissue after doxorubicin

therapy (Yeh et al 2009). An in vitro study produced a protective effect against radiation of human peripheral blood lymphocytes (Esmekaya et al 2011) and another found *G. biloba* may be helpful with cisplatin therapy sensitising ovarian cancer cells to treatment (Jiang et al 2014).

Little clinical research has been conducted thus far to determine its potential use in practice. One recent open-label clinical study enrolled 34 irradiated brain tumour patients who were given *G. biloba* (120 mg/day) for 24 weeks and found some improvement in quality of life and cognitive function (Attia et al 2012). Another trial with low-dose *G. biloba* (60 mg/day EGb 761) found no benefit in reducing cognitive dysfunction, which can often be associated with treatment in women who are undergoing chemotherapy for breast cancer (Barton et al 2013).

Patients ( $n = 23$ ) undergoing radioiodine therapy for differentiated thyroid cancer were assigned placebo or GBE before and after treatment (120 mg/day for a month). The treated group did not have a significant increase in lymphocytes and ginkgo was found to be protective from possible oxidative and genotoxic damage from the treatment (Dardano et al 2012).

### Asthma

Ginkgo shows promise as a treatment for asthma, according to studies using a mouse model of asthma (Babayigit et al 2008) and two clinical studies (Li et al 1997, Tang et al 2007b). Ginkgo significantly reduced airway hyperreactivity and improved clinical symptoms and pulmonary function in asthmatic patients in a placebo-controlled study (Li et al 1997). Platelet-activating factor inhibitor, antioxidant and anti-inflammatory activities are likely to be involved.

Reduced airway inflammation was reported in another study of 75 asthma patients, which compared the effects of fluticasone propionate with fluticasone propionate plus ginkgo (Tang et al 2007b). The addition of ginkgo to treatment resulted in a significant decrease in the infiltration of inflammatory cells such as eosinophils and lymphocytes in the asthmatic airway and relieved airway inflammation.

### Cancer prevention

A 2006 review proposes that *G. biloba* should be more widely used as a safe preventive agent for reducing cancer incidence. This recommendation is based on results from numerous in vitro and experimental studies showing that ginkgo affects many factors associated with the incidence and mortality of cancer (Eli & Fasciano 2006). However, a more recent secondary analysis of the Ginkgo Evaluation of Memory study, which is the largest placebo-controlled RCT of ginkgo, evaluated cancer hospitalisations during the 6.1-year follow-up and found no evidence of reduced incidence of cancer. The intervention of 120 mg twice daily of ginkgo extract (EGb 761) was chosen for cognition and not cancer

prevention, and the authors also suggested that the follow-up may have been too short to detect benefits with regard to cancer prevention (Biggs et al 2010).

### Cardiac surgery support

An RCT of 20 patients undergoing cardiac surgery found the GBE group (0.5 mg/kg Ginaton) increased the production of plasma VEGF, offering some myocardial protection in the perioperative period (Deng et al 2009). Another study with 80 CAD patients found that the GBE group caused an increase in coronary artery blood flow (Wu et al 2008a).

### Diabetic nephropathy

Ginkgo had a beneficial effect on vascular endothelial function in patients with early-stage diabetic nephropathy, according to an RCT of 64 patients (Li et al 2009). The known pharmacological mechanisms of ginkgo provide some basis for this finding.

### Migraine headache

Ginkgolide B demonstrates anti-inflammatory activity and a reduction of the excitatory effect of glutamate in the central nervous system, which may be of benefit in the treatment of migraine headache with and without aura. Initial studies have been undertaken, often with a combination of nutrients, showing promise in the prevention of migraine.

An open study of 50 women with a history of migraine with typical aura used a product (Migrasoll) containing ginkgolide B from *G. biloba* (60 mg) with coenzyme Q10 (11 mg) and vitamin B<sub>2</sub> (8.7 mg) for 4 months, whereby migraine frequency and duration were reduced, an effect seen after the first 2 months and further enhanced after taking the product for 4 months (D'Andrea et al 2009). Another open-label study with 119 school-aged volunteers with a history of migraine found that treatment with a combination product (ginkgolide B, coenzyme Q10, riboflavin and magnesium) taken twice daily as a prophylactic therapy for 3 months significantly reduced migraine frequency (Esposito & Carotenuto 2011). A similar combination of nutrients with ginkgolide B (80 mg), coenzyme Q10 (20 mg), vitamin B<sub>2</sub> (1.6 mg) and magnesium (300 mg) was given to 30 children twice a day for 3 months. In this open-label prospective trial the children were followed up over a year; combination treatment was shown to be an effective preventive treatment in significantly reducing migraine frequency and reducing analgesic medication after 3 months and at 1-year follow-up (Usai et al 2011).

### Multiple sclerosis

MS is a chronic demyelinating neurological disease afflicting young and middle-aged adults, resulting in problems with coordination, strength, cognition, affect and sensation. Several clinical studies have investigated whether ginkgo treatment may help

reduce some of these impairments, generally producing disappointing results.

Johnson et al (2006) conducted a randomised, double-blind study which compared the effects of ginkgo (EGb 761: 240 mg/day) to placebo on depression, anxiety, fatigue, symptom severity and functional performance using validated measures for each outcome. Twenty-two people with MS were enrolled in the study. Significantly, more people administered ginkgo showed improvement on four or more measures, with improvements associated with significantly larger effect sizes on measures of fatigue, symptom severity and functionality. The ginkgo group also exhibited less fatigue at follow-up compared with the placebo group and treatment was well tolerated, with no side effects or adverse effects reported.

The cognitive function of people with MS did not significantly improve after 12 weeks of treatment with GBE (120 mg twice a day), according to a randomised, double-blind, placebo-controlled trial (Lovera et al 2007). However, a treatment effect trend, limited to the Stroop test, indicated that ginkgo treatment may have an effect on cognitive domains assessed by this test, such as susceptibility to interference and mental flexibility. People with greater cognitive impairment at the start of the study experienced more improvement with treatment than higher-functioning people. No serious drug-related side effects occurred. A Cochrane systematic review of treatment for memory disorders in MS patients only found the 2007 Lovera study worthy of inclusion and confirmed *G. biloba* was not effective as an intervention in this group (He et al 2011). The same author, Lovera, repeated his earlier study with a RCT of 120 subjects with MS and *G. biloba* (120 mg twice daily) over 12 weeks and confirmed that there were no improvements in cognitive performance (Lovera et al 2012).

### Parkinson's disease

There is great interest in the application of safe substances, such as *G. biloba*, in neurodegenerative diseases such as Parkinson's disease because of their neuroprotective and mitochondrial protective effects. Currently, investigation with ginkgo is limited to animal studies of experimentally induced Parkinson's disease, which have shown it to afford some protection against neuronal loss (Ahmad et al 2005, Kim et al 2004) and neuronal damage (Rojas et al 2012).

### Schizophrenia — adjunctive treatment

*G. biloba* given as an adjunct to the atypical antipsychotic medicine clozapine in the treatment of refractory schizophrenia was shown to enhance drug effects on negative symptoms according to a placebo-controlled study involving 42 patients with chronic, treatment-resistant schizophrenia (Doruk et al 2008). Ginkgo was used at a dose of 120 mg/day for 12 weeks. This study has been further validated by a review and meta-analysis conducted in 2010

which included six studies of 466 patients taking ginkgo and 362 people taking placebo. When prescribed in combination with antipsychotic medication, *G. biloba* resulted in statistically significant positive effects with symptoms of chronic schizophrenia (Singh et al 2010). Since the publication of the meta-analysis a further randomised double-blind, placebo-controlled trial found benefit of using GBE (EGb 761) for reducing symptoms of tardive dyskinesia in schizophrenia patients. This trial recruited 157 in a psychiatric hospital in China and the treatment arm were given 240 mg/day of *G. biloba* or placebo for 12 weeks. The authors hypothesise that the improvement may be due to the antioxidant activity of this herb (Zhang et al 2011, 2012a).

### Tardive syndromes — including tardive dyskinesias

The American Academy of Neurology in 2013 conducted a broad literature review to make evidence-based recommendations regarding management of tardive syndromes, including tardive dyskinesias (Bhidayasiri et al 2013). They came to the conclusion that clonazepam probably improves tardive dyskinesias and ginkgo biloba probably improves tardive syndromes (both level B) and both should be considered as treatment.

### DOSAGE RANGE

The recommended dose varies, depending on indication and condition treated.

#### General guide

- Dried herb: 9–10 g/day.
- 120–240 mg of a 50:1 standardised extract daily in divided doses (40 mg extract is equivalent to 1.4–2.7 g leaves).
- Fluid extract (1:1): 0.5 mL three times daily.

#### According to clinical studies

- Asthma: 40 mg three times daily.
- Dementia and memory impairment: 120–240 mg standardised extract daily in divided doses.
- Generalised anxiety disorder: 240–480 mg daily.
- Intermittent claudication, vertigo: 120–320 mg standardised extract daily in divided doses.
- Normal-tension glaucoma: 120–160 mg standardised extract daily.
- MS — to improve energy levels, cognitive function and mood: 120 mg twice daily.
- PMS: 80 mg twice daily, starting on the 16th day of the menstrual cycle until the 5th day of the next cycle.
- Prevention of altitude sickness: 160 mg standardised extract daily, starting 5 days prior to ascent or ginkgo (80 mg per dose) every 12 hours, starting 24 hours before ascending and continuing throughout stay at high altitude.
- Schizophrenia: as an adjunct to clozapine in refractory cases: 120–240 mg daily.

- Raynaud's syndrome: 240–360 mg/day divided into three doses.
- Sexual dysfunction associated with antidepressant drugs: 200 mg standardised extract daily.
- Sexual dysfunction (women): 300 mg daily in conjunction with sex therapy.
- Vitiligo: 120 mg standardised extract daily.

Although some studies report positive effects after 4–6 weeks' continual use, a trial of at least 12 weeks is recommended in chronic conditions.

### ADVERSE REACTIONS

In most placebo-controlled studies, there is no difference between the side effect incidence with ginkgo and placebo. Standardised ginkgo leaf extracts have been used safely in trials lasting from several weeks to up to 6 years. In a few cases (less than 0.001%), gastrointestinal upset, headaches and dizziness were reported. Ginkgo does not appear to alter heart rate and blood pressure, change cholesterol and triglyceride levels or increase intraocular pressure in clinical studies (Chung et al 1999).

A 2011 systematic review of bleeding associated with *G. biloba* therapy found no higher bleeding risk associated with standardised GBE in a meta-analysis of 18 RCTs (Kellermann & Kloft 2011); however, rare case reports of subarachnoid haemorrhage, subdural haematoma, intracerebral haemorrhage, subphrenic haematoma, vitreous haemorrhage and postoperative bleeding have been reported.

Crude ginkgo plant parts that may contain concentrations of 5 ppm of the toxic ginkgolic acid constituents should be avoided, as they can induce severe allergic reactions.

### SIGNIFICANT INTERACTIONS

A small clinical study suggests that *G. biloba* inhibits P-gp, so caution is advised when taking GBE and P-gp substrates together, as drug doses may need to be adjusted. Various cytochromes have been evaluated, and drugs metabolised this way seem to have little risk of herb-drug interactions with *G. biloba* at doses of 240 mg/day or less (Gurley et al 2012).

#### Adriamycin

Studies with an animal model indicate that ginkgo extract EGb 761 reduces the hyperlipidaemia and proteinuria associated with Adriamycin-induced nephropathy, which might be beneficial to enhance the therapeutic index of Adriamycin (Abd-Allah & Mariee 2007). Clinical trials have not been conducted to confirm the activity.

#### Antidepressant drugs

Ginkgo may reduce the sexual dysfunction side effects of these drugs and improve sleep continuity; however, results from clinical studies are mixed — possible beneficial interaction.

**Clinical note — Does Ginkgo biloba cause significant bleeding and does it interact with warfarin?**

The current body of evidence casts doubt on the clinical significance of the proposed interaction between warfarin and ginkgo, revealing that there is little evidence from controlled studies to demonstrate significant platelet inhibition, bleeding or changes to international normalised ratio (INR) with use of ginkgo (especially EGb 761 or phytochemically similar extracts).

Several clinical trials have been published in peer-reviewed journals which demonstrate that *G. biloba* does not have a significant effect on platelet function, two studies showing no interaction with warfarin, one study showing no interaction with aspirin and a further study showing no interaction with clopidogrel (Aruna & Naidu 2007, Bal Dit et al 2003, Beckert et al 2007, Carlson et al 2007, Engelsen et al 2003, Gardner et al 2007, Jiang et al 2005, Kohler et al 2004). Studies have included young healthy volunteers and older adults, using doses up to 480 mg/day of ginkgo and time frames up to 4 months.

The first controlled study was published in 2003. Bal Dit et al conducted a double-blind, randomised, placebo-controlled study of 32 young healthy volunteers to evaluate the effect of three doses of GBE (120, 240 and 480 mg/day for 14 days) on haemostasis, coagulation and fibrinolysis (Bal Dit et al 2003). This escalating dose study found no effect on platelet function or coagulation for any dose tested. A year later, results from a larger randomised, placebo-controlled, crossover study that produced similar results were published (Kohler et al 2004). The study by Kohler et al investigated the effects of ginkgo (2 × 120 mg/day EGb 761) on 29 different coagulation and bleeding parameters. Once again, no evidence of inhibition of blood coagulation and platelet aggregation was detected. In Australia, Jiang et al (2005) investigated the interaction between warfarin and *G. biloba* using a randomised, cross-over study design. The study of 12 healthy males found no evidence that INR or platelet aggregation was affected by

*G. biloba*. Engelsen et al (2003) also found no evidence of an interaction between *G. biloba* and warfarin under double-blind, placebo-controlled trial conditions. The study involved patients stable on long-term warfarin and reported no changes to INR values.

In 2007, four more studies were published. Carlson et al (2007) conducted a study of 90 older adults (65–84 years) who were randomly assigned to placebo or a *G. biloba*-based supplement (160 mg/day) for 4 months. No evidence of alteration to platelet function was seen at this dose. Beckert et al (2007) conducted a smaller trial of 10 volunteers who were administered ginkgo for 2 weeks, after which in vivo platelet function was quantified using the PFA-100 assay. The study used aspirin as a control agent and found that platelet function was not affected by *G. biloba*, but was markedly inhibited by the administration of aspirin. No clinically or statistically significant differences were seen in a randomised, double-blind, placebo-controlled trial, which investigated the effects of *G. biloba* (EGb 761, 300 mg/day) on several measures of platelet aggregation among 55 older adults (age 69 ± 10 years) also consuming 325 mg/day aspirin (Gardner et al 2007). Reports of bleeding or bruising were infrequent and similar for both study groups. A study of 10 healthy volunteers investigated the effects of two different doses of *G. biloba* (120 mg and 240 mg) taken together with clopidogrel (75 mg) (Aruna & Naidu 2007). Platelet inhibition with the combination of *G. biloba* and clopidogrel was not statistically significant, compared with individual doses of drugs. Finally, a 2011 randomised, double-blind, placebo-controlled, two-way cross-over trial was conducted on 12 healthy volunteers for 5 weeks. It was found that there was no effect on clotting process alone and *G. biloba* had limited effects on the pharmacokinetics and no effect on the pharmacodynamics of single-dose warfarin in health volunteers (Zhou & Zeng 2011).

**Bleomycin**

Studies with an animal model indicate that ginkgo extract EGb 761 reduces oxidative stress induced by bleomycin. This may improve drug tolerance; however, clinical studies have not yet been conducted to test this further (Erdogan et al 2006).

**Cholinergic drugs**

Cholinergic activity has been identified for ginkgo; therefore, combined use may theoretically increase drug activity — observe patients using this combination, although the effects may be beneficial when used under supervision.

**Cilostazol**

Used for intermittent claudication with peripheral arterial disease. Adjunctive use with *G. biloba* may produce additional benefits based on in vivo studies (Jung et al 2012) — observe.

**Cisplatin**

As a herb with significant antioxidant activity, ginkgo has also been employed as a means of reducing the nephrotoxic effects of cisplatin, a use supported by two in vivo studies (Gulec et al 2006, Ozturk et al 2004). Other researchers using animal models have indicated that ginkgo may protect against cisplatin-induced ototoxicity (Huang et al

2007). Clinical trials are required to confirm significance — adjunctive use may be beneficial when used under professional supervision.

### Clozapine

Ginkgo may enhance the effects of clozapine on negative affect in refractory schizophrenic patients, according to a placebo-controlled study (Doruk et al 2008) — beneficial interaction.

### Doxorubicin

In vivo research suggests that ginkgo can prevent doxorubicin-induced cardiotoxicity, suggesting a potentially beneficial interaction, although no human studies are available to confirm clinical significance (Naidu et al 2002).

### Haloperidol

In three clinical trials, the effectiveness of haloperidol was enhanced when co-administered with 360 mg of ginkgo daily (Chavez et al 2006) — beneficial interaction under supervision.

### Platelet inhibitor drugs

Due to its platelet-activating factor antagonist activity, *G. biloba* may theoretically enhance the effects of these drugs and increase the risk of bruising or bleeding; however, evidence from recent clinical trials and a systematic review has cast doubt on the clinical significance of this activity (Diamond & Bailey 2013, Kim et al 2010, Ryu et al 2009) — observe.

### Valproate, Dilantin, Depakote

There is a report of 2 patients using valproate who experienced seizures with ginkgo use (Chavez et al 2006). There is also a report of a patient taking Dilantin, Depakote and ginkgo, together with other herbal medicines, who suffered a fatal breakthrough seizure, with no evidence of non-compliance with anticonvulsant medications (Kupiec & Raj 2005). The autopsy report revealed subtherapeutic serum levels for both anticonvulsants, Depakote and Dilantin; however, it is uncertain whether effects can be attributed to ginkgo — observe patient taking ginkgo with these medicines.

### Warfarin

Theoretically, ginkgo may increase bleeding risk when used together with warfarin; however, evidence from controlled clinical studies does not support this conclusion and has failed to identify any clinically significant pharmacodynamic or pharmacokinetic interaction. This conclusion is supported by a systematic review (Bone 2008) — observe.

### Cerebral haemorrhage and epilepsy

Rare case reports have suggested that ginkgo should be used with caution in people with known risk factors for cerebral haemorrhage and epilepsy until further investigation can clarify its safety (Benjamin et al 2001, Granger 2001, Vale 1998).

## ❓ CONTRAINDICATIONS AND PRECAUTIONS

If unusual bleeding or bruising occurs, stop use immediately. Although new clinical evidence suggests that *G. biloba* does not affect clotting times, it may be prudent to suspend use for 1 week prior to major surgery in at-risk populations.

## ⚠️ PREGNANCY USE

Insufficient reliable evidence in humans to determine safety. In clinical usage there would be no adverse effects expected (Bone 2003).

G

## Practice points/Patient counselling

- *G. biloba* is a complex herb that contains many different active constituents and works by means of multiple mechanisms. Therefore, it has applications in many varied conditions.
- Oral ginkgo extract improves cognitive function in people with mild to moderate cognitive impairment or those people with dementia with neuropsychiatric features, but it is less successful in people with normal cognitive function.
- Long-term use does not protect against the development of dementia.
- It may be an effective treatment in peripheral vascular diseases such as intermittent claudication; however, study findings are not always consistent. Due to the herb's inherent safety, a therapeutic trial may be useful in practice to determine an individual's response.
- Some positive evidence exists for PMS, sudden deafness, tardive syndromes, preventing altitude sickness, ischaemic stroke, SAD and vertigo.
- Largely based on the herb's physiological actions, ginkgo is also used to treat chilblains and haemorrhoids, and prevent macular degeneration, glaucoma, sexual dysfunction, impotence, allergies and asthma, and improve wellbeing.
- The form of ginkgo most often tested and used is a preparation known as EGb 761, which is standardised to 24% ginkgo flavonol glycosides and 6% terpene lactones.
- Overall, *G. biloba* is a very safe herb and is extremely well tolerated.

## ❗ PATIENTS' FAQs

### What will this herb do for me?

Ginkgo is a very popular herbal treatment that increases peripheral circulation, beneficially influences brain chemicals, protects nerve cells from damage and may stimulate immune function and reduce inflammation. Scientific evidence has shown that it may improve cognitive function in people with mild to moderate cognitive impairment when

used long-term in sufficient dosage, but it is less successful in people with normal function. It may also improve some aspects of memory in younger people when used short-term. Ginkgo may improve symptoms of intermittent claudication and be useful in treating chilblains, PMS and vitiligo, preventing altitude sickness, vertigo and SAD and possibly sexual dysfunction such as impotence. If taken long-term, it does not protect against the development of dementia in the future.

#### **When will it start to work?**

This will depend on the condition treated and the dose used. Generally, *G. biloba* is a slow-acting herb that can take anywhere from 4 weeks to 6 months to exert maximal effects.

#### **Are there any safety issues?**

Ginkgo has been extensively studied and appears to be extremely safe with virtually no side effects in healthy people. Some contraindications and interactions are possible, so it is recommended that it should be taken under professional supervision.

# Ginseng — Korean

G

**HISTORICAL NOTE** *Gin* refers to man and *seng* to essence in Chinese, whereas *Panax* is derived from the Greek word *pan* (all) and *akos* (cure), referring to its use as a cure-all. Ginseng is a slow-growing perennial herb, with fleshy roots native to Korea and China, and has been used as a herbal remedy in eastern Asia for thousands of years. It is considered to be the most potent Qi or energy tonic in traditional Chinese medicine (TCM). Modern indications include low vitality, poor immunity, cancer, cholesterol and cardiovascular disease, metabolic dysfunction and enhancement of physical performance and sexual function (Nagappan et al 2012). However, a systematic review of randomised controlled trials (RCTs) found that the efficacy of ginseng root extract could not be established beyond doubt for any of these indications (Coon & Ernst 2002). While many more clinical trials have been conducted in the past decade, and understanding of the active constituents has progressed markedly, no update to this systematic review, or any other, has been performed.

## COMMON NAME

Korean ginseng

## OTHER NAMES

Ren shen (Mandarin), red ginseng, white ginseng

## BOTANICAL NAME/FAMILY

*Panax ginseng* C.A. Meyer (family Araliaceae)

It should be differentiated from *P. aquifolium* (American ginseng), *P. notoginseng* (Tien chi, pseudoginseng), *Eleutherococcus senticosus* (Siberian ginseng), *Withania somnifera* (Indian Ginseng) and other ginsengs.

## PLANT PART USED

Main and lateral roots. The smaller root hairs are considered an inferior source. There are two types of preparations produced from ginseng: white ginseng, which is prepared by drying the raw herb, and red ginseng, prepared by steaming before drying. Cultivated ginseng differs from wild ginseng, and plants from different countries or regions may also differ greatly. Processing of the crude herb to produce red ginseng appears to increase its potency. Steaming has been shown to alter the composition of the ginsenosides; for example, steaming produces the active 20(S)-ginsenoside-Rg(3) (Matsuda et al 2003) and makes certain ginsenosides more cytotoxic (Park IH et al 2002). Kim et al (2010) suggest that two rounds of heating is optimal for producing Korean red ginseng (KRG) with the highest amount of arginyl-fructose (AF) and arginyl-fructose-glucose (AFG), which contribute to some of the antioxidant effects of KRG. This effect was specific to the hydroxyl radical scavenging capacity of KRG. Hydroxyl radicals are one of the most harmful radical oxygen species (ROS) found in the body. This effect of hydroxyl-preventing capacity was attributed to the metal-chelating capacity of AF and AFG. On the other hand, after seven rounds of heating, thus reducing the concentration, Kim et al (2010) found that the KRG extract decreased the extent of intracellular oxidative stress due to peroxy

radicals. This peroxy radical scavenging ability of KRG extract is thought to be due to total phenolic compound content providing the ability of bioactive substances to permeate the cell membrane. Studies have also found different therapeutic effects for different concentrations of ginsenosides in the rootlets versus body of the KRG. This indicates that elucidation from clinical trials as to dose range of therapeutics is required. De Souza et al (2011) found that extracts from the KRG body, although containing lower concentrations of ginsenosides, had a superior postprandial blood glucose lowering effect than the rootlets, which had no significant effect on glucose levels in diabetics.

The British Herbal Pharmacopoeia (1983) stipulates that ginseng should contain not less than 20% solids (70% ethanol). The German Pharmacopoeia requires not less than 1.5% total ginsenosides, calculated as ginsenoside Rg 1.

Chewing gums containing ginseng saponins have also been developed and demonstrate therapeutic effects in some trials (Ding et al 2004).

## CHEMICAL COMPONENTS

The most characteristic compounds in the ginseng roots are the ginsenosides, and most biological effects have been ascribed to these compounds. The ginsenosides are dammarane saponins and can be divided into two classes: the protopanaxatriol class consisting primarily of Rg1, Rg2, Rf and Re and the protopanaxadiol class consisting primarily of Rc, Rd, Rb1 and Rb2 (Ho et al 2012). Ginseng also contains other saponins, polysaccharides, amino acids (in particular glutamine and arginine) (Kuo et al 2003), essential oils and other compounds. Three sesquiterpene hydrocarbons have been isolated from the essential oil: panaxene, panaginsene and ginsinsene (Richter et al 2005). The major component of *Panax ginseng* is ginsenoside Rb1, otherwise the major component of KRG is Rg3 (Park et al 2012).

Ginsenosides Rh1, Rh2 and Rg3 are obtained from red ginseng as artifacts produced during steaming

and drying, which suggests the transformation of chemical and physiological properties and involves ginsenosides, peptides, polysaccharides, polyacetylenic alcohols and fatty acids (Park et al 2012). It is likely that ginsenoside is actually a prodrug that is converted in the body by intestinal bacterial deglycosylation and fatty acid esterification into an active metabolite (Hasegawa 2004). Rg3 has been shown to be metabolised to ginsenoside Rh2 by intestinal microflora. Jin et al (2012) have shown that the bioactive novel saponin metabolite, IH-901 (or compound K), is formed by intestinal flora, and fermentation by intestinal bacteria and enzymatic digestion of ginsenosides in vivo and in vitro produces its pharmacological effects. The authors suggest that fermentation in vitro may enhance its pharmacokinetic properties for medicinal purposes. Ho et al (2012) suggest that the metabolite compound K is then absorbed from the gastrointestinal tract, and has a variety of pharmacological activities, including antitumour, antidiabetic, anti-inflammatory and anti-allergic effects.

Therefore, extrapolation from in vitro studies or studies in which ginseng or isolated constituents were given by injection must be made very cautiously.

Commercial ginseng preparations are variable in quality. An analysis of 50 products sold in 11 countries showed that there was a large variation in the concentration of ginsenosides (from 1.9 to 9.0%). Some products were even found to be void of any specific ginsenosides. Some ginseng products have also been discovered to be contaminated with ephedrine. Therefore, it is essential that only quality ginseng products be used (Cui et al 1994). Although the root hairs have a higher level of total ginsenosides than the main root, the main and lateral roots are the preferred medicinal parts. In all probability, it is the ratio of ginsenosides that is important and other important compounds are also active.

## MAIN ACTIONS

### Adaptogen

The pharmacological effects of ginseng are many and varied, contributing to its reputation as a potent adaptogen. The adrenal gland and the pituitary gland are both known to have an effect on the body's ability to respond to stress and alter work capacity (Filaretov et al 1988), and ginseng is thought to profoundly influence the hypothalamic-pituitary-adrenal axis (Kim DH et al 2003). The active metabolites of protopanaxadiol and protopanaxatriol saponins reduce acetylcholine-induced catecholamine secretion in animal models (Tachikawa & Kudo 2004, Tachikawa et al 2003), and this may help to explain the purported antistress effects of ginseng.

Ginseng has been shown in numerous animal experiments to increase resistance to a wide variety of chemical, physical and biological stressors. Ginseng extract or its isolated constituents have

been shown to prevent immunosuppression induced by cold water swim stress (Luo et al 1993) and to counter stress-induced changes from heat stress (Yuan 1989), food deprivation (Lee et al 1990), electroshock (Banerjee & Izquierdo 1982) and radiation exposure (Takeda et al 1981). As there are more than 1500 studies on ginseng and its constituents, it is outside the scope of this monograph to include all studies, so we have attempted to include those studies most relevant to the oral use of ginseng.

Animal models suggest that ginseng is most useful for chronic rather than acute stress, significantly reducing elevated scores on ulcer index, adrenal gland weight, plasma glucose, triglycerides, creatine kinase activity and serum corticosterone during chronic stress (Rai et al 2003). Oxidative stress resulting from the excessive exposure to reactive oxygen species (ROS) is generated in many stressful situations and induces cell death by either apoptosis or necrosis. Ginsenosides, the main pharmacological constituents of ginseng, are reported to have anti-neoplastic, anti-stress, anti-inflammatory, antioxidant and hepatoprotective activities (Park et al 2012).

(Refer to the *Siberian ginseng* monograph for more information about adaptogens and allostasis.)

### Cardiovascular effects

According to in vitro and animal studies, ginseng may benefit the cardiovascular system 'through diverse mechanisms, including antioxidant, modifying vasomotor function, reducing platelet adhesion, influencing ion channels, altering autonomic neurotransmitter release, improving lipid profiles' and glycaemic control (Zhou et al 2004).

### Antihypertensive

Red ginseng has been used as an antihypertensive agent in Korea, but its clinical effect is unclear despite several in vivo and in vitro experimental studies. Data suggest that the antihypertensive effects may be partly attributed to an angiotensin-converting enzyme (ACE) inhibitory effect demonstrated by *P. ginseng* extract in vitro (Persson et al 2006). These effects were additive to the traditional ACE inhibitor enalapril.

A study of isolated muscle preparations of animal heart and aorta with an alcohol-based extract of ginseng suggested that the hypotensive effect of ginseng is associated with a direct inhibition of myocardial contractility due to a reduction of calcium ion influx into cardiac cells, as well as the inhibition of catecholamine-induced contractility of vascular smooth muscles (Hah et al 1978). Nagapan et al (2012) suggest that ginsenoside Rb1 releases nitric oxide and decreases intracellular-free calcium in cardiac myocytes.

In a prospective, randomised, double-blind, placebo-controlled study of 30 healthy adults, 200 mg ginseng extract given for 28 days was found to increase the QTc interval and decrease diastolic blood pressure 2 hours after ingestion on the first day of therapy. These changes, however, were

not thought to be clinically significant (Caron et al 2002).

Further, in a randomised controlled trial of Korean red ginseng (KRG) versus placebo on arterial stiffness in subjects with hypertension and taking antihypertensive medication, no difference was found between the groups in terms of arterial stiffness after 3 months of treatment. Blood pressure readings for both groups were significantly reduced in the study period (Rhee et al 2011).

Conversely, a study by Chen et al (2012) suggests that the reported effect of increasing blood pressure may provide KRG with a haemodynamic stabilising capacity in patients undergoing haemodialysis who commonly experience intradialytic hypotension (IDH). They found that chewing 3.5g KRG at each haemodialysis session over a 4-week period significantly reduced the degree of BP drop and the frequency of symptomatic IDH during haemodialysis. Activation of vasoconstrictors (endothelin-1 and angiotensin II) during haemodialysis was found, and the authors concluded that chewing KRG could be an effective adjunct treatment for IDH.

#### Antiplatelet

Although reports from in vitro and in vivo assays claim that *P. ginseng* is not one of the herbs that contributes to the antiplatelet effects of a Korean combination formula known as Dae-Jo-Hwan (Chang et al 2005), a number of studies have found that several ginsenosides inhibit platelet aggregation. Panaxynol has been shown to inhibit platelet aggregation induced by adenosine diphosphate, collagen and arachidonic acid. Panaxynol and ginsenosides Ro, Rg and Rg2 inhibit rabbit platelets, while panaxynol prevented platelet aggregation and thromboxane formation (Kuo et al 1990).

#### Antihyperlipidaemic

Ginsenoside Rb1 has been shown to lower triglyceride and cholesterol levels via cyclic adenosine monophosphate (cAMP) production in the rat liver (Park KH et al 2002). *P. ginseng* extract (6 g/day) for 8 weeks resulted in a reduction in serum total cholesterol, triglyceride, low density lipoprotein (LDL) and plasma malondialdehyde levels and an increase in high density lipoprotein (HDL) (Kim & Park 2003) in eight males. Ginseng has also been reported to decrease hepatic cholesterol and triglyceride levels in rats, indicating a potential use of ginseng in the treatment of fatty liver (Yamamoto et al 1983).

#### Other cardiovascular effects

Ginsenoside Rb2 has been shown to enhance the fibrinolytic activity of bovine aortic endothelial cells (Liu 2003). In animal studies, ginseng inhibits cardiomyocyte apoptosis induced by ischaemia and reperfusion injury (Zeng et al 2004) and the crude saponins have been shown to reduce body weight, food intake and fat content in rats fed a high-fat diet

(Kim J et al 2005). In vitro studies report that an extract of ginseng fruit can promote vascular endothelial cell proliferation, migration, DNA synthesis and vascular endothelial growth factor mRNA expression, suggesting an effect on the genesis and development of new vessels in the ischaemic myocardium (Lei et al 2008).

### Gastrointestinal

#### Hepatorestorative

Oral administration of Korean red ginseng (250 and 500 mg/kg) on liver regeneration has been investigated in 15 dogs with partial hepatectomy. All haematological values except leucocyte counts were within normal ranges for 3 days postoperatively. The levels of aspartate transaminase (AST) and alanine aminotransferase (ALT) in the ginseng groups were significantly decreased compared with those in the control group ( $P < 0.05$ ). The numbers of degenerative cells and areas of connective tissue were significantly decreased in the livers of the dogs treated with ginseng ( $P < 0.01$ ) (Kwon et al 2003).

In a recent study, Korean red ginseng (KRG) and its primary ginsenosides (Rg3 and Rh2) were examined for their effect on alcohol-induced oxidative injury to mouse hepatocytes (TIB-73). Hepatocytic injury was measured by: cell viability; lactate dehydrogenase (LDL); aspartate amino-transferase (AST); reactive oxygen species (ROS); and mitochondria membrane potential (MMP) in hepatocytes. The authors report that ROS can induce cell death, and induce 'MAPK' activation, by which hepatocytes mediate reaction to oxidative stress. This family of serine/threonine kinases is central to integrating signal transduction processes generating various cell responses. Chronic activation is reported to lead to cellular growth arrest (Park et al 2012).

Lee and Shukla (2007) found that an increase in ROS from alcohol exposure leads to injury and apoptosis in hepatocytes by mediating several signal transduction pathways. The study by Park et al (2012) found that KRG, Rg3 or Rh2 inhibited the alcohol-induced apoptotic changes. Alcohol was found to induce cell death in the mouse hepatocytes by an increase in membrane damage and intracellular ROS and by decreasing  $Mg^{2+}$ . Treatment with KRG, Rg3 or Rh2 significantly attenuated the alcohol-induced decrease in cell viability; recovered the decrease in cell numbers; and attenuated the increase in LDH release, AST protein and ROS. A decrease in cellular concentrations of magnesium ( $Mg^{2+}$ ), indicating cytotoxicity, was also inhibited by exposure to KRG and its primary ginsenosides. Therefore, the authors concluded that KRG and its primary constituents exert a protective effect on alcohol-induced hepatocytic injury.

#### Anti-ulcerative

Ginseng has been shown in several studies to protect against ulceration. Among the hexane, chloroform, butanol and water fractions, the butanol fraction of

a ginseng extract has been shown to be the most potent inhibitor of HCl-induced gastric lesions and ulcers induced by aspirin, acetic acid and Shay (ulcer induced by pylorus ligation). The butanol fraction showed significant increase in mucin secretion, and inhibited malondialdehyde and  $H^+/K^+$  ATPase activity in the stomach. These results indicate that the effectiveness of ginseng on gastric damage might be related to inhibition of acid secretion, increased mucin secretion and antioxidant properties (Jeong 2002). Furthermore, inhibition of *Helicobacter pylori*-stimulated 5-lipoxygenase activity may have a beneficial effect on *H. pylori*-associated gastric inflammation (Park et al 2007). Results from a mouse-model study investigating the effects of Korean red ginseng (KRG) and Korean red ginseng containing drug (KRGCD) found that both KRG and KRGCD significantly decreased ethanol- and indomethacin-induced gastric ulcer, and increased gastric mucosal blood flow. These preparations were significantly protective against gastric ulcers in a dose-dependent manner (100 mg/kg and 300 mg/kg being significantly and relatively effective); however, only KRGCD demonstrated a significant reduction in the measures of oxidative stress, shown by attenuation of lipid peroxidation in the gastric lining. This study suggests that KRG's anti-ulcer properties may lie primarily in its capacity to increase basal gastric mucosal blood flow, rather than via anti-oxidant activities (Oyagi et al 2010). The authors note that in previous studies (Chen et al 1997) that saponin fraction of KRG increased levels of nitric oxide in endothelial cells, in an endothelium-dependent manner, stating that vaso-relaxation may be the vehicle for effect.

### Effects on peristalsis

Ginseng root extract and its components, ginsenoside Rb1(4) and ginsenoside Rd(7), have been shown to significantly ameliorate chemically induced acceleration of small intestinal transit in vivo. The test results suggest that the protective mechanism involves both an inhibitory effect on the cholinergic nervous system and a direct suppressive effect on intestinal muscles (Hashimoto et al 2003).

### Anti-inflammatory

Both a crude and a standardised extract (G115) of ginseng varying in saponin concentrations have been found to protect against muscle fibre injury and inflammation after eccentric muscle contractions in rats on a treadmill. The oral ginseng extracts significantly reduced plasma creatine kinase levels by about 25% and lipid peroxidation by 15%. Certain markers of inflammation were also significantly reduced (Cabral de Oliveira et al 2001). In a later study, pretreatment with ginseng extract (3, 10, 100 or 500 mg/kg) administered orally for 3 months to male Wistar rats resulted in a 74% decrease in lipid peroxidation caused by eccentric exercise (Voces et al 2004).

The many and varied effects of ginseng may be partly associated with the inhibition of transcription factor nuclear factor (NF)- $\kappa$ B, which is pivotal in the regulation of inflammatory genes. Inhibition of NF- $\kappa$ B may reduce inflammation and protect cells against damage.

Topical application of several ginsenosides (Rb1, Rc, Re, Rg1, Rg3) significantly attenuated chemically-induced ear oedema in mice. The ginsenosides also suppressed expression of cyclooxygenase-2 (COX-2) and activation of NF- $\kappa$ B in the skin. Of the ginsenosides tested, Rg3 was found to be most effective (Surh et al 2002).

### Immunomodulation

The immunomodulatory effect of ginseng is based on the production of cytokines, activation of macrophages, stimulation of bone marrow cells and stimulation of inducible nitric oxide synthase (iNOS), which produces high levels of NO in response to activating signals from Th1-associated cytokines and plays an important role in cytotoxicity and cytostasis (growth inhibition) against many pathogenic microorganisms. In addition to its direct effector function, NO serves as a potent immunoregulatory factor.

Ginseng enhances interleukin (IL)-12 production and may therefore induce a stronger Th1 response, resulting in improved protection against infection from a variety of pathogens (Larsen et al 2004), including *Pseudomonas aeruginosa* lung infection in animal models (Song et al 2005). However, other studies suggest that it may also assist in the correction of Th1-dominant pathological disorders (Lee E-J et al 2004).

Ginseng polysaccharides have been shown to increase the cytotoxic activity of macrophages against melanoma cells, increase phagocytosis and induce the levels of cytokines, including tissue necrosis factor (TNF)- $\alpha$ , IL-1- $\beta$ , IL-6 and interferon- $\gamma$  in vitro (Shin et al 2002). Ginseng has been shown to be an immunomodulator and to enhance antitumour activity of macrophages in vitro (Song et al 2002). Ginseng has also been shown to significantly enhance natural killer (NK) function in an antibody-dependent cellular cytotoxicity of peripheral blood mononuclear cells in vitro (See et al 1997).

Incubation of macrophages with increasing amounts of an aqueous extract of ginseng showed a dose-dependent stimulation of iNOS. Polysaccharides isolated from ginseng showed strong stimulation of iNOS, whereas a triterpene-enriched fraction from an aqueous extract did not show any stimulation. As NO plays an important role in immune function, ginseng could modulate several aspects of host defence mechanisms due to stimulation of iNOS (Friedl et al 2001).

Ginseng promotes the production of granulocytes in the bone marrow (granulocytopenia). The ginseng saponins have been shown to directly and/or indirectly promote the stromal cells and

lymphocytes to produce human granulocyte-macrophage colony-stimulating factor (GM-CSF) and other cytokines, and induce bone marrow haematopoietic cells to express GM-CSF receptors, leading to a proliferation of human colony-forming units for granulocytes and macrophages in vitro (Wang et al 2003).

Ginseng polysaccharides have been shown to have potent antisepticaemic activity by stimulating macrophages and helping modulate the reaction against sepsis induced by *Staphylococcus aureus*. Ginseng polysaccharides have been shown to reduce the intracellular concentration of *S. aureus* in macrophages in infected animals by 50% compared with controls. Combination of the ginseng polysaccharides with vancomycin resulted in 100% survival of the animals, whereas only 67 or 50% of the animals survived, respectively, when treated with the ginseng polysaccharides or vancomycin alone (Lim DS et al 2002).

According to animal studies, long-term oral administration of ginseng extract may potentiate humoral immune response, but suppress spleen cell functions (Liou et al 2005).

### Anticancer

Oral intake of standardised *P. ginseng* extract demonstrates a dose-dependent (1, 3 or 10 mg/kg), chemoprotective and antimutagenic effect in animal studies (Panwar et al 2005), and ginsenoside Rg3 has recently been produced as an antiangiogenic anticarcinogenic drug in China (Shibata 2001).

Ho et al (2012) described the tumour-inhibitory activity of Rh2, which is reported to constrain cell growth in MCF-7 human breast cancer and SK-Hep1 hepatoma and can induce apoptosis in various cell lines (Oh et al 2005). Ginsenoside Rg3 has been reported to reduce the gelatinolytic activities of some matrix metalloproteinases (MMPs). MMPs degrade the extracellular matrix and are abundantly expressed in various malignant tumours and are critical in tumour metastasis. Inhibition of MMP activity is important in respect of preventing cell metastasis (Ho et al 2012). Other ginseng saponins with chemopreventive actions include Rb2, which may partly contribute to the inhibition of lung tumour metastasis by arresting tumour-associated angiogenesis (Yue et al 2006), and Rp1, derived from Rg5, whose anti-cancer effect is thought to be due to inhibition of tumour cell metastasis and viability, possibly through impeding adhesion and vessel formation (Kumar et al 2009).

Ho et al (2012) undertook a study to investigate the antimetastatic effect of KRG on human hepatoma as well as possible mechanisms of action. The authors found that the inhibitory effect of the water extract of KRG (WKRG), rather than ethanolic extract of KGR (EKRG), exerted a dose-dependent inhibitory effect on the invasion and motility, but not adhesion, of highly metastatic SK-Hep1 cells.

Jo et al (2013) demonstrated in their study that KRG extract alone was sufficient to induce growth

inhibition in acute promyelocytic leukaemia (APL), and describe a sequential molecular mechanism by which KRG extract operates to arrest growth in human APL. In a study by Park et al (2009), KRG extract treatment to U937 human leukaemia cells showed significant growth inhibition and induction of apoptosis in a concentration-dependent manner. The authors observed that KRG extract markedly inhibited COX-2 mRNA and protein expression in leukaemia cells, suggesting that inhibition of growth and induced apoptosis is consistent with COX-2 inhibition. Additionally, KRG progressively down-regulated the expression of human telomerase-related genes in U937 human leukaemia cells, which appeared to account for its anti-proliferative activity. Loss of COX-2 and telomerase activity may be a strategy for assessing the anti-tumour effects of KRG extract.

### Chemoprotection

Oral administration of red ginseng extracts (1% in diet for 40 weeks) significantly ( $P < 0.05$ ) suppressed spontaneous liver tumour formation in male mice. Oral white ginseng was also shown to suppress tumour promotion in vitro and in vivo (Nishino et al 2001).

Dietary administration of red ginseng in combination with 1,2-dimethylhydrazine suppresses colon carcinogenesis in rats (rats were fed 1% ginseng for 5 weeks). It is thought that the inhibition may be partly associated with inhibition of cell proliferation in the colonic mucosa (Fukushima et al 2001).

Oral administration of 50 mg/kg/day for 4 weeks of a ginseng intestinal metabolite has been shown to partially protect against doxorubicin-induced testicular toxicity in mice. The metabolite significantly ( $P < 0.01$ ) prevented decreases in body weight, spermatogenic activities, serum levels of lactate dehydrogenase and creatine phosphokinase induced by doxorubicin. It also significantly attenuated germ cell injuries (Kang et al 2002).

The methanol extract of red ginseng has been shown to attenuate the lipid peroxidation in rat brain and scavenge superoxides in differentiated human promyelocytic leukaemia (HL-60) cells. Topical application of the same extract, as well as purified ginsenoside Rg3, has been demonstrated to suppress skin tumour promotion in mice. Rg3 also suppresses COX, NF-kappaB and extracellular-regulated protein kinase, which are all involved in tumour promotion (Surh et al 2001).

Pretreatment with oral red ginseng extract significantly reduced the development of cancer from diethylnitrosamine-induced liver cancer nodules in rats (the developmental rate of liver cancer in the experimental group was 14.3% compared with 100% in the control group). When ginseng was given concomitantly with diethylnitrosamine, the hepatoma nodules were smaller than those of the control group, the structure of hepatic tissue was well preserved and the structure of hepatocytes was normal. Ginseng also prolonged the average life

span. These findings suggest benefits of ginseng in the prevention and treatment of liver cancer (Wu et al 2001).

#### Irradiation protection

Ginsenosides and specifically panaxadiol have been shown to have radioprotective effects in mice irradiated with high-dose and low-dose gamma radiation. Jejunal crypts were protected by pretreatment with extract of whole ginseng (50 mg/kg body weight intraperitoneally at 12 and 36 hours before irradiation,  $P < 0.005$ ). Extract of whole ginseng ( $P < 0.005$ ), total saponin ( $P < 0.01$ ) or panaxadiol ( $P < 0.05$ ) administration before irradiation (50 mg/kg body weight IP at 12 and 36 hours before irradiation) resulted in an increase in the formation of the endogenous spleen colony. The frequency of radiation-induced apoptosis in the intestinal crypt cells was also reduced by pretreatment with extract of whole ginseng, total saponin and panaxadiol (Kim DH et al 2003).

These radioprotective effects are partly associated with the immunomodulatory effect of ginseng. Ginsan, a purified polysaccharide isolated from ginseng, has been shown to have a mitogenic activity, induce lymphokine-activated killer cells and increase levels of several cytokines. Ginsan reduced mutagenicity in a dose-dependent manner when applied to rats 30 minutes before or 15 minutes after 1.5 Gy of gamma irradiation. The radioprotective effect of ginsan has been partly attributed to a reduction in radiation-induced genotoxicity (Ivanova et al 2006). Ginsan has also been found to increase the number of bone marrow cells, spleen cells, granulocyte-macrophage colony-forming cells and circulating neutrophils, lymphocytes and platelets significantly in irradiated mice (Song et al 2003).

One of the causes of radiation damage is lipid peroxidation, which alters lysosomal membrane permeability, leading to the release of hydrolytic enzymes. Ginseng has been shown to markedly inhibit lipid peroxidation and protect against radiation damage in testes of mice (Kumar et al 2003).

Antitumour, antiproliferative, antimetastatic and apoptosis-inducing stimulation of the phagocytic activity of macrophages may play a role in the anticarcinogenic and antimetastatic activities demonstrated for ginseng in vivo (Shin M 2004), and research has continually found tumour-inhibitory effects, especially in the promotion and progression phases (Helms 2004).

Ginsenosides Rg3, Rg5, Rk1, Rs5 and Rs4 have been shown to be cytotoxic to Hep-1 hepatoma cancer cells in vitro. Their 50% growth inhibition concentration (GI50) values were 41, 11, 13, 37 and 13 micromol/L, respectively. Cisplatin had a GI50 of 84 micromol/L in the same assay conditions (Park IH et al 2002). Several triterpenoids found in the leaves have also demonstrated cytotoxic activity in vitro (Huang et al 2008).

Constituents in ginseng have also been shown to inhibit proliferation of cancer cells. Panaxytriol

isolated from red ginseng was shown to have a significant dose-dependent cytotoxic activity and inhibit DNA synthesis in various tumour cells tested (Kim JY et al 2002). Ginsenoside Rg3 has displayed inhibitory activity against human prostate cancer cells in vitro (Liu et al 2000).

Ginsenosides, especially 20(R)-ginsenoside Rg3, have been shown to specifically inhibit cancer cell invasion and metastasis (Shibata 2001), and ginsenoside Rh2 has been shown to inhibit human ovarian cancer growth in mice (Nakata et al 1998). It is likely that the antitumour-promoting activity of Rg3 is mediated through down-regulation of NF-kappaB and other transcription factors (Keum et al 2003).

Oral administration of 20(S)-protopanaxatriol (M4), the main bacterial metabolite of protopanaxatriol-type ginsenosides, has been shown to inhibit melanoma growth in mice, and pretreatment was shown to reduce metastases to the lungs. This effect is thought to be due to stimulation of NK-mediated tumour lysis (Hasegawa et al 2002).

The antimetastatic effects of ginseng are related to inhibition of the adhesion and invasion of tumour cells and also to antiangiogenesis activity. Ginsenosides Rg3 and Rb2 have been shown to significantly inhibit adhesion of melanoma cells to fibronectin and laminin, as well as preventing invasion into the basement membrane in vitro. Other experiments have demonstrated that the saponins exert significant antiapoptotic activity, decreasing the number of blood vessels oriented towards the tumour mass (Mochizuki et al 1995, Sato et al 1994).

Ginseng saponins have also been found to promote apoptosis (programmed cell death) in cancer cells in vitro (Hwang et al 2002).

## Neurological

### Analgesia

Intraperitoneal administration of ginsenoside Rf has been shown to potentiate opioid-induced analgesia in mice. Furthermore, ginsenosides prevented tolerance to the opiate that was not associated with opioid or GABA receptors (Nemmani & Ramarao 2003).

### Neuroprotection

Ginseng saponins have demonstrated dose-dependent neuroprotective activity in vitro and in vivo (Kim J-H et al 2005). Ginsenosides Rb1 and Rg1 have a partial neurotrophic and neuroprotective role in dopaminergic cell cultures (Radad et al 2004), and Rg3 has been shown to inhibit chemically-induced injuries in hippocampal neurons. Pretreatment with ginsenosides (50 or 100 mg/kg for 7 days) has been shown to be neuroprotective in vivo. An in vitro survival assay demonstrated that ginsenosides Rb1 and Rg1 protect spinal cord neurons against damage. The ginsenosides protect spinal neurons from excitotoxicity induced by glutamate and kainic acid, as

well as oxidative stress induced by H<sub>2</sub>O<sub>2</sub>. The optimal doses are 20–40 micromol/L for ginsenosides Rb1 and Rg1 (Liao et al 2002). The lipophilic fraction of ginseng has been shown to induce differentiation of neurons and promote neuronal survival in the rat cortex. The effect is thought to be mediated via protein kinase-C-dependent pathways (Mizumaki et al 2002). In vitro studies have also suggested a benefit for ginseng in hypoxia-induced neuronal injury including ischaemia, trauma and degenerative diseases (Park et al 2007). Beneficial effects have yet to be demonstrated in clinical trials.

It has been suggested that the neuroprotective effects of ginseng against hypoperfusion/reperfusion-induced brain injury demonstrated in animal models suggest a potential for use in cardiovascular disease (CVD) (Shah et al 2005). In a study by Lee et al (2011), focal cerebral ischaemia/reperfusion injury rats were fed Korean red ginseng (KRG) extract (100 mg/kg/day) or saline after reperfusion. Infarct volume was significantly reduced in the KRG rats, and neurological deficits were rapidly improved. Serum levels of tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1 beta (IL-1 $\beta$ ) and IL-6 were significantly attenuated in the KRG rats after 7 days, and serum IL-10 levels were significantly increased. This suggests that KRG provides neuroprotection possibly due to raised IL-10 expression and a reduction in the serum levels of TNF $\alpha$ , IL-1 $\beta$  and IL-6.

### Cognitive function

Following oral consumption, the active metabolites of protopanaxadiol saponins may reactivate neuronal function in Alzheimer's disease according to in vivo evidence (Komatsu et al 2005). Ginseng also enhances the survival of newly generated neurons in the hippocampus, which may contribute to the purported benefits of ginseng for improving learning tasks (Qiao et al 2005).

### Anticonvulsant

Pretreatment (30 min) with 100 mg/kg ginseng significantly protected rats against pentylenetetrazole-induced seizures (Gupta et al 2001).

### Hearing loss

Pretreatment with ginseng extract has been shown to significantly attenuate the effect on auditory cell lines from chemotherapy drug cisplatin-induced increases in reactive oxygen species (ROS). KRG was demonstrated to inhibit the expression of caspase-3 and poly-ADP-ribose polymerase related to cisplatin-induced apoptosis. The cisplatin-induced toxicity involves ROS production, indicating an anti-apoptotic and anti-oxidative role of KRG in cisplatin-induced ototoxicity in auditory cell lines (Im et al 2010). Use of animoglycosides, such as gentamicin (GM), has been noted for its ototoxicity, including hearing loss and vestibular dysfunction. In a study examining GM-induced ototoxicity, Choung

et al (2011) found that co-treatment with KRG significantly limited stereocilia (hair cells) death and hearing loss in rats. KRG was thought to attenuate apoptosis, which is mediated by reactive oxygen species (ROS) and intracellular signalling pathways, highlighting its antioxidant and antiapoptotic effects. The saponin components Rb1 and/or Rb2 only were found to be effective as protective agents against GM-induced hearing loss.

### Antidiabetic

#### Hypoglycaemic/antihyperglycaemic effects

While human and animal studies have found American ginseng to lower blood glucose level (Vuksan et al 2000a, 2000b, 2000c, 2001a, 2001b), results for Korean ginseng are less consistent (Sievenpiper et al 2003, 2004). Both ginseng root and berry (150 mg/kg) have been shown to significantly decrease fasting blood glucose levels in hyperglycaemic rats (Dey et al 2003). Intraperitoneal administration of glycans (polysaccharides known as panaxans) and other unidentified compounds has demonstrated hypoglycaemic activity in both normal and alloxan-induced hyperglycaemic mice (Waki et al 1982).

Oral administration of *P. ginseng* root (125.0 mg/kg) three times daily for 3 days reduced hyperglycaemia and improved insulin sensitivity in rats fed a high-fructose chow, suggesting a possible role in delaying or preventing insulin resistance (Liu et al 2005). However, these doses are very high, and human trials need to be conducted to confirm these results.

In more recent studies, when KRG-rootlet and KRG-body preparations were compared for their effect on postprandial glucose levels on healthy individuals, it was found that despite the KRG-rootlets having >6-fold higher total ginsenosides than KRG-body, the KRG-body preparations were more effective in lowering postprandial glucose levels at 45, 60, 90 and 120 min during the test ( $P < 0.05$ ), giving an overall reduction of 27% in area under the curve (glucose) (de Souza et al 2011). This is important for potential dose range of therapeutics. Cho et al (2013) also found that a KRG-rootlet preparation for healthy overweight or obese adults without overt diabetes and hypertension had no significant effect on improving insulin sensitivity over time.

In a study investigating the prophylactic effects of KRG on type 1 diabetes (T1DM), which is a chronic autoimmune disease rather than a metabolic disorder characterised by insulin resistance as in type 2 diabetes (T2DM), Hong et al (2012) found that KRG extract significantly lowered glucose levels and improved glucose challenge testing. The histological findings report KRG extract protected against induced destruction of pancreatic tissue and restored insulin secretion. Importantly, this effect was accompanied by restoration of lymphocytes in secondary lymphoid organs, indicating a striking effect on immune homeostasis.

### Diabetic complications

Aqueous extract of ginseng was shown to exert no significant effect on weight in normal rats, while it prevented weight loss in rats with streptozotocin-induced diabetes. Cell proliferation in the dentate gyrus of diabetic rats was increased by ginseng treatment, but it had no effect on cell proliferation in normal rats. These results suggest that ginseng may help reduce the long-term central nervous system complications of diabetes mellitus (Lim BV et al 2002).

According to experimental studies, ginseng may also inhibit the formation of glycated haemoglobin due to its antioxidative activity (Bae & Lee 2004).

### Steroid receptor activity

Ginseng has been shown to increase the mounting behaviour of male rats and increase sperm counts in rabbit testes. The effect is not by a direct sex hormone-like function, but probably via a gonadotrophin-like action. Ginsenoside Rb1 has been shown to increase luteinising hormone (LH) secretion by acting directly on the anterior pituitary gland in male rats (Tsai et al 2003). Ginsenoside Rh1 failed to activate the glucocorticoid and androgen receptors, but did demonstrate an interaction with oestrogen receptors in vitro. The effect was much weaker than 17- $\beta$ -oestradiol. Ginseng is therefore considered to contain phyto-oestrogens (Lee et al 2003). However, there are conflicting reports about oestrogen-binding activity, which may in part be explained by the presence or absence of zearalenone, an oestrogenic mycotoxin contaminant (Gray et al 2004).

## OTHER ACTIONS

### Prevention of damage from toxins

Ginseng extract has been shown to be beneficial in the prevention and treatment of testicular damage induced by environmental pollutants. Dioxin is one of the most potent toxic environmental pollutants. Exposure to dioxin either in adulthood or during late fetal and early postnatal development causes a variety of adverse effects on the male reproductive system. The chemical decreases spermatogenesis and the ability to conceive and carry a pregnancy to full term. Pretreatment with 100 or 200 mg/kg ginseng aqueous extract intraperitoneally for 28 days prevented toxic effects of dioxin in guinea pigs. There was no loss in body weight, testicular weight or damage to spermatogenesis (Kim 1999). In guinea pigs, *P. ginseng* also improves the survival and quality of sperm exposed to dioxin (Hwang et al 2004).

### Promoting haemopoiesis

Ginseng is traditionally used to treat anaemia. The total saponin fraction, and specifically Rg1 and Rb1, has been shown to promote haematopoiesis by stimulating proliferation of human granulocyte-macrophage progenitors (Niu et al 2001). The total saponins at a concentration of 50 mcg/mL most

effectively promote CD34<sup>+</sup> cells to proliferate and differentiate by cooperating with haematopoietic growth factors (Wang et al 2006).

### Antioxidant

In vitro studies did not find various extracts of ginseng to be particularly potent antioxidants against several different free radicals (Kim YK et al 2002). However, animal models have demonstrated effects in type 2 diabetes (Ryu et al 2005), particularly for the leaf, which may suppress lipid peroxidation in diabetic rats (Jung et al 2005). Ginseng extract has also been shown to protect muscle from exercise-induced oxidative stress in animal studies (Voces et al 2004).

Whether these effects are directly due to the antioxidant activity of ginseng components or secondary to other mechanisms, such as blood glucose regulation, is unclear. Additionally, ginseng compounds may require in vivo conversion to active metabolites in order to exert their full effects.

### Antiviral

Pretreatment with Korean red ginseng (KRG) extract, reported to have immunomodulatory effects, was shown to be effective in increasing survival rates of mice infected with the influenza H1N1 strain. This was a particularly virulent influenza virus responsible for the 2009 pandemic. Daily oral treatment with KRG extract provided increased protection against two distinct viruses: H1N1 and H3N2. Infected mice showed lower levels of lung viral titres and IL-6, but higher levels of interferon- $\gamma$ , which is critical for innate and adaptive immunity against viral and intracellular bacterial infections and for tumour control (Yoo et al 2012). Additionally, KRG extract inhibited replication of the virus in vitro, demonstrating important antiviral properties in vivo and in vitro.

### Hair growth

Red ginseng extract (more so than white ginseng), and especially ginsenoside Rb1 and 20(S)-ginsenoside Rg3, has been shown to promote hair growth in mouse hair follicles in vitro (Matsuda et al 2003).

### Anti-allergic activity

Ginsenosides have been demonstrated to have anti-allergic activity in vitro. One of the metabolites, 20-O- $\beta$ -D-glucopyranosyl-20(S)-protopanaxadiol, was found to inhibit beta-hexosaminidase release from rat basophil leukaemia cells and potently reduce passive cutaneous anaphylaxis reaction. The inhibitory activity of protopanaxadiol was more potent than that of disodium cromoglycate, an anti-allergic drug. The compound stabilised membranes but had no effect on hyaluronidase and did not scavenge free radicals. These results suggest that the anti-allergic action of protopanaxadiol originates from its cell membrane-stabilising activity and that the ginsenosides are prodrugs with anti-allergic properties (Choo et al 2003).

### Anxiolytic effects

Ginsenosides, and especially ginsenoside R<sub>c</sub>, regulate GABA-A receptors in vitro (Choi SE et al 2003), and animal models have demonstrated an anxiolytic effect for ginseng saponins (Park J et al 2005).

### Antidepressant effects

In a mouse model of depression, a 2-week administration of: hydrolysed red ginseng (HRG); acetate-fermented red ginseng (ARG); ginsenoside Rg<sub>3</sub>; red ginseng (RG); and fluoxetine (a classical antidepressant) were assessed for their effects using forced swimming test (FST) compared with a control group. HRG, ARG, Rg<sub>3</sub>, RG and fluoxetine all significantly improved serum glucose levels and total protein levels compared with the control group ( $P < 0.05$ ), which indicated a beneficial effect in treating depressive-like behaviours (Kim & Kim 2011).

### Wound healing

Ginsenoside Rb<sub>2</sub> has been reported to improve wound healing. It is believed that ginsenoside Rb<sub>2</sub> enhances epidermal cell proliferation by enhancing the expressions of protein factors related to cell proliferation, such as epidermal growth factor and fibronectin (and their receptors), keratin and collagenase (Choi 2002). Ginsenoside Re may also enhance tissue regeneration by inducing angiogenesis (Huang et al 2005). Topical application of ginseng root extract may also promote collagen production via type I procollagen synthesis, suggesting potential anti-wrinkle effects (Lee 2007).

### Improves acne

In an animal model of acne, ginseng extracts reduced the size of comedones by altering keratinisation of the skin and desquamating horny cells in comedones. In a study of experimentally-induced hyperkeratosis, ginseng reduced the accumulation of lipids in the epidermis by regulating enzymes associated with epidermal metabolism (Kim et al 1990).

### Male fertility

Ginseng-treated rats exhibit a significant increase in sperm count and motility due to activation of cAMP-responsive element modulator in the testes (Park et al 2007).

## CLINICAL USE

In the scientific arena, ginseng and the various ginsenosides are used in many forms and administered via various routes. This review will focus primarily on those methods commonly used in clinical practice.

### Cancer prevention

The various anticancer actions of *P. ginseng*, as demonstrated in animal and in vitro trials, support its use as an agent to prevent the development and progression of cancer. A 5-year prospective study of 4634 patients over 40 years of age found that

ginseng reduced the relative risk of cancer by nearly 50% (Yun 1996).

A retrospective study of 905 case-controlled pairs taking ginseng showed that ginseng intake reduced the risk of cancer by 44% (odds ratio equal to 0.56). The powdered and extract forms of ginseng were more effective than fresh sliced ginseng, juice or tea. The preventive effect was highly significant ( $P < 0.001$ ). There was a significant decline in cancer occurrence with increasing ginseng intake ( $P < 0.05$ ) (Yun & Choi 1990).

Epidemiological studies in Korea strongly suggest that cultivated Korean ginseng is a non-organ-specific human cancer preventive agent. In case-control studies, odds ratios of cancer of the lip, oral cavity and pharynx, larynx, lung, oesophagus, stomach, liver, pancreas, ovary and colorectum were significantly reduced by ginseng use. The most active compounds are thought to be ginsenosides Rg<sub>3</sub>, Rg<sub>5</sub> and Rh<sub>2</sub> (Yun 2003).

Ginseng polysaccharide (18 mg/day) has also been shown to be effective in improving immunological function and quality of life (QOL) in elderly patients with non-small cell lung cancer (Zhang et al 2004).

In a randomised, double-blinded, placebo-controlled trial of 643 chronic atrophic gastritis patients in four hospitals in the Zhejiang Province, China, oral administration of KRG extract powder (1 g) per week for 3 years, with a follow-up period of 8 years, to determine the risk of all non-organ-specific cancers, showed a significant risk reduction of all cancers for male subjects of 65% (RR = 0.35;  $P = 0.03$ ). However the risk reduction was non-significant for whole group analysis including both genders (RR = 0.54;  $P = 0.13$ ). In the follow-up period 24 cancers of various organs were diagnosed, with 21 cases being male (Yun et al 2010).

### Chemotherapy

Overexpression of P-glycoprotein or multidrug resistance-associated protein may lead to multidrug resistance of cancer cells. Protopanaxatriol ginsenosides have been shown to sensitise cancer cells to chemotherapeutic agents in vitro by increasing the intracellular accumulation of the drugs through direct interaction with P-glycoprotein (Choi CH et al 2003, Kim S-W et al 2003). The ginsenoside Rh<sub>2</sub> possesses strong tumour-inhibiting properties and sensitises multidrug-resistant breast cancer cells to paclitaxel (Jia et al 2004), and animal models demonstrate a synergistic antitumour effect for ginseng acidic polysaccharides and paclitaxel (Shin H et al 2004).

*Panax ginseng* polysaccharide (12 mg IV daily) has also been trialled during treatment for ovarian cancer, and the authors suggest that it is 'effective, safe and reliable for reducing the toxic effects of chemotherapy' (Fu et al 2005).

In a cohort of 1455 patients with breast cancer recruited to the Shanghai Breast Cancer Study, ginseng use prior to diagnosis was associated with a

significantly reduced risk of death (adjusted hazard ratios 0.71; 95% confidence interval: 0.52–0.98). Use of the following diagnosis resulted in a dose-dependent improvement in QOL scores (especially for psychological and social wellbeing) (Cui et al 2006).

### Diabetes

The putative effects of Korean ginseng on blood glucose and lipid regulation, oxidative stress and protein glycation suggest a possible role as an adjunctive therapy in the management of diabetes and diabetic complications. Diabetes mellitus is characterised by excessive glucose production, which causes oxidative stress and the formation of advanced glycation end-products. These have been significantly linked to diabetic complications such as neuropathy, retinopathy and nephropathy (Kim HY et al 2008).

A double-blind, placebo-controlled study with 36 subjects found that 200 mg ginseng elevated mood, improved psychophysical performance and reduced fasting blood glucose and body weight in patients with newly-diagnosed type 2 diabetes (Sotaniemi et al 1995). A double-blind, randomised, dose-finding study reported that 2 g of Korean ginseng rootlets is sufficient to achieve reproducible reductions in postprandial glycaemia (Sievenpiper 2006), although studies using 200–400 mg have also demonstrated benefits for lowering fasting blood glucose levels (Reay et al 2006a).

In a clinical trial, 19 participants with well-controlled type 2 diabetes (sex: 11 M:8 F, age: 64 ± 2 years, body mass index (BMI): 28.9 ± 1.4 kg/m<sup>2</sup>, HbA<sub>1c</sub>: 6.5%) received 2 g Korean ginseng preparation (rootlets) 40 minutes prior to meals (total 6 g/day) for 12 weeks in addition to their usual antidiabetic therapy. While HbA<sub>1c</sub> levels remained unchanged, improvements were noted for plasma glucose (75 g-oral glucose tolerance test-plasma glucose (OGTT-PG) reduced by 8–11%), plasma insulin (PI) (fasting PI and 75 g-OGTT-PI reduced by 33–38%) and insulin sensitivity index (ISI) (75 g-OGTT-ISI increased by 33%) compared with placebo ( $P < 0.05$ ) (Vuksan et al 2008).

HY Kim et al (2008), in a study of KRG and heat-processed KRG (H-KRG) on diabetic renal damage, used streptozotocin-induced diabetic rats in a direct-comparison model. Protein expressions related to oxidative stress and advanced glycation end-products were significantly reduced in diabetic rats. Both formulations had a significant effect and may improve diabetic pathological conditions and prevent renal damage associated with diabetic nephropathy; however, H-KRG had a more pronounced effect than KRG.

In a study looking at KRG effects in obese insulin-resistant animal models, the KRG rats were fed 200 mg/kg, per oral and a high fat diet. Compared with a control group and a high-fat-diet-only group, the KRG rats had a significant reduction in weight, especially fat mass, and a significantly

increased insulin sensitivity. The authors conclude that KRG may have antidiabetic and antiobesity effects due to partly-increased insulin sensitivity by increased adipokine and partly-enhanced insulin signalling (Lee et al 2012). Kim and Kim (2012) concluded from their study of diabetic rats that KRG may primarily target processes that increase insulin action and insulin secretion and decrease  $\beta$ -cell mass, which causes the normalisation in glucose homeostasis. Conversely, HJ Kim et al (2012) found that in a human study, a preparation of ginseng roots, mulberry leaf water extract and banaba leaf extract (1:1:1; 6g/day for 24 weeks) had no impact on glucose homeostasis control measures, however, plasma intracellular adhesion molecule-1 (ICAM-1) concentration was decreased significantly between the groups, and vascular cell adhesion molecule-1 (VCAM-1) and the oxidised low-density lipoprotein (ox-LDL) concentration were decreased within the treatment group from baseline. The authors suggest that these markers indicate a suppression of the inflammatory responses in type 2 diabetes mellitus.

Bang and colleagues (2014) summarise four theories that could explain the anti-diabetic effect of KRG that have been supported by animal models: modulation of the way glucose is absorbed in the digestive system; increase of insulin secretion from the pancreatic islets and binding in the liver; modulation of glucose transport which is increased in various cell lines such as glucose transporter GLUT-1 protein expression; and lastly by an increase in enzymes related to glucose disposal, such as isomerase and lactate dehydrogenase. In their study, they suggest that results indicate a glucose transport mechanism coupled with insulin sensitisation, evidenced by the decreases in serum and whole blood glucose levels and decrease in insulin concentrations.

Different formulations of KRG and its constituents may demonstrate different mechanisms of action, or a combination of effect. Further studies are warranted, as KRG shows promise in the prevention and treatment of both type 1 and type 2 diabetes mellitus.

### Cardiovascular disease

A 2006 systematic review concluded that there is currently a lack of well-designed, randomised, controlled trials to support the use of ginseng to treat cardiovascular risk factors despite some studies suggesting improvements in blood pressure, blood glucose and lipid profiles (Buettner et al 2006).

Although there are reports of ginseng causing hypertension, red ginseng is actually used as an anti-hypertensive agent in Korea.

Acute administration of an aqueous preparation of Korean ginseng (100 mg/kg body weight) to 12 healthy, non-smoking male volunteers resulted in an increase in NO levels and a concomitant reduction in mean blood pressure and heart rate (Han et al 2005).

Ginseng is often used in practice as an adjuvant to both conventional and complementary and alternative medicine (CAM) treatments. Trials have reported that 1.5 g three times daily of Korean red ginseng (4.5 g/day) is useful as an adjuvant to anti-hypertensive medication (Han et al 1995, 1998). It should be noted, however, that results in these trials, while statistically significant (e.g. systolic pressure  $-5.7$  mmHg), may not be clinically significant. A combination of red ginseng and digoxin was found to be more beneficial than either drug alone in an open study of advanced congestive heart failure. There were no adverse reactions (Ding et al 1995). A combination of ginseng and ginkgo extracts has been found to improve circulation and lower blood pressure in a controlled single-dose study of 10 healthy young volunteers (Kiesewetter et al 1992).

Korean red ginseng has also been shown to improve vascular endothelial function in patients with hypertension. The effect is thought to be mediated through increasing the synthesis of nitric oxide (Sung et al 2000).

### Hyperlipidaemia

In a small trial of eight males receiving 2 g Panax ginseng extract three times daily (total Panax ginseng extract (PGE) 6 g/day) for 8 weeks, serum total cholesterol, LDL and triglyceride concentrations were decreased by 12, 45 and 24%, respectively, and a 44% increase in HDL was reported (Kim & Park 2003).

Red ginseng, 1.5 g three times daily before meals for 7 days, reduced liver cholesterol, decreased the atherogenic index and elevated HDL cholesterol in 11 patients (5 normal subjects and 6 with hyperlipidaemia). Serum cholesterol was not significantly altered, but serum triglycerides were significantly decreased (Yamamoto & Kumagai 1982).

### Immunomodulation

Ginseng has been shown to significantly enhance NK function in healthy subjects and in those suffering from chronic fatigue syndrome or AIDS ( $P < 0.01$ ) (See et al 1997).

Ginseng polysaccharide injection has been shown, in a randomised study, to improve immunity in 130 patients with nasopharyngeal carcinoma and to reduce adverse reactions to radiotherapy compared with controls (Xie et al 2001).

Red ginseng powder has been shown to restore immunity after chemotherapy and reduce the recurrence of stage III gastric cancer. The 5-year disease-free survival and overall survival rates were significantly higher in patients taking the red ginseng powder during postoperative chemotherapy versus control (68.2 vs 33.3%, 76.4 vs 38.5%, respectively,  $P < 0.05$ ). Despite the limitation of a small number of patients ( $n = 42$ ), these findings suggest that red ginseng powder may help to improve postoperative survival in these patients. Additionally, red ginseng powder may have some immunomodulatory properties associated with CD3 and CD4 activity in

patients with advanced gastric cancer during post-operative chemotherapy (Suh et al 2002).

### Vaccine adjuvant activity

Ginseng extract (100 mg ginsan G115/day) improved the response to an influenza vaccine in a multicentre, randomised, double-blind, placebo-controlled, two-arm study of 227 subjects. Compared with vaccine without the ginseng, the addition of ginseng resulted in fewer cases of influenza and common cold. Ginseng increased NK activity and increased antibody production (Scaglione et al 1996).

The addition of 2 mg ginseng dry extract per vaccine dose has been shown to potentiate the antibody response of commercial vaccines without altering their safety. The enhancing effect of ginseng was demonstrated during the vaccination of pigs against porcine parvovirus and *Erysipelothrix rhusiopathiae* infections using commercially available vaccines (Rivera et al 2003).

### Cognitive function

There is some contention about the benefits of ginseng for improving memory, concentration and learning (Persson et al 2004). Well-controlled clinical trials are lacking, and variations in dosage and standardisation may affect study results.

Some studies have demonstrated that ginseng improves the quality of memory and associated secondary memory (Kennedy et al 2001a). In a randomised, placebo-controlled, double-blind, balanced, crossover study of healthy, young adult volunteers, 400 mg ginseng was shown to improve secondary memory performance on a Cognitive Drug Research computerised assessment battery and two serial subtraction mental arithmetic tasks. Ginseng also improved attention and the speed of performing the memory tasks (Kennedy et al 2002). In a later double-blind, placebo-controlled, balanced, crossover study of 30 healthy young adults, acute administration of ginseng (400 mg) was again shown to improve speed of attention (Sunram-Lea et al 2005).

In a double-blind, placebo-controlled study of healthy young subjects, ginseng extract (G115) improved accuracy and slowed responses during one of two computerised serial subtraction tests (Serial Sevens) and it was also shown to improve mood during these tasks (Kennedy et al 2001b). In acute dosing trials, a single dose of ginseng (200 mg G115 extract, with or without 25 g glucose) and glucose has been shown to enhance cognitive performance in healthy young adults. Participants experienced enhanced performance on a mental arithmetic task and a reduction in subjective feelings of mental fatigue during the later stages of the sustained, cognitively demanding task (Reay et al 2006b).

In a double-blind, randomised, placebo-controlled 8–9-week trial, standardised ginseng extract 400 mg was found to significantly improve abstract thinking ( $P < 0.005$ ) and reaction time (not significant) in 112 healthy subjects over 40 years of

age. Ginseng was found not to affect concentration or memory (Sorensen & Sonne 1996).

In a controlled open-label study, 97 consecutive patients with Alzheimer's disease were randomly assigned to a treatment ( $n = 58$ ) or control group ( $n = 39$ ). The treatment group received Korean ginseng powder (4.5 g/day) for 12 weeks, which resulted in improvements in the cognitive subscale of Alzheimer's disease assessment scale (ADAS) and the mini-mental state examination (MMSE) ( $P = 0.029$  and  $P = 0.009$  vs baseline, respectively). After discontinuing ginseng, the improved ADAS and MMSE scores declined to the levels of the control group (Lee 2008). In addition, similar trials using 0, 4.5 or 9 g ginseng daily found that patients in the high-dose group showed significant improvement on the ADAS and Clinical Dementia Rating after 12 weeks of ginseng therapy ( $P = 0.032$  and  $0.006$ , respectively). Improvements in MMSE did not reach statistical significance (Heo et al 2008).

In clinical practice, Korean ginseng and *Ginkgo biloba* are frequently used in combination for cognitive benefits. Combining ginseng with ginkgo dramatically improves memory, concentration and speed of completing mental tasks (Kennedy et al 2001a, Scholey & Kennedy 2002). In clinical trials, ginseng directly modulates cerebral electrical activity on EEG recordings to a greater extent than *Ginkgo biloba* (Kennedy et al 2003).

In a double-blind, placebo-controlled study, postmenopausal women aged 51–66 years were randomly assigned to 12 weeks' treatment with a combination formula containing 120 mg *Ginkgo biloba* and 200 mg *Panax ginseng* ( $n = 30$ ) or matched placebo ( $n = 27$ ). The combination appeared to have no effect on mood or cognition after 6 and 12 weeks; however, these doses may be too low (Hartley et al 2004). According to other trials, it would appear that doses of 400–900 mg of ginseng are required for best results and 200 mg doses have been associated with 'cognitive costs', slowing performance on attention tasks (Kennedy & Scholey 2003).

### Menopausal symptoms

Korean red ginseng is used to alleviate symptoms associated with menopause; 6 g ginseng for 30 days was shown in a small study of 20 women significantly ( $P < 0.001$ ) to improve menopausal symptoms, in particular fatigue, insomnia and depression. The women treated had a significant decrease in cortisol and cortisol-to-dehydroepiandrosterone ratio ( $P < 0.05$ ). No adverse effects were recorded (Tode et al 1999).

### Erectile dysfunction

Korean red ginseng has been shown to alleviate erectile dysfunction and improve the ability to achieve and maintain erections even in patients with severe erectile dysfunction (Price & Gazewood 2003). Ginsenosides can facilitate penile erection by

directly inducing the vasodilation and relaxation of the penile corpus cavernosum. Moreover, the effects of ginseng on the corpus cavernosum appear to be mediated by the release and/or modification of release of NO from endothelial cells and perivascular nerves (Murphy & Lee 2002). In men with type 2 diabetes, oxidative stress has been suggested as a contributing factor to erectile dysfunction and animal studies suggest that ginseng can preserve 'potency' via its antioxidant effect (Ryu et al 2005).

In a double-blind, placebo-controlled study, 60 patients presenting with mild or mild to moderate erectile dysfunction received 1 g (three times daily) of Korean ginseng or placebo. In the five-item International Index of Erectile Function (IIEF)-5, 66.6% (20 patients) reported improved erection, rigidity, penetration and maintenance ( $P < 0.01$ ) after 12 weeks. Serum testosterone, prolactin and cholesterol were not significantly different (de Andrade et al 2007).

In a double-blind crossover study, 900 mg Korean red ginseng was found to significantly improve the Mean IIEF scores compared with placebo. Significant subjective improvements in penetration and maintenance were reported by participants, and penile tip rigidity on the RigiScan showed significant improvement for ginseng versus placebo (Hong et al 2002).

A significant improvement in erectile function, sexual desire and intercourse satisfaction was demonstrated in 45 subjects following 8 weeks' oral administration of Korean red ginseng (900 mg three times daily) in a double-blind, placebo-controlled, crossover trial. Subjects demonstrated significant improvement in mean IIEF scores compared with placebo (baseline,  $28 \pm 16.7$ ; Korean red ginseng,  $38.1 \pm 16.6$ ; placebo,  $30.9 \pm 15.7$ ) (Hong et al 2003).

### Quality of life

An 8-week, randomised, double-blind study found that 200 mg/day ginseng ( $n = 15$ , placebo:  $n = 15$ ) improved aspects of mental health and social functioning after 4 weeks' therapy, but that these differences disappeared with continued use (Ellis & Reddy 2002). A review of eight clinical studies with ginseng found some improvement in QOL scores. However, the findings were equivocal. Despite some positive results, improvement in overall health-related QOL cannot, given the current research, be attributed to *P. ginseng*. However, the possibility that various facets of QOL may have improved and the potential of early transient effects cannot be discounted (Coleman et al 2003). A double-blind, placebo-controlled, randomised clinical trial of 83 subjects also did not find ginseng to enhance psychological wellbeing in healthy young adults (Cardinal & Engels 2001).

A double-blind, placebo-controlled, crossover study found that 1200 mg ginseng was only slightly more effective than placebo and not as effective as a good night's sleep in improving bodily feelings,

mood and fatigue in 12 fatigued night nurses. Volunteers slept less and experienced less fatigue, but rated sleep quality worse after ginseng administration (Hallstrom et al 1982).

A recent double-blind, placebo-controlled, balanced, crossover design of 30 healthy young adults taking *P. ginseng* extract (200 or 400 mg) or placebo demonstrated improvements in performance and subjective feelings of mental fatigue during sustained mental activity. It has been hypothesised that this effect may be due in part to the ability of ginseng to regulate blood glucose levels (Reay et al 2005).

### Adaptogenic and tonic effects

A randomised double-blind study involving 232 subjects between the ages of 25 and 60 years found that extract equivalent to about 400 mg ginseng root for 4 weeks significantly improved fatigue. Side effects were uncommon, with only two subjects withdrawing from the study (Le Gal & Cathebras 1996).

A randomised double-blind study of 83 subjects found that extract equivalent to 1 g ginseng root for 4 months decreased the risk of contracting a common cold or bronchitis and improved appetite, sleep, wellbeing and physical performance (Gianoli & Riebenfeld 1984).

### Improved athletic performance

Ginseng is used by many athletes to improve stamina and to facilitate rapid recovery from injuries; however, supporting evidence from well-designed clinical trials is lacking. To examine the effects of ginseng supplements on hormonal status following acute resistance exercise, eight male college students were randomly given water (control group) or 20 g ginseng root extract treatment immediately after a standardised training exercise. Human growth hormone, testosterone, cortisol and insulin-like growth factor 1 levels were determined by radioimmunoassay. The responses of plasma hormones following ginseng consumption were not significant between the control and the ginseng groups during the 2-hour recovery period (Youl et al 2002).

Although ginseng is commonly used to improve endurance, a double-blind study of 19 healthy, active women found that 400 mg of a ginseng extract (G115) did not improve supramaximal exercise performance or short-term recovery. Analysis of variance using pretest to posttest change scores revealed no significant difference between the ginseng and placebo study groups for the following variables measured: peak anaerobic power output, mean anaerobic power output, rate of fatigue and immediate postexercise recovery heart rates (Engels et al 2001). A recent study by the same authors also failed to find any benefit from ginseng (400 mg/day G115; equivalent to 2 g *P. ginseng* C.A. Meyer root material for 8 weeks) on improving physical performance and heart rate recovery of individuals undergoing repeated bouts of exhausting exercise (Engels et al 2003). When 60 men from the Naval Medical

Corps, Royal Thai Navy (aged 17–22 years), given 3 g/day of ginseng or placebo for an 8-week period, were measured for blood lactic acid levels for determination of lactate threshold (LT), no improvements were noted, nor was there any beneficial effect on physical performance (Kulaputana et al 2007).

A small study of seven healthy male subjects given 2 g ginseng (three times daily) for 8 weeks reported a significant increase in exercise duration until exhaustion (+1.5 min;  $P < 0.05$ ), which was related to improvements in lipid peroxidation and scavenger enzymes (Kim et al 2005); however, this study is too small to make generalisations.

### OTHER USES

#### Gastroprotection during heart surgery

In a trial of 24 children undergoing heart surgery for congenital heart defects, 12 children received 1.35 mg/kg ginsenoside compound or placebo intravenously before and throughout the course of cardiopulmonary bypass surgery. Ginseng administration resulted in attenuation of gastrointestinal injury and inflammation (Xia et al 2005).

#### Respiratory disease

Ginseng extract (G115) has been shown to significantly ( $P < 0.05$ ) improve pulmonary function test, maximum voluntary ventilation, maximum inspiratory pressure and maximal oxygen consumption ( $VO_{2max}$ ) in a study of 92 patients suffering moderately severe chronic obstructive pulmonary disease ( $n = 49$ , G115 100 mg twice daily for 3 months) (Gross et al 2002).

#### Helicobacter pylori

*Helicobacter pylori* can provoke gastric inflammation, ulceration and DNA damage, resulting in an increased risk of carcinogenesis. As preliminary evidence suggests that *P. ginseng* inhibits the growth of *H. pylori* (Kim J et al 2003) and can inhibit adhesion (Lee J et al 2004), it may be useful as a gastroprotective agent against *H. pylori*-associated gastric mucosal cell damage (Park S et al 2005).

#### HIV infection

Long-term intake of Korean ginseng slows the depletion of CD4<sup>+</sup> T cells and may delay disease progression in people with HIV type 1 (Sung et al 2005). Ginseng intake in HIV-1-infected patients may also be associated with the occurrence of grossly deleted nef genes (gDeltanef) (Cho et al 2006) and gross deletions (gDelta) in HIV-1 5'-LTR and gag regions (Cho & Jung 2008). Long-term intake ( $60 \pm 15$  months) has also been shown to delay the development of resistance mutation to zidovudine (Cho et al 2001).

#### DOSAGE RANGE

- Extract equivalent to 0.9–3 g crude ginseng root (Bensky & Gamble 1986).

- Standardised extract: 1.5–4.0% total ginsenosides calculated as ginsenoside Rg1.
- Liquid extract (1:2): 1–6 mL/day.
- Cognitive function: Clinical trials using 1.5–3 g three times daily have reported benefits. Lower doses may be associated with ‘cognitive costs’ and slowing performance on attention tasks (Kennedy & Scholey 2003).
- Cardiovascular use: 1.5–2 g three times daily.

Many of the clinical studies published in the scientific literature have used a proprietary extract of ginseng standardised to 4% total ginsenosides (G115 or Ginsana produced by Pharmaton, Lugano, Switzerland).

Ginseng is usually given in the earlier part of the day. It should not be given in the evening, unless it is used to promote wakefulness. Ginseng is usually not given to children.

### ADVERSE REACTIONS

Ginseng abuse syndrome (hypertension, nervousness, insomnia, morning diarrhoea, inability to concentrate and skin reactions) has been reported, and there has been a report of a 28-year-old woman who had a severe headache after ingesting a large quantity of ethanol-extracted ginseng. Cerebral angiograms showed ‘beading’ appearance in the anterior and posterior cerebral and superior cerebellar arteries, consistent with cerebral arteritis (Ryu & Chien 1995). High doses (15 g/day) have been associated with confusion, depression and depersonalisation in four patients (Coon & Ernst 2002).

However, the majority of the scientific data suggest that ginseng is rarely associated with adverse events or drug interactions. A systematic review found that the most commonly experienced adverse events are headache, sleep and gastrointestinal disorders. Data from clinical trials suggest that the incidence of adverse events with ginseng monoprparations is similar to that of placebo. Any documented effects are usually mild and transient. Combined preparations are more often associated with adverse events, but causal attribution is usually not possible (Coon & Ernst 2002).

Allergic reactions to Korean ginseng, including occupation asthma, may occur via an IgE-mediated mechanism (Kim KM 2008). A case of suspected ginseng allergy has recently been reported in the scientific literature. The case involved a 20-year-old male who developed urticaria, dyspnoea and hypotension after ingesting ginseng syrup. The subject recovered fully and was discharged after 24 hours (Wiwanitkit & Taungjaruwina 2004).

While ginseng use has been associated with the development of hypertension, it has actually been shown to reduce blood pressure in several studies (Coon & Ernst 2002).

Ginseng has very low toxicity. Subacute doses of 1.5–15 mg/kg of a 5:1 ginseng extract did not produce negative effect on body weight, food consumption, haematological or biochemical parameters

or histological findings in dogs (Hess et al 1983), and no effects have been observed from the administration of similar doses in two generations of rat offspring (Hess et al 1982).

Traditionally, ginseng is not recommended with other stimulants such as caffeine and nicotine, and a case report exists of a 39-year-old female experiencing menometrorrhagia, arrhythmia and tachycardia after using oral and topical ginseng, along with coffee and cigarettes (Kabalak et al 2004).

### SIGNIFICANT INTERACTIONS

#### Albendazole

*Panax ginseng* significantly accelerated the intestinal clearance of the anthelmintic albendazole sulfoxide, when coadministered to rats (Merino et al 2003).

#### Alcohol

Ginseng may increase the clearance of alcohol from the blood according to an open trial of 14 healthy volunteers (Coon & Ernst 2002) — beneficial interaction possible, but needs confirmation.

#### Chemotherapy, radiotherapy and general anaesthetics

Preliminary evidence suggests that *P. ginseng* saponins may reduce nausea and vomiting associated with chemotherapy, radiotherapy and general anaesthetics by antagonising serotonin (5-hydroxytryptamine) type 3A receptors (Min et al 2003). Ginseng may also help to sensitise cancer cells to chemotherapeutic agents according to preliminary evidence.

#### Digoxin

Ginseng contains glycosides with structural similarities to digoxin, which may modestly interfere with digoxin results (Dasgupta et al 2003). These naturally-occurring glycosides may cause false elevation of fluorescence polarisation and falsely low microparticle enzyme results, although Tina-quant results appear unaffected (Dasgupta & Reyes 2005). It should be noted that measuring free digoxin does not eliminate these modest interferences in serum digoxin measurement by the Digoxin III assay (Dasgupta et al 2008). There are no confirmed case reports of actual interaction (Chow et al 2003, Dasgupta et al 2003).

#### Drugs metabolised chiefly by CYP1A, CYP2D6 and CYP3A4

Mixed reports exist as to whether ginseng may act as an inhibitor of cytochrome CYP1A (Gurley et al 2005, Lee HC et al 2002, Yu et al 2005) or CYP2D6 (Gurley et al 2005). Ginsenosides F1 and Rh1 (but not ginseng extract) may inhibit CYP3A4 at 10 micromolar (Etheridge et al 2007). Whether these effects are likely to be clinically significant has not been established. Observe for increased drug bioavailability and clinical effects.

### Nifedipine

Ginseng increased the mean plasma concentration of the calcium channel blocker nifedipine by 53% at 30 minutes in an open trial of 22 healthy subjects. Effects at other time points were not reported (Smith et al 2001).

### Vancomycin

In animal studies, the combination of ginseng polysaccharides with vancomycin resulted in a 100% survival rate for animals treated for *Staphylococcus aureus* compared to only 67 or 50% survival in animals treated with ginseng polysaccharides or vancomycin alone (Lim BV et al 2002). A beneficial additive effect is possible, but clinical use in humans has not yet been established.

### Warfarin

No effects on the pharmacokinetics or pharmacodynamics of either S-warfarin or R-warfarin were revealed in an open-label, crossover randomised trial of 12 healthy male subjects who received a single 25-mg dose of warfarin alone or after 7 days' pretreatment with ginseng (Jiang et al 2004). Whether these effects are consistent in less 'healthy' people likely to be taking warfarin or for prolonged concurrent use is unclear.

There have been two case reports of ginseng reducing the antithrombotic effects of warfarin (Janetzky & Morreale 1997, Rosado 2003). Additionally, it inhibits platelet aggregation according to both in vitro and animal studies. Avoid using this combination unless under medical supervision to monitor antithrombotic effects.

### Zidovudine

Long-term intake (60 ± 15 months) of Korean red ginseng in HIV-1-infected patients has been shown

to delay the development of resistance mutation to zidovudine (Cho et al 2001).

### CONTRAINDICATIONS AND PRECAUTIONS

Korean ginseng is generally contraindicated in acute infections with fever and in persons who are very hot, tense and overly stimulated. Overuse may result in headache, insomnia and palpitation (Bensky & Gamble 1986). Ginseng should not be taken concurrently with other stimulants including caffeine and should be discontinued 1 week before major surgery. Use in hypertension should be supervised; however, it may prove beneficial for this indication.

G

### PREGNANCY USE

Ginseng is traditionally used in Korea as a tonic during pregnancy. Commission E does not list any restrictions (Blumenthal 2001). There is in vitro evidence of teratogenicity based on exposure to isolated ginsenosides (especially Rb1) (Chan et al 2003) at much higher levels than achievable through normal consumption in humans and conflicting evidence as to its oestrogenic properties. In light of the lack of good clinical evidence, Korean ginseng should be used cautiously during pregnancy (especially the first trimester) and lactation until more data are available (Seely et al 2008).

In a two-generation rat study, a ginseng extract fed at doses as high as 15 mg/kg/day did not produce adverse effects on reproductive performance, including embryo development and lactation (Hess et al 1982).

### Practice points/Patient counselling

Traditional use:

Ginseng is traditionally used for deficiency of Qi (energy/life force) manifested by shallow respiration, shortness of breath, cold limbs, profuse sweating and a weak pulse (such as may occur from severe blood loss). Ginseng is also used for wheezing, lethargy, lack of appetite, abdominal distension and chronic diarrhoea. Ginseng may also be used for palpitations, anxiety, insomnia, forgetfulness and restlessness associated with low energy and anaemia (Bensky & Gamble 1986).

Scientific evidence:

There is some scientific evidence for the beneficial effects of ginseng for the following conditions. In practice, it is mostly used as a supportive treatment and combined with other herbs to treat a specific condition.

- Prevention and supportive treatment of cancer
- Chronic immune deficiency
- Menopausal symptoms
- Erectile dysfunction

- Chronic respiratory disease
- Enhancement of psychomotor activity, memory and concentration
- Adaptogenic effects in any chronic condition and for the elderly and infirm
- Type 1 diabetes
- Cardiovascular disease (the effects on hypertension/hypotension remain to be fully investigated)
- QOL (equivocal scientific support)

Commission E recommends ginseng as a tonic for invigoration and fortification in times of fatigue, debility and convalescence or declining capacity for work and concentration. The World Health Organization suggests that ginseng can be used as a prophylactic and restorative agent for enhancement of mental and physical capacities, in cases of weakness, exhaustion, tiredness and loss of concentration and during convalescence (Blumenthal 2001).

## ! PATIENTS' FAQs

### *What will this herb do for me?*

Ginseng is a safe herb used to support the body during times of prolonged stress or chronic disease and to restore mental and physical functioning during the rehabilitative process. Numerous studies have identified a range of pharmacological activities that suggest that it may be useful in the treatment of many conditions.

### *When will it start to work?*

In practice, it generally appears that ginseng has a quick onset of action with the condition continuing to improve with long-term use; however, this will vary depending on the individual and the indication.

### *Are there any safety issues?*

Ginseng may interact with warfarin and other blood-thinning drugs and should not be used with these medications, unless under medical supervision. Avoid use in children or in hypertension, unless under supervision. Use with caution in pregnancy.

# Ginseng — Siberian

**HISTORICAL NOTE** Siberian ginseng has been used for over 2000 years, according to Chinese medical records, where it is referred to as *ci wu jia*. It was used to prevent colds and flu and to increase vitality and energy. In modern times, it has been used by Russian cosmonauts to improve alertness and energy and to aid in adaptation to the stresses of life in space. It also has been used as an ergogenic aid by Russian athletes before international competitions (Mills & Bone 2000) and after the Chernobyl accident to counteract the effects of radiation (Chevallier 1996).

## Clinical note — Allostasis

Allostasis is the body's adaptation to stress. Allostatic (adaptive) systems are critical to survival and enable us to respond to changes in our physical (such as asleep, awake, standing, sitting, eating, exercising and infection) and psychological states (such as anticipation, fear, isolation, worry and lack of control). The consumption of tobacco, alcohol and our dietary choices also induces allostatic responses (McEwan 1998). These systems are complex and have broad boundaries, in contrast to the body's homeostatic systems (e.g. blood pH and body temperature), which are maintained within a narrow range.

Most commonly, allostatic responses involve the sympathetic nervous system and the hypothalamic-pituitary-adrenal (HPA) axis. Upon activation (e.g. when a challenge is perceived), catecholamines are released from nerves and the adrenal medulla, corticotrophin is secreted from the pituitary and cortisol is released from the adrenal cortex. Once the threat has passed (e.g. the environment is more comfortable or infection is controlled), the system is inactivated and levels of cortisol and catecholamine secretion return to baseline.

Chronic exposure to stress can lead to allostatic load, a situation resulting from chronic overactivity or underactivity of allostatic systems. The situation is characterised by maladaptive responses whereby systems become inefficient or do not turn off appropriately. Currently, there is much interest in understanding the association between numerous diseases such as cardiovascular disease and overwhelming allostatic load.

One measure that is used to gauge an individual's allostatic response is the cortisol response to a variety of stressors. As such, cortisol is seen as the classical 'stress' hormone.

## OTHER NAMES

Ci wu jia, devil's bush, devil's shrub, eleuthero, eleutherococcus, eleuthero root, gokahi, ogap'I, russisk rod, taigawurzel, touch-me-not, wu jia pi

## BOTANICAL NAME/FAMILY

*Eleutherococcus senticosus* (synonym: *Acanthopanax senticosus*) (family Araliaceae)

## PLANT PART USED

Root, rhizome

## CHEMICAL COMPONENTS

Glycosides (eleutherosides A–M, including saponins, coumarins, lignans, phenylpropanoids, oleanolic acids, triterpenes, betulinic acid and vitamins), steroid glycoside (eleutheroside A), lignans (syringin, sesamin, chlorogenic acid), glycans (eleutherans A–G), triterpenoid saponins (friedelin), saponin (protoprimulagenin A), hydroxycoumarin (isofraxidin), phenolics, polysaccharides, lignans, coumarins and resin.

Nutrients include magnesium 723 mcg/g, aluminium 188 mcg/g and manganese 37 mcg/g and vitamins A and E (*Eleutherococcus senticosus* 2006, Meacham et al 2002, Nissen 2003, Panossian et al 1999, Skidmore-Roth 2001).

## MAIN ACTIONS

### Adaptogenic (modulates stress response)

Siberian ginseng appears to alter the levels of different neurotransmitters and hormones involved in the stress response, chiefly at the HPA axis. Various mechanisms have been proposed, including inhibition of catechol-O-methyltransferase, which inactivates catecholamines (Gaffney et al 2001a). As a result, catecholamine levels are not depleted and release of new catecholamines from nerve synapses is decreased (Panossian et al 1999). In theory, this may reduce the risk of the organism's adaptive responses becoming depleted and moving into the exhaustion phase of the stress response. In addition, eleutherosides have been shown to improve carbohydrate metabolism and energy provision and increase the synthesis of protein and nucleic acids, although the direct molecular targets responsible for this adaptive response remain unknown (Panossian et al 1999). Eleutherosides have also been reported to bind to receptor sites for progesterin, oestrogen, mineralocorticoids and glucocorticoids in vitro and therefore may theoretically exert numerous pharma-

collogical actions important for the body's stress response (Pearce et al 1982).

Owing to such actions, herbalists and naturopaths describe the herb's overall action as 'adaptogenic'. The term 'adaptogen' describes substances that increase the ability of an organism to adapt to environmental factors and to avoid damage from such factors (Panossian et al 1999). The term 'allostasis' (see Clinical note) has been adopted in the medical arena to describe 'the ability to achieve stability through change'.

Although the mechanism of action responsible is still unclear, several theories have been proposed to explain the effect of Siberian ginseng on allostatic systems, largely based on the pharmacological actions observed in test tube and animal studies. Depending on the stage of the stress response, Siberian ginseng can act in different ways to support the 'stress system'. Research suggests that there is a threshold of stress below which the herb increases the stress response and above which it decreases the stress response (Gaffney et al 2001b). Therefore, for example, if allostatic load is such that responses have become inadequate, then the resulting increase in hormone levels would theoretically induce a more efficient response. Alternatively, situations of chronic overactivity, also due to allostatic load, would respond to Siberian ginseng in a different way, with negative-feedback systems being triggered to inactivate the stress response (Gaffney et al 2001a).

The dosing regimen may also be significant. While multidose administration in chronic stress engages the HPA axis, balancing the switch-on and switch-off responses, single doses (~4 mL) in acute stress trigger a rapid response from the sympatho-adrenal system, resulting in secretion of catecholamines, neuropeptides, adenosine triphosphate and nitric oxide (NO) (Panossian & Wagner 2005). Studies have demonstrated that maximal effects are achieved around 4 weeks but do not persist at the 8-week time point, which may help to explain the practice of giving Siberian ginseng for 6 weeks with a 2-week break before repeating.

### Immunomodulation

Siberian ginseng appears to exert an immunomodulatory rather than just an immunosuppressive or stimulating action; however, evidence for the immune-enhancing effects of Siberian ginseng is contradictory. Clinical studies, in vitro and in vivo, have revealed stimulation of general non-specific resistance and an influence on T lymphocytes, natural killer (NK) cells and cytokines (Bohn et al 1987, Schmolz et al 2001), although other studies suggest that Siberian ginseng does not significantly stimulate the innate macrophage immune functions that influence cellular immune responses (Wang et al 2003). Alternatively, another in vitro study has demonstrated that activation of macrophages and NK cells does occur and may be responsible for inhibiting tumour metastasis both prophylactically and therapeutically (Yoon et al 2004).

The main constituents responsible appear to be lignans (sesamin, syringin) and polysaccharides, such as glycans, which demonstrate immunostimulant effects in vitro (Davydov & Krikorian 2000, Wagner et al 1984). Additionally, effects on the HPA axis will influence immune responses.

A liposoluble fraction from a crude extract of Siberian ginseng enhanced the forced swimming capacity of mice by decreasing muscle damage, effectively preventing the increase in blood urea nitrogen concentration and increasing fat utilisation (Huang et al 2010).

### Antiviral

In vitro studies show a strong antiviral action, inhibiting the replication of ribonucleic acid-type viruses such as human rhinovirus, respiratory syncytial virus and influenza A virus (Glatthaar-Saalmuller et al 2001).

### Anabolic activity

Syringin and other eleutherosides appear to improve carbohydrate metabolism and energy provision by increasing the formation of glucose-6-phosphate and activating glucagon transport (Panossian et al 1999), and Siberian ginseng extracts have been reported to improve the metabolism of lactic and pyruvic acids (Farnsworth et al 1985).

While initial animal studies showed promise for improving weight gain and increasing organ and muscle weight (Farnsworth et al 1985, Kaemmerer & Fink 1980), clinical studies confirming whether anabolic effects occur also in humans could not be located.

### Anti-inflammatory

Excess production of NO is a characteristic of inflammation, and Siberian ginseng has been shown to significantly suppress NO production and inducible NO synthase (iNOS) gene expression in a dose-dependent manner (Lin et al 2008). The downregulation of iNOS expression may be the result of inhibition of intracellular peroxide production (Lin et al 2008) or through blocking c-Jun NH<sub>2</sub>-terminal kinase (JNK) and Akt activation (Jung et al 2007). Cyanidin-3-O-(2''-xylosyl)-glucoside (C-3-O-(2''-xylosyl)-G), which was analysed as an active constituent from the fruit of Siberian ginseng, was shown to act by suppressing cyclooxygenase-2 expression and AP-1 and NF-κB transactivation and JNK, MAPKK3/6 and MEK/ERK1/2 phosphorylation (Jung et al 2013). *Acanthopanax senticosus* also exhibited significantly higher immunomodulatory activities against lymphocyte proliferation in vitro. It also demonstrated pronounced reductive power, strong hydroxyl radical-scavenging activity, moderate superoxide radicals and 2,2-diphenyl-1-picrylhydrazyl radical-scavenging activities. This however needs to be further explored for use in functional foods or medicine (Chen et al 2011).

### Glycaemic control and insulin-sensitising effect

Animal studies have indicated a potential for hypoglycaemic effects when used intravenously. Syringin appears to enhance glucose utilisation (Niu et al 2008) and lower plasma glucose levels in animal experiments. The effect may be due to an increase in the release of acetylcholine from nerve terminals, stimulating muscarinic M<sub>3</sub> receptors in pancreatic cells to increase insulin release (Liu et al 2008). Syringin may also enhance the secretion of beta-endorphin from the adrenal medulla to stimulate peripheral micro-opioid receptors, resulting in a decrease of plasma glucose in insulin-depleted diabetic rats (Niu et al 2007).

Eleutherans A–G exert marked hypoglycaemic effects in normal and alloxan-induced hyperglycaemic mice (Hikino et al 1986), and eleutherosides show an insulin-like action in diabetic rats (Dardymov et al 1978). However, these effects have not been borne out in human studies (Farnsworth et al 1985). A glucose tolerance study in db/db mice orally administered *Acanthopanax senticosus* lowered plasma glucose levels more than the control group 30 minutes after sucrose loading, without affecting plasma insulin levels, and significantly inhibited  $\alpha$ -glucosidase activity in the small-intestine mucosa (Watanabe et al 2010).

A small, double-blind, randomised, multiple, crossover study using 12 healthy participants actually showed an increase in postprandial plasma glucose at 90 and 120 minutes when 3 g Siberian ginseng was given orally 40 minutes before a 75-g oral glucose tolerance test (Sievenpiper et al 2004). More recently, oral administration of an aqueous extract of Siberian ginseng was shown to improve insulin sensitivity and delay the development of insulin resistance in rats (Liu et al 2005). As a result, further trials in people with impaired glucose tolerance and/or insulin resistance are warranted.

### Hepatoprotective

Animal studies have demonstrated that an intravenous extract of Siberian ginseng decreased thioacetamide-induced liver toxicity when given before and after thioacetamide administration (Shen et al 1991). More recently, oral administration of aqueous extract and polysaccharide was found to attenuate fulminant hepatic failure induced by D-galactosamine/lipopolysaccharide in mice, reducing serum aspartate aminotransferase, alanine aminotransferase and tissue necrosis factor- $\alpha$  levels (Park et al 2004). The protective effect is thought to be due to the water-soluble polysaccharides. Coadministration of Siberian ginseng may also act to enhance the action of amizole, improving the protective effect on hepatic antioxidant function and lipid metabolism (Kushnerova & Rakhmanin 2008). Diabetic rats treated with *Acanthopanax senticosus* plus metformin showed a more beneficial promotion for relieving the symptoms of diabetes and

reversing liver and kidney damage to normal level than only metformin administration (Fu et al 2012).

### Neuroprotective

Preliminary animal studies have suggested possible neuroprotective effects in transient middle cerebral artery occlusion in Sprague-Dawley rats. Infarct volume was reduced by 36.6% by inhibiting inflammation and microglial activation in brain ischaemia after intraperitoneal injection of a water extract of Siberian ginseng (Bu et al 2005). Similarly, intraperitoneal injection of Siberian ginseng was found to relieve damage to neurons following hippocampal ischaemia hypoxia and improve the learning and memory of rats with experimentally induced vascular dementia (Ge et al 2004). Siberian ginseng extract appears to protect against neuritic atrophy and cell death under amyloid beta treatment; the effect is thought to be due at least in part to eleutheroside B (Tohda et al 2008). The saponins present in Siberian ginseng have also been shown to protect against cortical neuron injury induced by anoxia/reoxygenation by inhibiting the release of NO and neuron apoptosis in vitro (Chen et al 2004).

Using a cerebral-ischaemic rat model, researchers demonstrated that an ethanolic extract of Siberian ginseng, given at the time of the ischaemic event and 90 minutes after, was protective against delayed neuronal cell death and also attenuated inflammatory markers, suggesting that some of the protective effect may be attributed to an anti-inflammatory effect (Lee et al 2012). In the Parkinson-induced mice model, oral administration of Siberian ginseng at low dose, 45 mg/kg, and high dose, 182 mg/kg, increased dopamine levels in the substantia nigra and enhanced coordination and motor function (Liu et al 2012). The researchers noted that more dopamine was present in the low-dose group (equivalent to 9 g/day for humans), suggesting that therapeutic effect is not necessarily a function of increasing dose.

In an in vitro depression model induced by stress hormone corticosterone, Siberian ginseng prolonged cell life and may account for the antidepressant effects reported in in vivo models (Wu et al 2013). And in sleep-deprived mice, treatment with eleutheroside E reduced the monoamines induced through sleep deprivation and restored their behaviour, suggesting that this component of Siberian ginseng could be valuable for the stress experienced from chronic sleeplessness (Huang et al 2011).

## OTHER ACTIONS

### Anticoagulant and antiplatelet effects

Animal studies have demonstrated prevention against thrombosis induced by immobilisation (Shakhmatov et al 2007), and the 3,4-dihydroxybenzoic acid constituent of Siberian ginseng has demonstrated antiplatelet activity in vivo (Yun-Choi et al 1987). A

controlled trial using Siberian ginseng tincture for 20 days in 20 athletes detected a decrease in the blood coagulation potential and activity of the blood coagulation factors that are normally induced by intensive training of the athletes (Azizov 1997). Whether the effects also occur in non-athletes is unknown.

### Antiallergic

In vitro studies demonstrate that Siberian ginseng has antiallergic properties in mast cell-mediated allergic reactions (Jeong et al 2001). The mechanism appears to involve inhibition of histamine, tumour necrosis factor- $\alpha$  and interleukin-6.

### Antioxidant

Results using aqueous extracts of *Acanthopanax senticosus* indicated that it protects against oxidative stress which may be generated via the induction of Nrf2 and related antioxidant enzymes (Wang et al 2010). It was shown that *A. senticosus* orally administered to rats experienced significantly lower oxidative stress, as indicated by the expression of certain genes (Kim et al 2010).

### Cardioprotective

Oral administration of Siberian ginseng (1 mL/kg) to rats for 8 days prevented stress-induced heart damage and chronic administration increased beta-endorphin levels and improved cardiac tolerance to D,L-isoproterenol and arrhythmia caused by adrenaline. The cardioprotective and antiarrhythmic effect may be related to an increase in endogenous opioid peptide levels (Maslov & Guzarova 2007). Benefits following a 45-minute coronary artery occlusion were not demonstrated in this study (Maslov & Guzarova 2007) but have been in studies using Siberian ginseng in a polypharmacy combination known as Tonizid (Lishmanov et al 2008).

### Radioprotective

Animal studies have found that administration of Siberian ginseng prior to a lethal dose of radiation produced an 80% survival rate in mice (Miyanomae & Frindel 1988). Interestingly,  $\alpha$ -difluoromethylornithine (DFMO), a chemotherapeutic drug which has a cytostatic effect, had a more pronounced effect than Siberian ginseng root tincture (SGRT) in radiation-induced carcinogenesis; however, in combination DFMO and SGRT increased survival rate and decreased frequency and multiplicity of malignant and benign tumours in irradiated rats (Bespalov et al 2013).

### Vascular relaxant

In vitro studies have demonstrated vasorelaxant effects for Siberian ginseng. The effect is thought to be endothelium-dependent and mediated by NO and/or endothelium-derived hyperpolarising factor, depending on the size of the blood vessel. Other vasorelaxation pathways may also be involved (Kwan et al 2004).

## CLINICAL USE

Due to its long history of use and myriad pharmacological actions, Siberian ginseng is used for many varied indications.

### Stress

Siberian ginseng is widely used to treat individuals with nervous exhaustion or anxiety due to chronic exposure to stress or what is now termed 'allostatic load situations'. The biochemical effects on stress responses observed in experimental and human studies provide a theoretical basis for this indication (Abramova et al 1972, Gaffney et al 2001a).

One placebo-controlled study conducted over 6 weeks investigated the effects of an ethanolic extract of Siberian ginseng (8 mL/day, equivalent to 4 g/day dried root). In the study, active treatment resulted in increased cortisol levels, which may be consistent with animal research, suggesting a threshold of stress below which Siberian ginseng increases the stress response and above which it decreases the stress response (Gaffney et al 2001b). In a randomised, controlled study in 144 participants suffering from asthenia and reduced working capacity related to chronic stress, *Eleutherococcus senticosus* improved parameters over time and a significant difference was found in mental fatigue and restlessness, both in favour of *E. senticosus* versus 2-day professional stress management training (Schaffler et al 2013).

### Fatigue

Siberian ginseng is used to improve physical and mental responses during convalescence or fatigue states. While traditional stimulants can produce a temporary increase in work capacity followed by a period of marked decrease, the initial increase in performance from adaptogens is followed by only a slight dip and performance remains above basal levels (Panossian et al 1999). The ability of Siberian ginseng to increase levels of noradrenaline, serotonin, adrenaline and cortisol provides a theoretical basis for its use in situations of fatigue. However, controlled studies are limited.

A randomised, double-blind, placebo-controlled trial of 300 mg/day (*E. senticosus* dry extract) for 8 weeks assessed health-related quality-of-life scores in 20 elderly people. Improvements were observed in social functioning after 4 weeks of therapy but did not persist to the 8-week time point. It would appear that improvements diminish with continued use (Cicero et al 2004), which may help to explain the practice of giving Siberian ginseng for 6 weeks with a 2-week break before repeating.

A randomised placebo-controlled trial evaluated the effectiveness of Siberian ginseng in chronic fatigue syndrome (CFS). No significant improvements were demonstrated overall; however, subgroup analysis showed improvements in fatigue severity and duration ( $P < 0.05$ ) in CFS sufferers with less severe fatigue at 2-month follow-up (Hartz

et al 2004). Further studies are required to determine whether Siberian ginseng may be a useful therapeutic option in cases of mild to moderate fatigue.

#### IN COMBINATION

A double-blind, placebo-controlled, randomised study of single-dose effects of a standardised fixed combination of *Rhodiola rosea*, *Schisandra chinensis* and *Eleutherococcus senticosus* extracts on mental performance, such as attention, speed and accuracy, in tired individuals performing stressful cognitive tasks showed that subjects gained improved attention and increased speed and accuracy during stressful cognitive tasks, in comparison to placebo (Aslanyan et al 2010).

Commission E approves the use of Siberian ginseng as a tonic in times of fatigue and debility, for declining capacity for work or concentration and during convalescence (Blumenthal et al 2000). In practice, it is often used in low doses in cases of fatigue due to chronic stress (Gaffney et al 2001a).

#### Cardioprotective

Due to its effects on vascular relaxation, stress response, anti-inflammatory and antioxidant activities, it is also believed to be a good tonic for the heart. Furthermore, a 2008 study shows that *Acanthopanax senticosus* significantly decreased serum low-density lipoprotein (LDL) ( $127.54 \pm 29.79$  mg/dL vs  $110.33 \pm 22.26$  mg/dL) and the LDL/high-density lipoprotein ratio ( $2.40 \pm 0.65$  vs  $2.11 \pm 0.58$ ) after supplementation in 40 postmenopausal women (Lee et al 2008).

#### Ergogenic aid

While initial animal studies showed promise for improving weight gain, increasing organ and muscle weight, improving the use of glycogen and metabolism of lactic and pyruvic acids (Farnsworth et al 1985, Wagner et al 1985), randomised controlled trials have produced inconsistent results in healthy individuals and athletes (Asano et al 1986, Dowling et al 1996, Eschbach et al 2000, Goulet & Dionne 2005, Kuo et al 2010, Mahady et al 2000). The evidence to date is inconsistent and further research is required to determine the potential role for Siberian ginseng in improving performance in sports.

In the mid-1980s, a Japanese controlled study conducted on six male athletes over 8 days showed that Siberian ginseng extract (2 mL twice daily) improved work capacity compared with a placebo (23.3 vs 7.5%) in male athletes, owing to increased oxygen uptake ( $P < 0.01$ ). Time to exhaustion (stamina) also increased (16.3 vs 5.4%,  $P < 0.005$ ) (Asano et al 1986). Other research however has failed to confirm these effects (Dowling et al 1996, Eschbach et al 2000).

A randomised, double-blind, crossover trial using a lower dose of 1200 mg/day Siberian ginseng for 7 days reported that treatment did not alter steady-state substrate use or 10-km cycling performance time (Eschbach et al 2000). Additionally, an 8-week,

double-blind, placebo-controlled study involving 20 experienced distance runners failed to detect significant changes to heart rate, oxygen consumption, expired minute volume, respiratory exchange ratio, perceived exertion or serum lactate levels compared with placebo. Overall, both submaximal and maximal exercise performance were unchanged (Dowling et al 1996).

More recently, when recreationally trained males were treated for 8 weeks with *Eleutherococcus senticosus* supplementation there was marked enhancement in endurance time and elevated cardiovascular functions and this altered the metabolism of plasma free fatty acid and glucose after 8-week supplementation. This is the first well-controlled study that showed positive effects of Siberian ginseng on endurance exercise capacity in human clinical studies (Kuo et al 2010).

Siberian ginseng may however reduce blood coagulation factors induced by intensive training in athletes (Azizov 1997) and has been shown in combination with micronutrients to improve iron metabolism and immunological responsiveness in 39 high-grade unarmed self-defence sportsmen (Nasolodin et al 2006). Whether these effects also occur in other scenarios is yet to be established.

Siberian ginseng does not appear on the 2014 Prohibited List of the World Anti-doping Agency (WADA 2014).

#### Prevention of infection

Due to the herb's ability to directly and indirectly modulate immune responses, it is also used to increase resistance to infection. One double-blind study of 1000 Siberian factory workers supports this, reporting a 50% reduction in general illness and a 40% reduction in absenteeism over a 12-month period, following 30 days' administration of Siberian ginseng (Farnsworth et al 1985). More recently, a 6-month controlled trial in males and females with recurrent herpes infection found that Siberian ginseng (2 g/day) successfully reduced the frequency of infection by 50% (Williams 1995).

In practice, Siberian ginseng is generally used as a preventive medicine, as administration during acute infections is widely thought to increase the severity of the illness, although this has not been borne out in controlled studies using Siberian ginseng in combination with other herbs.

#### IN COMBINATION

A small randomised controlled trial demonstrated a significant reduction in the severity of familial Mediterranean fever in children using a combination of Siberian ginseng with licorice, andrographis and schisandra (Amaryan et al 2003), and a combination of Siberian ginseng with schisandra and rhodiola was found to expedite the recovery of patients with acute non-specific pneumonia (Narimanian et al 2005).

There is also clinical research conducted with an oral combination of Siberian ginseng and *Andrographis paniculata*, which is commonly known as Kan Jang,

showing significant improvement of cold and flu symptoms (see *Andrographis* monograph for details).

### Herpes simplex virus type 2 infection

Siberian ginseng (standardised to eleutheroside 0.3%) taken orally for 3 months reduced the severity, duration and frequency of genital herpes outbreaks; however more research is required before recommendations can be made about use (Ulbricht 2012).

### Cancer therapy

A polypharmacy preparation known as AdMax, which contains *Eleutherococcus senticosus* in combination with *Leuzea carthamoides*, *Rhodiola rosea* and *Schizandra chinensis*, has been shown to boost suppressed immunity in patients with ovarian cancer who are subject to chemotherapy (Kormosh et al 2006). Which herb or combination of herbs is responsible for the effect is unclear.

### OTHER USES

Given the herb's ability to increase levels of serotonin and noradrenaline in animal studies (Abramova et al 1972), a theoretical basis exists for the use of Siberian ginseng in depression.

In traditional Chinese medicine, Siberian ginseng is used to encourage the smooth flow of Qi and blood when obstructed, particularly in the elderly, and is viewed as a general tonic. It is therefore used for a myriad of indications, usually in combination with other herbal medicines. Numerous studies use Siberian ginseng in combination with other adaptogens, such as *Rhodiola rosea* and *Schizandra chinensis*, which may potentially act synergistically for improved effects.

### DOSAGE RANGE

- 1–4 g/day dried root or equivalent preparations.
- Fluid extract (1:2): 2–8 mL/day (15–55 mL/week).
- Tincture (1:5): 10–15 mL/day.
- Acute dosing: 4 mL in a single dose before activity.

Extracts with standardised levels of eleutheroside E (syringin) (>0.5 mg/mL) are recommended. Russian and Korean sources appear to have higher levels of this constituent. So, variations in therapeutic activity may be predicted (Wagner et al 1982). As there can be a significant product variability in the level of eleutherosides between capsules and liquids, standardisation may be necessary for quality assurance (Harkey et al 2001).

In practice, Siberian ginseng is often given for 6 weeks with a break of at least 2 weeks before resuming treatment.

### ADVERSE REACTIONS

Clinical trials of 6 months' duration have shown no side effects from treatment (Bohn et al 1987). High doses may cause slight drowsiness, irritability, anxiety, mastalgia, palpitations or tachycardia,

#### Clinical note — Case reports of Siberian ginseng need careful consideration

Some adverse reactions attributed to Siberian ginseng have subsequently been found to be due to poor product quality, herbal substitution and/or interference with test results. For example, initial reports linking maternal ginseng use to neonatal androgenisation are now suspected to be due to substitution with another herb, *Periploca sepium* (called Wu jia or silk vine), as American herb companies importing Siberian ginseng from China have been known to be supplied with two or three species of *Periploca* (Awang 1991). Additionally, rat studies have failed to detect significant androgenic action (Awang 1991, Waller et al 1992) for Siberian ginseng.

Another example is the purported interaction between digoxin and Siberian ginseng, which was based on a single case report of a 74-year-old man found to have elevated digoxin levels for many years (McRae 1996). It was subsequently purported that the herbal product may have been adulterated with digitalis. Additionally, Siberian ginseng contains glycosides with structural similarities to digoxin that may modestly interfere with digoxin fluorescence polarisation (FPIA), microparticle enzyme (MEIA) results, falsely elevating digoxin values with FPIA and falsely lowering digoxin values with MEIA (Dasgupta & Reyes 2005). It should be noted that measuring free digoxin does not eliminate these modest interferences in serum digoxin measurement by the Digoxin III assay (Dasgupta et al 2008).

although these side effects may be more relevant to *Panax ginseng*.

### SIGNIFICANT INTERACTIONS

As controlled studies are not available, interactions are currently speculative and based on evidence of pharmacological activity and case reports. Studies have reported that normal doses of Siberian ginseng are unlikely to affect drugs metabolised by CYP2D6 or CYP3A4 (Donovan et al 2003).

### Anticoagulants

An in vivo study demonstrated that an isolated constituent in Siberian ginseng has anticoagulant activity (Yun-Choi et al 1987), and a clinical trial found a reduction in blood coagulation induced by intensive training in athletes (Azizov 1997). Whether these effects also occur in non-athletes is unknown. Given that a study looking at the concomitant application of Kan Jang (Siberian ginseng in combination with andrographis) and warfarin did not produce significant effects on the pharmacokinetics or pharmacodynamics of the drug (Hovhannisyan et al 2006), a negative clinical effect is unlikely.

## Chemotherapy

An increased tolerance for chemotherapy and improved immune function has been demonstrated in women with breast (Kupin 1984, Kupin & Pol-evaia 1986) and ovarian (Kormosh et al 2006) cancer undergoing chemotherapy treatment. Caution — as coadministration may theoretically reduce drug effects. However, beneficial interaction may be possible under medical supervision.

### **?** CONTRAINDICATIONS AND PRECAUTIONS

Some authors suggest that high-dose Siberian ginseng should be avoided by those with cardiovascular disease or hypertension (blood pressure > 80/90 mmHg) (Mahady et al 2000). Others merely suggest a caution, as reports are largely unsubstantiated (Holford & Cass 2001). As such, it is recommended that people with hypertension should be monitored.

### Practice points/Patient counselling

- Siberian ginseng appears to alter the levels of different neurotransmitters and hormones involved in the stress response, chiefly at the HPA axis.
- It is widely used to treat individuals with nervous exhaustion or anxiety due to chronic exposure to stress or what are now termed 'allostatic load situations'. It is also recommended during convalescence or fatigue to improve mental and physical responses.
- Siberian ginseng may increase resistance to infection and has been shown to reduce frequency of genital herpes outbreaks with long-term use.
- The herb is popular among athletes in the belief that endurance, performance and power may improve with its use, but clinical studies have produced inconsistent results.
- It is not recommended for use in pregnancy, and people with hypertension should be monitored if using high doses.
- In a study of elderly people with hypertension, 8 weeks of Siberian ginseng use did not affect blood pressure control (Cicero et al 2004).
- Due to possible effects on glycaemic control (Sievenpiper et al 2004), care should be taken in people with diabetes until safety is established. Suspend use 1 week before major surgery.
- Traditional contraindications include hormonal changes, excess energy states, fever, acute infection, concurrent use of other stimulants and prolonged use.

## Diabetic medications

Claims that Siberian ginseng has hypoglycaemic effects are based on intravenous use in animal studies and not observed in humans, for whom oral intake may actually increase postprandial glycaemia (Sievenpiper et al 2004). Observe diabetic patients taking ginseng.

## Influenza virus vaccine

Ginseng may reduce the risk of postvaccine reactions (Zykov & Protasova 1984), a possible beneficial interaction.

### **S** PREGNANCY USE

Insufficient reliable information is available, but the herb is not traditionally used in pregnancy.

### **!** PATIENTS' FAQs

#### *What will this herb do for me?*

Siberian ginseng affects many chemicals involved in switching on and off the body's stress responses. As such, it is used to improve wellbeing during times of chronic stress and enhance physical performance and recovery from exercise. The scientific research has yet to fully investigate its use in this regard; however, experimental findings suggest that the neuroprotective, anti-inflammatory and antioxidant properties of the herb may be responsible.

It may also boost immune function and reduce the frequency of genital herpes outbreaks. Evidence for improved performance in athletes is inconsistent so its role remains unclear.

#### *When will it start to work?*

Effects on stress levels should develop within 6 weeks, whereas immune responses develop within 30 days.

#### *Are there any safety issues?*

It should not be used in pregnancy, and high doses should be used with care by those with hypertension.

## Globe artichoke

**HISTORICAL NOTE** Artichoke has a long history of use as a vegetable delicacy and medicinal agent, and its cultivation in Europe dates back to ancient Greece and Rome. It was domesticated in Roman times, possibly in Sicily, and spread by the Arabs during the early Middle Ages. Traditional use of artichoke has always pertained to the liver, where it is considered to increase bile flow and act as a protective agent against various toxins. As such, it has been used for jaundice, dyspepsia, nausea, gout, pruritus and urinary stones. It is still a popular medicine in Europe today.

### COMMON NAME

Artichoke

### OTHER NAMES

Alcachofa, artichaut, alcaucil, carciofo, cynara, cynaræ folium (ESCOP 2009)

### BOTANICAL NAME/FAMILY

*Cynara cardunculus* L., formerly *Cynara scolymus* L. (family Asteraceae) (WHO 2009)

### PLANT PART USED

Leaf

### CHEMICAL COMPONENTS

Key constituents of the leaf include phenolic acids, mainly caffeic acid derivatives (e.g. chlorogenic acid,

cynarin), sesquiterpenes, lactones (e.g. cynaropicrin) and flavonoids (e.g. cynaroside, luteolin derivatives, anthocyanin), phytosterols, inulin and free luteolin.

### MAIN ACTIONS

The main pharmacologically active constituents are thought to be the phenolic acids and flavonoids.

#### Antioxidant

Artichoke leaf extract (ALE) exerts antioxidant effects, according to in vitro and clinical studies (Juzyszyn et al 2010, Kusku-Kiraz et al 2010, Skarpanska-Stejnborn et al 2008, Speroni et al 2003). According to a double-blind trial, ALE (400 mg three times daily for 5 weeks) significantly elevates plasma total antioxidant capacity compared to placebo (Skarpanska-Stejnborn et al 2008). Even

edible artichokes were able to protect hepatocytes from oxidative stress (Miccadei et al 2008). ALE significantly inhibited the oxidation of the mitochondrial respiratory chain complex I and II substrates (Juzyszyn et al 2010).

### Hepatoprotective

The hepatoprotective action of *Cynara scolymus* is synonymous with its choleric and antioxidant actions (Speroni et al 2003). As well as improving the synthesis and flow of bile (Saenz et al 2002, Speroni et al 2003) it can protect the bile canalicular membrane from chemically induced distortions (Gebhardt 2002b).

Tests with primary hepatocyte cultures and animal models support the suggestion that the hepatoprotective effect of globe artichoke may be due to its direct antioxidant action (Gebhardt 1997, Mehmetcik et al 2008, Miccadei et al 2008), as well as indirectly by increasing glutathione peroxidase by up to 39.5% in rat livers (Mehmetcik et al 2008).

### Choleric and cholagogue

Choleric activity was reported in a randomised, double-blind, placebo-controlled study, with maximum effects on mean bile secretion observed 60 minutes after a single dose (Kirchhoff et al 1994). A significant increase in bile flow was also demonstrated in studies using isolated perfused rat liver in vivo after acute treatment, as well as after repeated administration (Saenz et al 2002).

A study that evaluated the choleric and hepatoprotective effects of four commercially available ALEs in terms of their cynarin, chlorogenic acid and caffeoyl derivatives content determined that the effect was dose-dependent: the extract with the highest concentration of phenolic derivatives exerted the strongest choleric and antioxidant effects (Speroni et al 2003). However chlorogenic acid or cynarin alone did not exert a protective effect, suggesting a synergistic relationship between plant components and effects.

### Lipid lowering

ALE inhibited cholesterol biosynthesis in primary cultured rat hepatocytes (Gebhardt 1998); indirect modulation of hydroxymethylglutaryl-CoA-reductase activity is the most likely inhibitory mechanism. When several known constituents were screened for activity, cynaroside, and particularly its aglycone, luteolin, were mainly responsible for the effect (Gebhardt 2002). Clinical studies have found that ALE compared to placebo causes a modest but statistically significant reduction in total cholesterol (Bundy et al 2008, Skarpanska-Stejnborn et al 2008, Wider et al 2009) and low-density lipoprotein (LDL) cholesterol (Wider et al 2009).

In addition, ALE lowered plasma cholesterol levels by a mechanism involving greater faecal excretion of neutral bile acids and sterols, an effect that was more pronounced in male compared to female hamsters (Qiang et al 2012).

### OTHER ACTIONS

According to German Commission E, human studies have confirmed carminative, spasmolytic and antiemetic actions (Blumenthal et al 2000). The antispasmodic activity of some fractions and cynaropicrin, a sesquiterpene lactone from *Cynara* spp., has been confirmed in vivo (Emendorfer et al 2005).

Artichoke administration (500–1500 mg/kg) led to a significant decrease in postprandial glycaemia in normal and obese rats (Fantini et al 2011).

Studies with implications for atherosclerosis using artichoke leaf juice showed that it protected in vitro endothelial cells and improved brachial flow-mediated vasodilation, most likely by its antioxidant constituents (Juzyszyn et al 2008, Lupattelli et al 2004).

Fresh artichoke buds (115–125 g) were found to have an apoptotic effect in the human breast cancer cell line, oestrogen receptor-negative (MDA-MB231) (Mileo et al 2012). Previously, the artichoke buds were found to have an apoptotic effect in a human hepatoma cell line (HepG2) (Miccadei et al 2008).

Ten per cent fish oil and 1 g of artichoke leaves or heads administered for 25 days was protective against diethylnitrosamine-induced hepatocellular carcinoma in rats (Metwally et al 2011).

### Pharmacokinetics

Studies further confirm the bioavailability of the metabolites of hydroxycinnamic acids after ingestion of cooked edible globe artichoke (Azzini et al 2007).

Cooked baby artichokes had higher total phenolics, caffeic acid, chlorogenic acid and cynarin content ( $P < 0.05$ ) compared to cooked mature artichokes (Lutz et al 2011).

#### Clinical note — Inulin: a natural prebiotic

Inulin is a plant-derived carbohydrate that is not digested or absorbed in the small intestine, but is fermented in the colon by beneficial bacteria. It functions as a prebiotic, stimulating growth of bifidobacteria in the intestine, and has been associated with the enhanced function of the gastrointestinal system and immune system (Di Bartolomeo et al 2013, Lopez-Molina et al 2005). Increasing levels of beneficial bacteria, such as bifidobacteria, allow them to 'outcompete' potentially detrimental organisms and improve the health of the host. Inulin also increases calcium and magnesium absorption, influences blood glucose levels and reduces the levels of cholesterol and serum lipids. Globe artichoke contains 3% of fresh-weight inulin and smaller amounts are found in the leaves. According to animal studies, this concentration is sufficient to favourably affect the intestinal health (Goñi et al 2005).

## CLINICAL USE

Treatment of digestive complaints (e.g. dyspepsia, feeling of fullness, flatulence, nausea, stomach ache and vomiting). Adjunct treatment of mild to moderate hypercholesterolaemia (WHO 2009).

### Hyperlipidaemia

European Scientific Co-operative of Phytotherapy (ESCOP) approves the use of artichoke leaf as an adjunct to a low-fat diet in the treatment of mild to moderate hyperlipidaemia (ESCOP 2003, 2009).

Overall, evidence from five uncontrolled studies, case series and placebo-controlled trials suggests that ALE and cynarin have lipid-lowering effects and a possible role as adjunctive therapy in hyperlipidaemia (Ulbricht & Basch 2005).

Data are available from both controlled and uncontrolled studies that have investigated the effects of ALE in hyperlipidaemia. Most studies use Hepar SL forte (600 mg) or Valverde Artischocke bei Verdauungsbeschwerden (artichoke dry extract) containing 450 mg of herbal extract as a coated tablet.

A Cochrane systematic review that analysed the results of three studies concluded that ALE appears to have a modest positive effect on the levels of total cholesterol and LDL; however, the evidence is not compelling enough to recommend it as a treatment option for hypercholesterolaemia. The results from the two controlled studies suggest that patients with severely elevated total cholesterol levels at baseline might benefit more from ALE than those with moderately elevated levels (Wider et al 2009). One of the studies was a randomised, placebo-controlled, double-blind, multicentre trial involving 143 subjects with total cholesterol levels > 7.3 mmol/L (>280 g/dL) (Englisch et al 2000). A dose of 1800 mg ALE was administered daily for 6 weeks. Active treatment resulted in 18.5% decrease in serum cholesterol compared with 8.6% for placebo, a result that was significant. No differences were observed between the groups for blood levels of either high-density lipoprotein (HDL) or triglycerides. Although dietary habits were recorded, the food intake was not strictly controlled in the entire patient sample.

The second randomised, placebo-controlled, double-blind study involved 44 healthy volunteers and compared 1920 mg artichoke extract daily to placebo over a 12-week treatment period. No significant effects on serum cholesterol levels were observed in this study; however, subgroup analyses suggested that patients with higher initial total cholesterol levels experienced a significant reduction in total cholesterol levels compared to placebo (Petrowicz et al 1997, Wider et al 2009).

Two placebo-controlled clinical studies were published which further demonstrated modest but significant reductions in total cholesterol for ALE. Bundy et al (2008) conducted a 12-week, randomised study of 75 adults which found that treatment with artichoke leaf (1280 mg of a standardised

extract, PE 4–6:1) significantly reduced plasma total cholesterol by an average of 4.2% (from 7.16 mmol/L [SD 0.62] to 6.86 mmol/L [SD 0.68]) compared with controls, although no significant differences were observed for LDL cholesterol, HDL cholesterol or triglyceride levels.

A smaller randomised, double-blind study of 22 volunteers found that oral ALE (400 mg three times daily) significantly reduced serum total cholesterol levels by the end of the 5-week study compared to placebo (Skarpanska-Stejnborn et al 2008).

In a randomised, double-blind, placebo-controlled clinical trial, 92 patients with mild hypercholesterolaemia (5.4–7.0 mmol/L) took two daily doses of 250 mg of standardised ALE for 8 weeks. The mean HDL cholesterol (HDL-C) significantly increased in the ALE group compared to the placebo group (primary outcome measure). The LDL:HDL ratio significantly improved in the supplemented group but not in the placebo group (Rondanelli et al 2013). It is postulated that chlorogenic acid in ALE may enhance the activity of paroxonase, an enzyme which prevents the oxidation of HDL-C.

### Dyspepsia

The German Commission E approves artichoke leaf and preparations made from artichoke leaf as a choleric agent for dyspeptic problems (Blumenthal et al 2000). ALE has been studied as a bile secretion stimulant and primarily recommended in this way for non-ulcer dyspepsia.

A double-blind, randomised, placebo-controlled trial of 247 patients with functional dyspepsia (persistent or recurrent pain or discomfort in the upper abdomen with one or more of the following symptoms: early satiety, postprandial fullness, bloating and nausea) found that treatment with two capsules of 320 mg ALE LI 220 (Hepar SL) taken three times daily significantly improved overall symptoms over the 6 weeks compared with placebo (Holtmann et al 2003). Additionally, active treatment significantly improved global quality of life (QOL) scores compared with the placebo.

A randomised, open study of 454 subjects investigated the efficacy of a low-dose ALE (320 mg or 640 mg daily) on amelioration of dyspeptic symptoms and improvement of QOL (Marakis et al 2002). Both doses achieved a significant reduction of all dyspeptic symptoms, with an average reduction of 40% in global dyspepsia score. Although no differences in primary outcome measures were reported between the two treatment groups, the higher dosage resulted in greater improvements in anxiety.

An uncontrolled study of 553 patients with non-specific digestive disorders (dyspeptic discomfort, functional biliary colic and severe constipation) demonstrated a significant reduction of symptoms after 6 weeks of treatment with artichoke extract. Symptoms improved by an average of 70.5%, with strongest effects on vomiting (88.3%), nausea (82.4%), abdominal pain (76.2%), loss of appetite

(72.3%), constipation (71.0%), flatulence (68.2%) and fat intolerance (58.8%). In 85% of patients, the global therapeutic efficacy of artichoke extract was judged by the doctors as excellent or good (Fintelmann 1996).

### Constipation

In a randomised, double-blind trial, 20 patients with constipation were given 180 g per day of artichoke alone or artichoke enriched with *Lactobacillus paracasei* ( $2 \times 10^{10}$  colony-forming unit) for 15 days. The results showed that the Gastrointestinal Symptom Rating Scale for constipation was significantly lower in the probiotic-enriched artichoke group compared to the ordinary artichoke group (Riezzo et al 2012).

### Appetite control and glycaemia reduction — in combination

A double-blind randomized controlled trial of 39 overweight patients compared placebo to 300 mg of standardised *Phaseolus vulgaris* (kidney bean) and 600 mg standardised *Cynara scolymus* flowering bud extract taken daily in three divided doses for 2 months. The participants were also placed on a concurrent hypocaloric diet. Active treatment resulted in a significant increase in the Haber's satiety scale in the treatment group compared to the placebo group (primary outcome measure). There was also a significant reduction in glycaemia (homeostasis model assessment [HOMA]) and the quantitative insulin sensitivity check index [QUICKI]), indicating that *Phaseolus vulgaris* and *Cynara scolymus* may be useful in the treatment of overweight patients with dysglycaemia (Rondanelli et al 2011).

### Hepatitis C

An open prospective study of 17 chronic hepatitis C patients administered 3200 mg of standardised ALE for 12 weeks found that no patients had alanine aminotransferase normalisation (primary outcome measure). Significant improvements in fatigue and joint pain occurred at week 4, but this improvement was lost at week 12. However, as the numbers in this study were small, the trial was of short duration and there was no control group, it is hard to draw meaningful clinical conclusions from this study (Huber et al 2009).

### Irritable-bowel syndrome (IBS)

ALE appears to have substantial benefits in IBS, according to the available evidence; however, large controlled studies are required to confirm these observations. The antispasmodic and prebiotic activities of artichoke leaf are likely to contribute to the beneficial effects produced by this preparation.

A subgroup of patients with IBS symptoms was identified from a sample of subjects with dyspeptic syndrome who were being monitored for 6 weeks (Walker et al 2001). Analysis of the data revealed that 96% of patients rated ALE as better than or at least equal to previous therapies administered for

their symptoms. Doctors also provided favourable reports on the effects of ALE in these patients.

In a study of 208 adults with IBS, changes in symptoms were observed before and after a 2-month intervention period (Bundy et al 2004). A significant reduction in the incidence of IBS by 26.4% and a significant shift in self-reported usual bowel pattern towards 'normal' were also reported after treatment. The Nepean Dyspepsia Index (NDI) total symptom score significantly decreased by 41% after treatment and there was a significant 20% improvement in the NDI total QOL score.

### OTHER USES

Traditional uses include treatment for jaundice, dyspepsia, nausea, gout, pruritus and urinary stones. Due to its choleric effect, it has also been used to improve fat digestion.

Wild artichoke significantly restores proper vasomotion after simulation of oxidative stress in rat models. This may have clinical significance for treatment in the elderly, where a progressive loss of vascular endothelial function and concurrent loss of vasomotor control are frequently seen (Rossoni et al 2005). The antioxidant activity of artichoke has been shown to offer a protective effect on gonads of cadmium-treated rats (Gurel et al 2007).

### DOSAGE RANGE

- 1:2 liquid extract: 3–8 mL/day in divided doses.
- 6 g daily of dried cut leaves, pressed juice of the fresh plant or equivalent.

### According to clinical studies

- Hyperlipidaemia: 4–9 g/day of dried leaves or 1800 mg/day of ALE.
- Dyspepsia: ALE 640 mg/day.
- IBS: ALE 640 mg/day.

### ADVERSE REACTIONS

Studies with hyperlipidaemic subjects indicate that globe ALE is generally well tolerated. Mild symptoms of flatulence, hunger and weakness were reported in approximately 1% of subjects when the fresh plant was used (Fintelmann 1996). Contact dermatitis is possible with the fresh plant and urticaria–angio-oedema has been reported in one case of ingestion of raw and boiled herb (Mills & Bone 2005).

### ⚠️ CONTRAINDICATIONS AND PRECAUTIONS

Not to be used by people with known allergy to globe artichoke or other members of the Asteraceae/Compositae family of plants.

Herbs with choleric and cholagogue activities should be used with caution by people with bile duct obstruction (Blumenthal et al 2000), acute or severe hepatocellular disease (e.g. cirrhosis), septic cholecystitis, intestinal spasm or ileus, liver cancer or with unconjugated hyperbilirubinaemia (Mills & Bone 2005).

## SIGNIFICANT INTERACTIONS

None known.

### PREGNANCY USE

Safety has not been scientifically established for the leaf extract. Dietary intake is likely to be safe.

### PATIENTS' FAQs

#### What will this herb do for me?

ALE effectively reduces symptoms in non-ulcer dyspepsia and possibly IBS. It also modestly reduces total cholesterol levels and improves digestion, flatulence and nausea.

#### When will it start to work?

Symptomatic relief in dyspepsia and IBS appears after 2–3 weeks of treatment; however, further improvements are possible with long-term use. A reduction in cholesterol may take 4–6 weeks and is best achieved when combined with a low-fat Mediterranean diet.

#### Are there any safety issues?

The extract is well tolerated with few side effects, but should not be used by people with known allergy to globe artichoke or other members of the Asteraceae/Compositae family of plants. It should be used with caution in bile duct obstruction,

acute or severe hepatocellular disease (e.g. cirrhosis), septic cholecystitis, intestinal spasm or ileus, liver cancer or in people with unconjugated hyperbilirubinaemia.

### Practice points/Patient counselling

- ALE has antioxidant, choleric, apoptotic, diuretic, antispasmodic and lipid-lowering activity and hepatoprotective, hypoglycaemic, chemopreventive and antiemetic effects.
- According to controlled clinical trials, ALE has a modest but significant effect in lowering total cholesterol and LDL levels, and may increase HDL cholesterol levels. ESCOP recommends that a low-fat diet should also be undertaken when ALE is used for mild to moderate hyperlipidaemia.
- ALE is an effective symptomatic treatment for non-ulcer dyspepsia and shows promise for IBS.
- ALE may be beneficial in overweight patients with dysglycaemia.
- Include baby artichokes in your diet for optimal antioxidant activity and to improve beneficial bacteria in the gut.
- The extract is well tolerated, with few side effects, but should not be used by people with known allergy to globe artichoke or other members of the Asteraceae/Compositae family of plants. It should be used with caution in bile duct obstruction, acute or severe hepatocellular disease (e.g. cirrhosis), septic cholecystitis, intestinal spasm or ileus or liver cancer or in people with unconjugated hyperbilirubinaemia.

## Glucosamine

### OTHER NAMES

D-Glucosamine, amino monosaccharide, glucosamine sulfate, glucosamine hydrochloride, glucosamine hydroiodide, N-acetyl D-glucosamine, 2-amino-2-deoxy-beta-D-glucopyranose

### BACKGROUND AND RELEVANT PHARMACOKINETICS

Glucosamine is a naturally occurring substance that is required for the production of proteoglycans, mucopolysaccharides and hyaluronic acid, which are substances that make up joint tissue, such as articular cartilage, tendons and synovial fluid. It is also a component of blood vessels, heart valves and mucus secretions (Kelly 1998).

Glucosamine sulfate is 90% absorbed after oral administration. The bioavailability is approximately 20% after first-pass metabolism (Aghazadeh-Habashi et al 2002). Unbound glucosamine is concentrated in the articular cartilage and the elimination half-life is 70 hours, with excretion as CO<sub>2</sub> in expired air, as well as by the kidneys and in faeces (Setnikar & Canali 1993). A study of the pharmacokinetics of glucosamine sulfate in humans found that it is rapidly absorbed after oral administration and its elimination half-life was tentatively estimated to average 15 hours, therefore supporting once-daily dosing (Persiani et al 2005). Twice-daily dosing with 500 mg of a time-release formula has also been shown to provide comparable serum levels after 24 hours as three divided doses of 500 mg (Basak et al 2004).

A further study suggests that glucosamine is bioavailable both systemically and at the joint, and that steady state concentrations in human plasma and synovial fluid were correlated and in line with levels

deemed effective in in vitro studies (Persiani et al 2007). This is contrasted by the suggestion from a study of 18 people with osteoarthritis (OA) which found serum glucosamine levels were significantly less than those previously shown to have in vitro effects (Biggee et al 2006). Similar results were reported in an equine study that found levels attained in serum and synovial fluid were 500-fold lower than those reported to modify chondrocyte anabolic and catabolic activities in tissue and cell culture experiments (Lavery et al 2005).

It is interesting to note that co-administration of glucosamine and chondroitin has been observed to reduce plasma levels of glucosamine compared to administration of glucosamine alone (Jackson et al 2010). There is also some research being undertaken to improve the intestinal absorption of glucosamine, due to the large first pass effect. For example, one study found that glucosamine oral formulations containing chitosan (0.5% w/v) (QD-Glu solution and QD-Glu tablet) increased C<sub>max</sub> (2.8-fold) and AUC<sub>0-infinity</sub> (2.5-fold) of glucosamine (Qian et al 2013). Further pharmacokinetic studies in beagle dogs demonstrated that QD-Glu solution and QD-Glu tablets had higher relative bioavailabilities of 313% and 186%, compared to several other glucosamine products (Wellesse solution and Voltaflex tablet respectively).

### CHEMICAL COMPONENTS

2-amino-2-deoxy-D-glucose

### FOOD SOURCES

Glucosamine is present in chitin from the shells of prawns and other crustaceans. As a supplement,

glucosamine is derived from marine exoskeletons or produced synthetically and is available in salt forms, including glucosamine sulfate, glucosamine hydrochloride, glucosamine hydroiodide and *N*-acetyl glucosamine. Glucosamine salts are likely to be completely ionised in the stomach, although clinical equivalence of the different salts has not been established. The purity and content of products has been questioned in the USA, where glucosamine is regarded as a food supplement and its quality was largely unregulated before GMP in 2010.

## MAIN ACTIONS

### Chondroprotective effect

Glucosamine is a primary substrate and stimulant of proteoglycan biosynthesis and inhibitor of proteoglycan degradation (Roman-Blas et al 2010). Glucosamine also stimulates synovial production of hyaluronic acid, a compound responsible for the lubricating and shock-absorbing properties of synovial fluid (McCarty 1998a, McCarty et al 2000) with the production of hyaluronic acid being higher in synovial cells than chondrocytes (Nagaoka et al 2012). Glucosamine also causes a statistically significant stimulation of proteoglycan production by chondrocytes from human osteoarthritic cartilage culture (Bassleer et al 1998) and modifies cultured OA chondrocyte metabolism by acting on protein kinase C, cellular phospholipase A<sub>2</sub>, protein synthesis and possibly collagenase activation (Piperno et al 2000).

In animal models of OA, glucosamine has demonstrated limited site-specific, partial disease-modifying effects (Tiralocche et al 2005) which have been attributed to the inhibition of the cytokine intracellular signalling pathways and reversal of the proinflammatory and joint-degenerating effects of IL-1 (Roman-Blas et al 2010). In rabbits, *N*-acetyl glucosamine has been found to produce proliferation of matured cartilaginous tissues and matured cartilage substrate in experimentally produced cartilaginous injuries (Tamai et al 2003) and partially reverse structural effects of OA, restoring cartilage thickness to that of healthy joints and preventing superficial fibrillation (López et al 2013). In another animal model, co-administration with chondroitin was seen to prevent both biochemical and histological alterations and provide pain reduction (Silva et al 2009). Glucosamine is also reported to induce osteoblastic cell differentiation and suppress the osteoclastic cell differentiation, thereby increasing bone matrix deposition and decreasing bone resorption to modulate bone metabolism in OA (Nagaoka et al 2012).

An *in vitro* study using bovine chondrocytes suggested that the experimental effects of glucosamine were sensitive to the model, dose and length of treatment (de Mattei et al 2002). In another *in vitro* study, exogenous glucosamine was found not to stimulate chondroitin sulfate synthesis in human chondrocytes and the capacity to form glucosamine from glucose was estimated to be far in excess of

the levels achievable through oral administration (Mroz & Silbert 2004). In human trials, glucosamine is suspected of reducing joint loading with decreased serum cartilage oligomeric matrix protein observed over a 12-week physical training period (Petersen et al 2010). Glucosamine, however, had no effect on type 2 collagen fragment levels in serum or urine in a 6-month RCT of 137 subjects with OA of the knee (Cibere et al 2005).

Part of the chondroprotective action of glucosamine sulfate is due to the provision of a source of additional inorganic sulfur, which is essential for glycosaminoglycan (GAG) synthesis as well as being a structural component of glutathione and other key enzymes, coenzymes and metabolites that play fundamental roles in cellular homeostasis and control of inflammation (Nimni & Cordoba 2006).

### Anti-inflammatory

A number of *in vitro* and *in vivo* tests have identified anti-inflammatory activity for glucosamine (Nagaoka et al 2011). Anti-inflammatory and chondroprotective activities have been observed in human OA cartilage (Sumantran et al 2008). *In vitro* studies have found that glucosamine sulphate exerts anti-inflammatory effects by altering production of TNF- $\alpha$ , interleukins and prostaglandin E<sub>2</sub> in macrophage cells (Kim et al 2007), as well as suppression of mast cell activation (Sakai et al 2010).

Glucosamine restores proteoglycan synthesis and prevents the production of inflammatory mediators induced by the cytokine IL-1- $\beta$  in rat articular chondrocytes according to *in vitro* research (Gouze et al 2001). Glucosamine sulfate and *N*-acetyl glucosamine have also been found to inhibit IL-1- $\beta$ - and TNF- $\alpha$ -induced NO production in normal human articular chondrocytes (Shikhman et al 2001) and it is suggested that the anti-IL-1 $\beta$  effect of glucosamine is accomplished by suppression of NF- $\kappa$ B activation. It is further suggested that glucosamine sulfate inhibits IL-1 $\beta$ -stimulated gene expression of COX-2, inducible nitric oxide synthase, cytokines and metalloproteinases at concentrations found in human plasma and synovial fluid after administration of glucosamine sulfate standard oral doses (Roman-Blas 2010). It is further reported that glucosamine has epigenetic effects and can prevent cytokine-induced demethylation of a specific CpG site in the IL-1- $\beta$  promoter which is associated with decreased expression of IL-1- $\beta$  (Imagawa et al 2011).

Glucosamine demonstrates an ability to suppress PGE<sub>2</sub> production and partly suppress NO production in chondrocytes *in vitro* (Mello et al 2004, Nakamura et al 2004) and to suppress the production of matrix metalloproteinases in normal chondrocytes and synoviocytes (Nakamura et al 2004). Glucosamine is further reported to exert an anti-inflammatory action through suppression of neutrophil function such as superoxide generation, phagocytosis, granule enzyme release and chemotaxis (Hua et al 2002).

## Glucose metabolism

Exogenous glucosamine is actively taken up by cells. Its entry into cells is stimulated by insulin and involves the glucose transporter system (Pouwels et al 2001); however, the affinity of glucosamine for these transporters is substantially lower than that of glucose (Nelson et al 2000).

Early preliminary evidence suggested that glucosamine may cause changes in glucose metabolism and insulin secretion similar to those seen in type 2 diabetes in both rats (Balkan & Dunning 1994, Giaccari et al 1995, Lippiello et al 2000, Shankar et al 1998) and humans (Monauni et al 2000); however, these findings have been disputed (Echard et al 2001). In the 10 years following the original research, most clinical trial evidence has failed to find any significant effect on glucose metabolism in humans (Anderson et al 2005, Tannis et al 2004, Onigbinde et al 2011). It is suggested, however, that there could be some effect in people with impaired glucose tolerance or insulin resistance (Dostrovsky et al 2011).

## Gastrointestinal protection

Glycoproteins are important in protecting the bowel mucosa from damage, and the breakdown of glycosaminoglycans is an important consequence of inflammation of mucosal surfaces (Salvatore et al 2000). Abnormalities in colonic glycoprotein synthesis have been implicated in the pathogenesis of ulcerative colitis and Crohn's disease (Burton & Anderson 1983, Winslet et al 1994).

## OTHER ACTIONS

Glucosamine might have some activity against HIV. Preliminary evidence shows that it inhibits intracellular viral movement and blocks viral replication (Bagasra et al 1991). Other studies have found that glucosamine has immunosuppressive properties and can prolong graft survival in mice (Ma et al 2002). Oral, intraperitoneal and intravenously administered glucosamine significantly reduces CNS inflammation and demyelination in an animal model of multiple sclerosis (Zhang et al 2005).

## CLINICAL USE

### Osteoarthritis

There is very good evidence to suggest that glucosamine sulphate is effective in treating the symptoms of OA, in particular moderate severity OA, as well as slowing disease progression as per studies mainly investigating knee OA. This is further supported by studies with animal models that unequivocally confirm glucosamine has anti-inflammatory and disease modifying effects.

While there have been some inconsistencies in human studies, reviews of clinical trials generally confirm the efficacy of glucosamine sulphate in providing pain relief from OA whereas studies investigating glucosamine hydrochloride tend to produce inconsistent results (Black et al 2009, Bruyere & Reginster 2007, Chan and Ng 2011, Fox &

Stephens 2009, Henrotin et al 2012, Kwoh et al 2013, Miller & Clegg 2011, Provenza et al 2014, Reginster et al 2007, 2012, Vangness et al 2009, Wandel et al 2010, Wu et al 2013). Benefits appear most consistent when glucosamine sulfate is taken together with chondroitin sulfate long term.

### Clinical note

In 2014, the European Society for Clinical and Economic Aspects of Osteoporosis and Osteoarthritis (ESCEO) gathered an international task force of 13 members to determine clinical management of patients with OA. They concluded that the first step for patients with OA and pain is to use either glucosamine sulfate +/- chondroitin sulphate or paracetamol on a regular basis, while NSAIDs should only be used as an advanced step, if response is not adequate. They recommended that the safer, more sensible approach is not to use paracetamol due to its side effects and questionable efficacy on pain with chronic use, but to recommend chronic symptomatic slow-acting drugs for osteoarthritis such as glucosamine sulphate (Bruyere et al 2014). Interestingly, they noted that US groups are reluctant to recommend dietary supplements due to quality issues, whereas there is less concern in Europe as pharmaceutical grade preparations are used.

One explanation for the inconsistent results could relate to dosing. Pharmacokinetic studies have shown that glucosamine is easily absorbed, but the current treatment doses (1500 mg/day) barely reach the required therapeutic concentration in plasma and tissue. Therefore, it is likely that many patients, in particular obese patients, are being under-dosed at the current tested concentrations (Aghazadeh-Habashi & Jamali 2011, Henrotin et al 2012). Other reasons for some of the inconsistent results include: inconsistency in the chemical potency of some products used as well as variable and erratic bioavailability indices. Some support for a higher dose was recently obtained via a 12-week randomised study that showed 3000 mg/day of glucosamine sulphate provided effective symptom relief in knee OA. All outcome measures (WOMAC and Lequesne algorithm indices) were significantly improved (Coulson et al 2013).

### Compared to standard treatments

Several clinical studies indicate that glucosamine is at least as effective as NSAIDs in treating the symptoms of OA however the effect takes longer to be established (approximately 2–6 weeks) (Herrero-Beaumont et al 2007, Muller-Fassbender et al 1994, Reichelt et al 1994, Rovati 1992, Ruane & Griffiths 2002). In addition, a double-blind, random controlled trial (RCT) involving 318 people with moderately severe knee OA showed that more people responded to daily glucosamine sulphate (1500 mg/day) than paracetamol (3 gm/day) or placebo over

6 months, as seen by improvements to the Lequesne score (Herrero-Beaumont et al 2007).

The first Cochrane systematic review was published in 2003 and analysed results from 16 RCTs testing glucosamine for OA. It concluded that 'there is good evidence that glucosamine is both effective and safe in treating OA' and that 'glucosamine therapy may indeed represent a significant breakthrough in the pharmacological management of OA' (Towheed et al 2003). The most recent Cochrane review (updated in 2008) looked at 20 studies involving a total of 2570 patients and found that the Rottapharm glucosamine sulfate preparation was superior to placebo in the treatment of pain and functional impairment, whereas studies using non-Rottapharm glucosamine hydrochloride preparations failed to show benefit in pain and function (Towheed et al 2006).

The first placebo-controlled clinical trials investigating glucosamine in OA were published in the early 1980s. Drovanti et al (1980) showed that a dose of 1500 mg glucosamine sulfate significantly reduced symptoms of OA, almost twice as effectively and twice as fast as placebo. Perhaps the most exciting results were found when electron microscopy analysis of cartilage showed that those people taking glucosamine sulfate had cartilage more similar to healthy joints than the placebo group. Based on this finding, researchers suggested that glucosamine sulfate had not only provided symptom relief but also had the potential to induce rebuilding of the damaged cartilage.

Since that time, multiple human clinical trials lasting from a few weeks (Coulson et al 2013, Crolle & D'Este 1980, Drovanti et al 1980, Lopes Vaz 1982, McAlindon 2001, Pujalte et al 1980, Qiu et al 1998) to 3 years (Pavelka et al 2002, Reginster et al 2001), as well as systematic reviews (Poolsup et al 2005, Towheed et al 2003, 2006) and meta-analyses (McAlindon et al 2000, Richy et al 2003) have shown that glucosamine sulfate (1500 mg/day) can significantly improve symptoms of pain and functionality measures in patients with OA of the knee, with side effects comparable to those of placebo. This is not to say that all studies have produced positive results for symptom relief in OA.

Probably the most well-known study showing 'apparent' negative results was published in 2005 after the National Institutes of Health (NIH) spent US\$14 million on a Glucosamine hydrochloride and Chondroitin Arthritis Intervention Trial (GAIT). The 24-week, placebo-controlled, parallel, double-blind, five-arm trial involving 1583 patients aimed to answer the question as to whether glucosamine hydrochloride and/or chondroitin was more effective than placebo or the COX-2 inhibitor celecoxib for symptom relief (Clegg et al 2006, NIH 2002). The results of this study provide evidence that glucosamine hydrochloride and chondroitin are more effective when given in combination than when either substance is given alone and that

combined treatment with glucosamine hydrochloride and chondroitin is more effective than celecoxib for treating moderate-to-severe, but not mild, arthritis. Furthermore, the combined treatment was significantly better than placebo for patients with either mild or moderate-to-severe disease when the internationally accepted Outcome Measures in Rheumatology-Osteoarthritis Research Society International (OMERACT-OARSI) response criteria for judging clinical trials of OA was used (Clegg et al 2006). A 2-year sub-study however, found no clinically important differences in symptoms or function with any treatments compared to placebo (Sawitzke et al 2010) and no reductions in joint space narrowing, although there was a trend for improvement in knees with Kellgren and Lawrence (K/L) grade 2 radiographic OA. The authors acknowledge that the statistical power of this 2-year follow-up study was diminished by the limited sample size, variance of joint space width measurements and a smaller than expected loss in joint space (Sawitzke et al 2008).

The design and overall inconclusive results of the GAIT trial have been strongly criticised for the fact that the trial included a large number of people with very mild disease at baseline who were more likely to be susceptible to placebo (as evidenced by the very high (60%) placebo response) and who were given ready access to rescue medication. Furthermore, the unusually high 50% drop-out rate at 2 years meant that the structural study was underpowered. The use of intention-to-treat rather than an according-to-protocol analysis further compromised the ability to detect any significant differences (Pelletier et al 2010).

#### Long-term use

A meta-analysis of six studies involving 1052 cases suggests that daily administration of glucosamine sulfate delays radiological progression of OA of the knee after 3 years (Lee et al 2010). A small to moderate protective effect on minimum joint space narrowing ( $P < 0.001$ ) was observed after long-term use, but not yet apparent after the first 12 months. This was further confirmed in a more recent 2013 meta-analysis of 19 RCTs ( $n = 3159$ ) which identified that long-term use (over 6 months) of glucosamine sulphate exerts disease-modifying effects in OA (Wu et al 2013).

The first of these long term structural studies was performed by Reginster et al (2000) and compared the effects of 1500 mg glucosamine sulfate with placebo daily over 3 years in 212 patients aged over 50 years with primary knee OA. This was heralded as a landmark study at the time because it not only detected modest symptom-relieving effects, but also was the first to identify significant joint-preserving activity with long-term use. Two years later, Pavelka et al confirmed these results in another randomised, double-blind study that involved 202 patients with knee OA (Pavelka et al 2002) and once again observed that long-term treatment with

glucosamine sulfate retarded disease progression. A post hoc analysis of these studies found that the disease-modifying effect was evident in 319 postmenopausal women (Bruyere et al 2004) and another sub-analysis found that patients with less severe radiographic knee OA, who are likely to experience the most dramatic disease progression, may be particularly responsive to treatment with glucosamine (Bruyere et al 2003). A 1-year trial involving 104 subjects with OA of the hands, hip and knee also found that treatment with both glucosamine and chondroitin reduced pain and significantly slowed disease progression as measured by radiographs and measures of urinary C-terminal cross-linking telopeptides of type I collagen (Scarpellini et al 2008).

A recent 2-year double blind RCT with 605 participants that compared glucosamine sulfate (1500 mg/day) with or without chondroitin sulfate (1200 mg/day) to placebo, found that while those in the combination group experienced significant reduction in joint space narrowing after 2 years, and all groups experienced a reduction in pain, none of the treatment groups demonstrated significant symptomatic benefit above placebo (Fransen et al 2014).

Furthermore, results confirming a disease-modifying effect using cartilage volume assessment were also obtained in the National Institutes of Health Osteoarthritis Initiative (OAI) (a longitudinal observational cohort study) which analysed a sub-group of 600 people with knee osteoarthritis, who were followed over a 2-year period (Martel-Pelletier et al 2013). The cohort had complete radiographic and MRI data for the most symptomatic knee enabling close observation of disease progression. Importantly, this was the first study to use fully automated MRI analysis and not rely on manual or semi-automated techniques. The protective effect of glucosamine plus chondroitin appears to mainly target the medial subregions in subjects with less severe damage and in the more early stages of knee OA. This is highly relevant as the MRI parameter of medial compartment cartilage volume/thickness loss seems to be able to predict progression to total knee replacement, according to a recent report by the European Society for Clinical and Economic Aspects of Osteoporosis and Osteoarthritis (ESCEO). While this was not a controlled study, over 85% of subjects that reported using glucosamine plus chondroitin stated they did this nearly every day or every day; however, no details were obtained about the forms or doses used.

It is therefore interesting to note the results of a pharmacoeconomic study which suggests that treatment with glucosamine sulfate for at least 12 months results in significant reduction in health resource utilisation even after treatment is discontinued. This study, which involved 275 subjects previously involved in 12-month glucosamine intervention trials, followed subjects for up to 5 years after treatment was discontinued (making up a total of 2178 patient-years of observation). The study showed that

#### **Clinical note: Theories to explain inconsistencies across studies**

Although many forms of glucosamine are used in practice, there is significantly more evidence supporting the use of the glucosamine sulfate than glucosamine hydrochloride. It has been suggested the inconsistent results may be due to the type of preparation, inadequate allocation concealment and industry bias as most clinical trials of glucosamine sulfate have used a specific patented oral formulation from Rottapharm, Italy, which is available as a prescription medicine in Europe (Vlad et al 2007). The greater efficacy seen with the Rottapharm glucosamine sulfate formulation may be due to the fact it uses vacuum sealed sachets to protect the physiologically active and highly hygroscopic, crystalline glucosamine sulfate from degradation in air, while the less hygroscopic 'stabilised' glucosamine hydrochloride preparations have been found to crystallise out of solution and therefore may contain less than the optimal amount of the physiologically active ingredient (Sahoo et al 2012). Pharmacokinetic studies have also suggested that the current treatment doses (500 mg three times daily) barely reach the required therapeutic concentration in plasma and tissue and it is likely that many patients are being underdosed at the current tested concentrations (Aghazadeh-Habashi & Jamali 2011, Henrotin et al 2012). This is most likely with obese patients who tend to require higher doses of many medications. Henrotin et al (2012) further suggest that inconsistent results are likely to be due to inconsistency in the chemical potency of some products used as well as variable and erratic bioavailability indices.

total knee replacement had occurred in over twice as many patients from the placebo group (19/131 or 14.5%), than in those formerly receiving glucosamine sulphate (9/144 or 6.3%) (Bruyere et al 2008).

#### **Combination therapy**

**With chondroitin sulfate (see Chondroitin monograph for more information)**

Chondroitin sulfate and glucosamine are frequently marketed together in combination products and many studies suggest that this combination is effective in treating symptoms (Clegg et al 2006, Das & Hammad 2000, Leffler et al 1999, McAlindon et al 2000, Nguyen et al 2001, NIH 2002) and reducing joint space narrowing (Rai et al 2004). In a cluster-randomised, placebo-controlled trial in 251 patients, a combination of chondroitin sulfate and glucosamine hydrochloride but not glucosamine hydrochloride alone was found to be effective in alleviating symptoms and improving the dysfunction with Kashin-Beck disease (Yue et al 2012). This is

supported by *in vitro* studies using horse cartilage, which report that a combination of glucosamine sulfate and chondroitin sulfate can partially mitigate the catabolic response to inflammatory stress and mechanical trauma (Harlan et al 2012) and that combination treatment is more effective than either product alone in preventing articular cartilage glycosaminoglycan degradation (Dechant et al 2005). Further support for combination therapy comes from an *in vivo* study of rats, which found that combined treatment with chondroitin and glucosamine sulfate prevented the development of cartilage damage and was associated with a reduction in IL-1-beta and matrix metalloproteinase-9 synthesis (Chou et al 2005). While combination therapy with glucosamine and chondroitin is supported by clinical evidence, the mechanism of any synergistic action is unknown. Furthermore, research indicates that co-administration of chondroitin actually reduces the uptake of glucosamine sulphate resulting in reduced circulating plasma levels. Thus, it is suggested that any combined effect may be due to effects on the gut lining or liver rather than the joint space (Jackson et al 2010).

#### With omega-3 EFAs

Results from a recent study further suggest that glucosamine may be more effective in combination with omega-3 fatty acids. A recent RCT involving 177 patients with moderate to severe hip or knee osteoarthritis compared glucosamine sulfate (1500 mg/day) alone with glucosamine sulfate in combination with the omega-3 polyunsaturated fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). After 26 weeks the combination therapy group was significantly superior to glucosamine sulphate alone in reducing WOMAC by either 80% ( $P = 0.044$ ) or 90% ( $P = 0.015$ ). (Gruenwald et al 2009).

#### With MSM

In a 12-week, randomised, placebo-controlled trial of glucosamine and methylsulfonylmethane involving 118 patients, combined therapy was found to produce a greater and more rapid reduction in pain, swelling and loss of function than either agent alone (Usha & Naidu 2004).

#### Topical, with camphor

A topical preparation containing glucosamine along with chondroitin and camphor has been shown to reduce pain from OA of the knee in one randomised controlled trial (Cohen et al 2003).

#### With NSAIDs

Although glucosamine has not been shown to have direct analgesic activity, certain combinations with non-opioid analgesics have demonstrated synergistic (e.g. ibuprofen and ketoprofen), additive (e.g. diclofenac, indomethacin, naproxen and piroxicam) or sub-additive (e.g. aspirin and paracetamol) effects in animal pain models, suggesting that combinations of certain ratios of glucosamine and specific

non-steroidal anti-inflammatory drugs (NSAIDs) might enhance pain relief or provide adequate pain relief with lower doses of NSAIDs (Tallarida et al 2003).

#### Comparisons with NSAIDs

There are many studies suggesting that glucosamine is at least as effective as NSAIDs in treating the symptoms of OA (Herrero-Beaumont et al 2007, Muller-Fassbender et al 1994, Reichelt et al 1994, Rovati 1992, Ruane & Griffiths 2002), although glucosamine has a slower onset of action, taking 2–6 weeks to establish an effect. The GAIT trial (see earlier) found that the combination of glucosamine hydrochloride and chondroitin was more effective than celecoxib in treating moderate to severe OA in the shorter term, whereas glucosamine alone was not (Clegg et al 2006).

#### Inflammatory bowel disease

*In vitro* and *in vivo* studies suggest that glucosamine may be useful in treating inflammatory bowel disease with *in vitro* studies demonstrating suppression of cytokine-induced activation of intestinal epithelial cells and *in vivo* studies finding that glucosamine improved clinical symptoms and suppressed colonic inflammation and tissue injury in a rat model of inflammatory bowel diseases (Yomogida et al 2008). The anti-inflammatory activity of glucosamine is partly mediated by an increased production of heparan sulfate proteoglycans by the vascular endothelium, thereby improving the endothelium's barrier function (McCarty 1998b). It is possible that the step in glycoprotein synthesis involving the amino sugar is relatively deficient in patients with inflammatory bowel disease and this could reduce the synthesis of the glycoprotein cover that protects the mucosa from damage by bowel contents (Burton & Anderson 1983, Winslet et al 1994). In a pilot study, *N*-acetyl glucosamine proved beneficial in children with chronic inflammatory bowel disease (Salvatore et al 2000).

#### Chronic lower back pain

A systematic review of 3 RCTs concluded that there was insufficient data to determine whether the use of glucosamine is useful for lower back pain (Sodha et al 2013). Wilkens et al (2012) conducted a double blind RCT over 6 months of 250 subjects with chronic lower back pain (>6 months) and MRI findings indicating degenerative lumbar disease, finding no significant pain relieving effects with glucosamine sulfate (1500 mg/day) (Wilkens et al 2012). Similarly, no pain relief was observed in a small double blind, placebo controlled, cross-over study which tested a combination of glucosamine HCl (1500 mg/day), chondroitin sulfate (1200 mg/day) and manganese ascorbate (228 mg/day) over 16 weeks (Leffler et al 1999). In contrast, Tant et al (2005) conducted an open label, RCT of glucosamine taken over 12 weeks in combination with other ingredients such as MSM (methylsulfonylmethane) and found a clinically significant

reduction in pain; however, the trial was an open study using a multiple ingredient combination treatment.

### OTHER USES

There is the suggestion from one small RCT that glucosamine may provide symptomatic relief for people with rheumatoid arthritis (Nakamura et al 2007).

### Veterinary use

Glucosamine demonstrates benefits in alleviating symptoms of degenerative joint disease in both horses (Forsyth et al 2006, Baccarin et al 2012) and dogs (McCarthy et al 2007).

### Skincare use

It has been suggested that glucosamine may be a suitable cosmetic ingredient for use in skin care products. Because of its stimulation of hyaluronic acid synthesis, glucosamine has been shown to accelerate wound healing, improve skin hydration and decrease wrinkles. In addition, as an inhibitor of tyrosinase activation, it inhibits melanin production and is useful in treatment of disorders of hyperpigmentation (Bissett 2006). This is supported by an 8-week, double-blind, placebo-controlled trial, which found that hyperpigmentation was reduced with topical use of *N*-acetyl glucosamine with the effect being enhanced by niacinamide (Bissett et al 2007).

### DOSAGE RANGE

- Typical dosing is 1500 mg glucosamine (either HCl or sulphate)/day (500 mg three times daily). This is based on preclinical animal models which used 20 mg/kg of body weight per day, which translates to 1500 mg/day for a 75 kg adult. Higher dosing may therefore be required in heavier individuals.
- A 2–3-month trial is generally used to determine whether it is effective for an individual patient. Use for 3+ years is required to slow down knee joint degeneration and potentially reduce the risk of knee replacement.
- Intramuscular glucosamine sulfate: 400 or 800 mg three times/week (Reichelt et al 1994) for 4–6 weeks or longer if required.
- Glucosamine sulfate, hydrochloride, hydroiodide and *N*-acetyl forms are available. Most research has been done on the sulfate forms. Topical, intravenous, intramuscular and intraarticular forms are also available in some countries.

### ADVERSE REACTIONS

Glucosamine has been used safely in multiple clinical trials lasting from 4 weeks to 3 years with minimal or no adverse effects (Lopes Vaz 1982, Pavelka et al 2002, Pujalte et al 1980, Reginster et al 2001). A 2006 Cochrane systematic review concluded that glucosamine is as safe as placebo (Towheed et al 2006). Glucosamine has an observed safe level (OSL) of 2000 mg/day and while it is

considered safe, some uncommon and minor adverse effects have been reported, including epigastric pain or tenderness (3.5%), heartburn (2.7%), diarrhoea (2.5%) and nausea (1%) (Sherman et al 2012).

Glucosamine sulphate has no significant effect on serum lipids (Albert et al 2007, Østergaard et al 2007). While it is unlikely that glucosamine has any significant effects on glucose tolerance, people with impaired glucose tolerance or insulin resistance should be monitored (Dostrovsky et al 2011).

There is one case report of asthma being exacerbated by glucosamine–chondroitin supplementation (Tallia & Cardone 2002).

### SIGNIFICANT INTERACTIONS

Controlled studies are not available so interactions remain speculative and are based on evidence of pharmacological activity.

### Non-steroidal anti-inflammatory drugs

Glucosamine reduces the requirements for NSAID use by people with knee OA according to a large French study (Bertin & Taieb 2013) — drug dosage may require modification after several weeks' glucosamine use — a potentially beneficial combination.

### Warfarin

Case reports exist of glucosamine and glucosamine/chondroitin combinations increasing bruising, bleeding and INR amongst people taking warfarin (Knudsen & Sokol 2008). Until the interaction can be tested in a controlled study, caution is advised.

### Practice points/Patient counselling

- Glucosamine is a naturally occurring building block of joint tissue and cartilage.
- Glucosamine sulphate is an effective symptomatic treatment for pain and disability associated with OA, with most research conducted with knee OA. When used long term (more than 6 months) it slows the progression of the disease, and appears to work best long-term with chondroitin sulfate.
- It is considered extremely safe and may reduce the need for NSAIDs (which can have serious side effects).
- People who are overweight or obese may require higher doses than the usual dose of 1500 mg/day.
- People with severe shellfish allergy should be advised to use a form that is not derived from shellfish.
- Patients with diabetes should monitor their blood glucose levels while taking glucosamine, although no significant changes are anticipated.

### ! PATIENTS' FAQs

#### What will this supplement do for me?

Multiple scientific studies have shown that glucosamine sulfate reduces symptoms of OA and also slows progression of the condition when used

**Clinical note — Should people with diabetes avoid glucosamine?**

Clinicians' concern about the safety of glucosamine in diabetes were probably first fuelled by an article published in *Lancet* in 1999 (Adams 1999). The article entitled 'Hype about glucosamine' by Adams stated that glucosamine increases glucose resistance in normal and in experimentally diabetic animals (McClain & Crook 1996) and intravenous glucosamine in doses as low as 0.1 mg/kg/minute result in a 50% reduction in the rate of glucose uptake in skeletal muscle (Baron et al 1995). Adams concluded by suggesting that perhaps all people, but especially those who are overweight or have diabetes, should be urged to have caution when using glucosamine. In 2005, a critical review of 33 clinical studies involving 3063 human subjects concluded that glucosamine does not affect glucose metabolism, and that there are no adverse effects of oral glucosamine administration on blood, urine or faecal parameters (Anderson et al 2005). A more recent systematic review of 11 studies, however, suggests that glucosamine may have some effect on glucose metabolism in people with impaired glucose tolerance or insulin resistance and that more studies are required before definitive conclusion can be made (Dostrovsky et al 2011).

**CONTRAINDICATIONS AND PRECAUTIONS**

Diabetics using glucosamine should have their blood sugar levels checked regularly.

Glucosamine is made from shellfish and, although it is not extracted from the protein component and appears to pose no threat to shrimp-allergic individuals (Villacis et al 2006), it should be used with caution in patients with shellfish allergy.

Whether glucosamine poses a serious bleeding risk in major surgery is unclear. Multiple case reports suggesting an interaction between warfarin and glucosamine have been collected by the FDA and WHO however it is unknown whether the interaction is pharmacokinetic or pharmacodynamic (Knudsen & Sokol 2008). Of the 21 documented case reports indicating increased INR and held in the WHO adverse drug reaction database, 17 resolved when glucosamine was ceased. While this does not provide strong evidence that glucosamine used by itself will cause bleeding, caution is advised. Due to the fact that glucosamine is long term therapy, suspending use one week before major surgery and resuming use afterwards seems reasonable.

long-term. The sulfate form is superior to the hydrochloride form for improving symptoms. Some people find that they do not require NSAIDs as often when taking it.

**PREGNANCY USE**

Insufficient reliable information is available to advise on safety in pregnancy. Some limited data suggest no increased risk for major malformations or other adverse fetal effects with glucosamine use during pregnancy (Sivojelezova et al 2007).

**When will it start to work?**

Symptom relief generally takes 2–6 weeks to establish, but joint protection effects occur only with long-term use of at least 6 months to several years.

**Are there any safety issues?**

Although considered very safe for the general population, it should be used with caution in people with severe shellfish allergies.

# Goji

**HISTORICAL NOTE** For thousands of years in traditional Chinese medicine, the fruit of the lycium shrub has been used as both a food and an important medicinal substance. In fact, the earliest known Chinese medicinal monograph documented the medicinal use of *Lycium barbarum* around 2300 years ago. According to this tradition, it is believed that the fruit has antiageing properties, nourishes the kidneys and liver by tonifying yin deficiency and brightens the eyes. It also has a long history of use as a traditional remedy for male infertility and is included in most fertility-promoting Chinese herbal remedies (Luo et al 2006). In China it is known by several names, such as Gou Qi Zi or Gouqizi, which probably led to the name it is known as here, goji.

## COMMON NAME

Goji

## OTHER NAMES

Gou Qi Zi, Gouqizi, Fructus lycii, Kei Tze, wolfberry

## SCIENTIFIC NAME

*Lycium barbarum* (Solanaceae family)

## PLANT PART USED

Fruit

Goji berry is a deep-red, dried fruit about the same size as a raisin, but with a different taste. The berries have a slight chewy consistency and taste like a mixture of cherries and cranberries, without the sweetness of raisins.

## CHEMICAL COMPONENTS

The reddish orange colour of the fruit is derived from a group of carotenoids, which make up only 0.03–0.5% of the dried fruit. The predominant carotenoid is zeaxanthin, which comprises about one-third to one-half of the total carotenoids present (Inbaraj et al 2008). The fruit also contains various small molecules, such as betaine, cerebroside, beta-sitosterol, *p*-coumaric acid, various vitamins (e.g. B<sub>1</sub>, B<sub>2</sub>, vitamin C) and minerals (e.g. iron, selenium, zinc). Among these chemical constituents, the most valuable and pharmacologically active components are a group of unique, water-soluble glycoconjugates — collectively termed *Lycium barbarum* polysaccharides (LBPs). Nineteen different constituents of LBP have been isolated, and they are estimated to comprise 5–8% of the dried fruit (Amagase et al 2009a, Tang et al 2012).

## MAIN ACTIONS

### Antioxidant

LBPs have demonstrated high antioxidant activity in a number of in vitro and in vivo studies (Amagase et al 2009a, Guoliang et al 2011, Ke et al 2011, Lin et al 2009, Niu 2008, Zhang et al 2011a). Pretreatment with LBP increased endurance, decreased malondialdehyde and increased superoxide

dismutase and glutathione peroxidase (GSH-Px) levels in rats subjected to exhaustive exercise (Shan et al 2011).

Pretreatment of pregnant rats with LBP prevented prenatal stress-induced cognitive dysfunction in offspring, possibly via prevention of oxidative damage to brain tissue mitochondria (Feng et al 2010).

A study of streptozocin-induced diabetic animals found that LBP restored abnormal oxidative indices to near-normal levels (Li 2007).

Goji stimulates endogenous antioxidant mechanisms and has been shown to significantly increase superoxide dismutase and GSH-Px, and reduce lipid peroxidation (indicated by decreased levels of malondialdehyde) in humans (Amagase et al 2009a, Liang et al 2011).

The zeaxanthin component found in whole goji berries is bioavailable in humans (Cheng et al 2005) and is likely to contribute the fruit's in vivo antioxidant effects. Bioavailability of zeaxanthin from freeze-dried wolfberries can be greatly enhanced when consumed in hot skimmed milk compared to hot water or warm milk (Benzie et al 2006).

Conversely, a hepatic ischaemia-reperfusion injury rat model found that LBP did not attenuate ischaemia-reperfusion-induced free radical production, and in fact resulted in an increased production of hydroxyl radicals. Explanations for these unexpected results include loss of antioxidant components during isolation of LBP, and mediation of hepatic injury via pathways other than free radical production. Since the results of this study are not in accord with other studies demonstrating antioxidant activity for LBP, further investigations are needed to expand upon the findings of this study (Wang et al 2009).

### Antidiabetic

Goji exhibits a variety of mechanisms of relevance in diabetes.

A study by Zhao et al (2005b) demonstrated that diabetic animals treated with LBP for 3 weeks resulted in a significant decrease in the concentration of plasma triglyceride and weight in non-insulin-dependent diabetes mellitus (NIDDM) rats. Furthermore, LBP markedly decreased the plasma

cholesterol levels, fasting plasma insulin levels and postprandial glucose levels at 30 minutes during oral glucose tolerance test and significantly increased the Insulin Sensitivity Index in NIDDM rats.

An acidic polysaccharide isolated from *L. barbarum* (LBP-I) has been shown to protect pancreatic islet cells from oxidative damage, significantly enhance cell survival and inhibit the development of insulin resistance in HepG2 cells in vitro (Zou et al 2010).

Furthermore, LBP prevented diabetic nephropathy in streptozotocin-induced diabetic mice via mediation of oxidative stress and inhibition of protein kinase C, which play a major role in oxidative stress-induced glomerular injury (Zhao et al 2009).

The fruit extract of goji has also shown hypoglycaemic and lipid-lowering activities in diabetic animals while not affecting healthy animals (Jing et al 2009, Luo et al 2004). It appears that the polysaccharides and vitamin antioxidants may be responsible for these particular effects.

### Neuroprotective

Goji berry extract and LBP display neuroprotective activity in several different experimental models (Yao et al 2011).

An aqueous extract isolated from *L. barbarum* exhibited significant protection on cultured neurons against harmful chemical toxins (A beta and dithiothreitol) by reducing the activity of both caspase-3 and -2, but not caspase-8 and -9 (Yu et al 2007). A new arabinogalactan-protein (LBP-III) was isolated from LBP, which appeared to have the strongest effect.

The polysaccharide-containing extract (LBP) from LBP protects neurons against beta-amyloid peptide toxicity in neuronal cell cultures (Chang & So 2008) and demonstrates neuroprotective effects in the retina in several experimental models, including retinal ischaemia-reperfusion injury, glaucoma and diabetic retinopathy (Chan et al 2007, Chang & So 2008, Hu et al 2012, Li et al 2011, Miranda et al 2010, Song et al 2011, 2012, Yang et al 2011, Yu et al 2007) as well as ocular hypertension in animal models (Chiu et al 2010, Mi et al 2012, Yu et al 2007).

In vivo studies suggest that LBP may be used to protect neuronal brain cells from a range of insults. LBP attenuated neuronal damage in rat hippocampal neurons injured by oxygen glucose deprivation/reperfusion in a dose-dependent manner (Rui et al 2012). Prophylactic treatment with LBP improved neurological deficits and decreased infarct size in an experimental stroke model using mice (Yang et al 2012). LBP enhanced learning and memory capabilities of manganese-poisoned mice via promotion of neurogenesis in the hippocampus (Wen et al 2010).

Pre-treatment with LBP has been found to prevent homocysteine- and glutamate-induced apoptosis in cortical neuronal cells (Ho et al 2009, 2010).

Whether *L. barbarum* has a potential role in degenerative diseases such as Alzheimer's disease and Parkinson's disease, as homocysteine and glutamate neurotoxicity have been implicated in their pathophysiology, remains to be tested.

### Anticancer

The antiproliferative activity of LBP has been demonstrated in several in vitro models. LBP demonstrated inhibition of proliferation of human cervical carcinoma cells (HeLa cells) via changing cell cycle distribution and inducing apoptosis (Zhu & Zhang 2012). Another study found that AA-2 $\beta$ G (a vitamin C analogue in *L. barbarum*) induced apoptosis and repressed the proliferation of HeLa cells via stabilisation of p53 protein (Zhang et al 2011b).

In vitro studies have also demonstrated that LBP inhibited the growth of breast cancer cells (MCF-7) by arresting the cell cycle in S phase and inducing apoptosis through the extracellular signal-regulated protein kinase (ERK) pathway, which is an important regulating pathway of cell proliferation (Shen & Du 2012).

Pre-treatment of human epidermal keratinocyte cell lines and dermal fibroblasts with LBP attenuated the ultraviolet (UV) B radiation-induced expression of p1, p21 and p53 genes (Wang X et al 2011). Juice of the *L. barbarum* berry protected mouse epithelia cells from UV radiation-induced skin damage by preventing UV-induced lipid peroxidation and immunosuppression (Reeve et al 2010).

Furthermore, LBP has been shown to inhibit the growth of human colon cancer cells and human gastric cancer cells by inducing cell cycle arrest at G0/G1 and S phase (Bucheli et al 2011, Mao et al 2011, Miao 2010). It inhibits growth and induces apoptosis in human prostate cancer cells in vitro and prevents prostate tumour growth in vivo (Luo et al 2009). LBP has also been shown to inhibit the growth of oestrogen receptor-positive breast cancer cells in vitro by altering oestradiol metabolism (Li et al 2009).

### Reduces chemotherapy- and radiotherapy-induced toxicity

LBP elicited a typical cardioprotective effect on doxorubicin-related oxidative stress in an experimental model (Xin et al 2007). Furthermore, an in vitro cytotoxic study showed the antitumour activity of doxorubicin was not compromised by LBP.

Interestingly, another animal study identified that LBP promotes the peripheral blood recovery of irradiation- or chemotherapy-induced myelosuppressive mice (Gong et al 2005). Compared to controls, 50 mg/kg LBP significantly ameliorated the decrease of peripheral white blood cells and peripheral red cells in irradiated myelosuppressive mice. Higher doses significantly enhanced peripheral platelet counts.

Ototoxicity is a major dose-limiting side effect of cisplatin. Uptake of cisplatin by hair cells in the organ of Corti results in increased local reactive oxygen species production and hair cell damage, leading to progressive and irreversible hearing loss. An animal study found that LBP attenuated cisplatin-induced damage to the organ of Corti via antioxidant activity (Liu et al 2011). Further research is required to determine whether using goji extracts and cisplatin at the same time affects the chemotherapeutic activity of cisplatin.

### Immune modulation

LBP has been known to have a variety of immunomodulatory functions, including activation of T cells, B cells, natural killer (NK) cells and macrophages (Chen et al 2008, Zhang et al 2011c, Zhu et al 2007).

A polysaccharide-protein complex isolated from *L. barbarum* (LBP) activated macrophages in vivo (Chen et al 2009). The mechanism may be through activation of transcription factors nuclear factor- $\kappa$ B and activator protein-1 to induce tumour necrosis factor- $\alpha$  production and upregulation of major histocompatibility complex class II costimulatory molecules. LBP also activates T cells.

A milk-based *L. barbarum* preparation attenuated symptoms and pathology of influenza virus A infection in mice via enhanced systemic T-cell function and reduced inflammatory cytokines (Ren et al 2012).

*L. barbarum* glycopeptide 3, a specific polysaccharide, was found to reverse apoptotic resistance of T cells in aged mice (Yuan et al 2008). Apoptotic resistance of T cells occurs as part of the ageing process. The ability of *L. barbarum* glycopeptides 3 to regulate T-cell apoptosis suggests that it may be of use to promote healthy ageing.

### Sexual behaviour and male reproductive function

Studies with experimental models suggest the polysaccharides in goji berries may improve sexual behaviour and reproductive function (Luo et al 2006, 2011). LBP improved the copulatory performance and reproductive function of hemicastrated male rats, such as shortened penis erection latency and mount latency, regulated secretion of sexual hormones and increased hormone levels, raised accessory sexual organ weights and improved sperm quantity and quality (Luo et al 2006). Another study found that LBP improved the copulatory performance, including increase of copulatory efficiency, increase of ejaculation frequency and shortening of ejaculation latency in male rats. LBP prevented corticosterone-induced sexual inhibition and reversed corticosterone-induced suppression of neurogenesis in the subventricular zone and hippocampus. Prosexual effects were not seen in rats in which neurogenesis was blocked, suggesting the prosexual effect of LBP may be modulated via regulation of neurogenesis (Lau et al 2012).

Studies with LBP indicate a protective effect on testicular cells against a variety of insults. Pretreatment with LBP reversed a number of parameters of testicular oxidative stress and toxicity in doxorubicin-treated rats. LBP reversed the doxorubicin-induced increase in abnormal sperm rate and tissue oxidation, and the reduction in sperm concentration, percentage of motile sperm and testicular weight. LBP-treated rats also had significantly increased plasma testosterone levels compared to controls (Xin et al 2012).

Luo et al (2006) demonstrated a dose-dependent protective effect for LBP against DNA oxidative damage of mouse testicular cells in vivo. LBP also inhibits time- and hyperthermia-induced structural damage in murine seminiferous epithelium in vitro (Wang et al 2002). Moreover, LBP delays apoptosis in this system, both at normothermic and hyperthermic culture conditions. Considering the oxidative stress is suspected to be a major cause of structural degradation and apoptosis in hyperthermic testes, the protective effect of LBP may be mediated by an antioxidant mechanism of action.

### Hepatoprotective

Animal studies have demonstrated the protective activity of *L. barbarum* against the hepatotoxic effects of alcohol and a high-fat diet (Cheng & Kong 2011, Cui et al 2011, Wu et al 2010).

Pretreatment with LBP effectively reduced oxidative stress, hepatic necrosis and serum alanine transaminase levels in mice with CCL4-induced acute hepatotoxicity (Xiao et al 2012). Similar results were found in a study using an aqueous extract of *L. barbarum* and *Rehmannia glutinosa*; however it is difficult to determine the individual efficacy of *L. barbarum* due to the use of the herbal combination (Wu et al 2011).

### Cardioprotective

Pretreatment with LBP significantly reduced doxorubicin-induced cardiac conduction abnormalities, and alleviated doxorubicin-induced increases in serum creatine kinase and aspartate transaminase. The suggested mechanism for the cardioprotective effect of LBP is via mediation of oxidative stress (Xin et al 2011a, 2011b).

Supplementation with LBP attenuated myocardial cell apoptosis in rats with ischaemia-reperfusion injury (Lu & Zhao 2010).

### OTHER ACTIONS

One of *L. barbarum*'s glycoconjugates promoted the survival of human fibroblasts cultured in suboptimal conditions and demonstrated important skin-protective properties (Zhao et al 2005a).

LBP reduced heat stress-induced apoptosis of germ cells in rats (Tan et al 2012).

Cationised LBP nanoparticles successfully facilitated nuclear uptake of DNA encoding for transforming growth factor- $\beta$  1 by rat mesenchymal stem cells in vitro. That cationised LBP may have

a role as a carrier for gene delivery is a promising result for the field of gene therapy, as research in this area is attempting to develop new therapies for genetically-based and infectious diseases, such as haemophilia and cystic fibrosis, by introducing nucleic acids into the cell nucleus (Wang, M et al 2011).

LBP's demonstrated antidepressant activity in an animal model, potentially by enhancing synaptic plasticity (Zhang et al 2012). Administration of LBP to mice fed a high-fat diet significantly decreased total cholesterol, low-density lipoprotein, triglycerides and blood glucose (Ming et al 2009).

Administration of LBP to ovariectomised rats resulted in increased bone gene expression, bone mineral density and bone mineral content (Zhu et al 2010).

## CLINICAL USE

Goji has become more popular in the last few years due to its public acceptance as a 'functional food' with highly advantageous nutritive and antioxidant properties. It is touted as being able to improve wellbeing and protect against cancer and other serious diseases. Most investigation with goji has been conducted in China and there is little clinical research information available in English-language journals.

### Improved wellbeing

A meta-analysis of four small, randomised, placebo-controlled trials (three double-blind and one single-blind) was conducted to examine the effects a standardised *L. barbarum* fruit juice (GoChi, FreeLife International, Phoenix, AZ) on perceived general wellbeing. All four studies involved oral consumption of 120 mL/day of the standardised juice. A total of 161 participants, aged 18–72 years, were given a questionnaire consisting of symptoms graded 0–5. Pre- and posttreatment symptom scores were compared. The treatment group ( $n = 81$ ) showed significant improvements in a number of subjective measurements of overall feelings of health and wellbeing, including fatigue, depression, stress, calmness, weakness, mental acuity, focus on activity, sleep quality, ease of awakening, daydreaming and shortness of breath, compared to the control group ( $n = 80$ ) (Hsu et al 2012).

A randomised, double-blind, placebo-controlled clinical trial examined the general effects of orally consumed goji berry, *L. barbarum*, as a standardised juice (GoChi; FreeLife International, Phoenix, AZ) in healthy adults for 14 days (Amagase & Nance 2008). The study was designed to measure multiple outcomes based on the traditionally understood properties of the product. Comparisons between day 1 and day 15 revealed that goji treatment significantly increased ratings for energy level, athletic performance, quality of sleep, ease of awakening, ability to focus on activities, mental acuity, calmness and subjective feelings of general wellbeing. Furthermore, goji significantly reduced fatigue and

stress, and improved regularity of gastrointestinal function. In contrast, the placebo group ( $n = 18$ ) showed only two significant changes: decreased heartburn and elevated mood.

### Immunomodulating

A randomised, double-blind, placebo-controlled trial examined the immunomodulatory effects of a standardised *L. barbarum* fruit juice (GoChi, FreeLife International, Phoenix, AZ). Sixty participants aged 55–72 years consumed 120 mL/day (equivalent to 150 g of fresh fruit) or placebo for 30 days. The treatment group showed statistically significant increases in lymphocytes (27%), interleukin-2 (IL-2) (58%) and immunoglobulin G (IgG) (19%) compared to both the placebo group and pretreatment levels. Other outcomes measured include levels of CD4, CD8, NK cells, IL-4 and IgA; however no significant changes were seen in any of these outcomes. The treatment group also reported significant improvement in general wellbeing, energy, sleep, short-term memory and concentration compared to both the placebo group and pretreatment reports. No adverse reactions were reported (Amagase et al 2009b).

A randomised, double-blind, placebo-controlled trial evaluated the effect of a milk-based *L. barbarum* formulation (Lacto-Wolfberry; Nestlé R&D Centre Shanghai, Shanghai, China) on immune function in the elderly. A total of 150 healthy elderly Chinese people aged 65–70 years were given a milk-based *L. barbarum* formulation or placebo (13.7 g/day) for 90 days. The treatment group had significantly higher postvaccination serum influenza-specific IgG levels and seroconversion rate, between days 30 and 90, compared with the placebo group. There was no statistically significant difference in postvaccination positive rate, delayed-type hypersensitivity response or inflammatory markers between the treatment group and the placebo group. No serious adverse reactions were reported. This study suggests the milk-based *L. barbarum* formulation can enhance the immune response to an antigenic challenge in elderly subjects without adversely affecting immune function (Vidal et al 2012).

### Weight loss

Amagase and Nance (2011) conducted two small, randomised, double-blind, placebo-controlled studies on *L. barbarum* standardised juice (GoChi; FreeLife International, Phoenix, AZ) and its effect on caloric expenditure and waist circumference. One was an acute dosing study and the other tested the effects of treatment after 14 days.

In the first study, after a 12-hour overnight fast, 8 healthy participants received a nutritional beverage containing 360 kcal and one of three doses of standardised juice (30, 60 or 120 mL) or placebo (a formulation designed to match the colour and flavour of the juice). Resting metabolic rate (RMR) was measured at baseline, 1, 2 and 4 hours postintervention. The RMR rose in all groups from

baseline, and after 4 hours had returned to baseline levels in all groups except the 120 mL *L. barbarum* treatment group. This group had an RMR that was significantly higher than placebo and other doses of *L. barbarum*.

In the second study, 33 participants were administered 90 mL of standardised juice or placebo in the morning with food and 30 mL at bedtime for 14 days. Caloric intake was restricted to 1200 kcal/day, and 15 minutes of walking each day was implemented for all subjects. Waist circumference was measured as baseline, midintervention and postintervention. The treatment group showed significant reductions in waist circumference at both mid- and postintervention assessment, whereas no significant change in waist circumference was seen in the placebo group. The results of both studies are promising; however, larger-scale studies of longer duration are required to clarify these findings.

### Aphrodisiac and increased male fertility

Traditional evidence and animal studies provide some support for its use; however, well-controlled clinical studies are not available to determine the effectiveness of goji in this capacity.

### Age-related macular degeneration

A randomised, double-blind, placebo-controlled trial evaluated the effect of a milk-based goji berry formulation (Lacto-Wolfberry; Nestlé R&D Centre Shanghai, Shanghai, China) on the clinical risk factors for age-related macular degeneration. A total of 133 healthy volunteers aged 65–70 years were administered 13.7 g Laco-Wolfberry (LBW, containing 530 mg/g goji berry, 290 mg/g skim milk powder and 180 mg/g maltodextrin) or placebo (290 mg/g skim milk powder, 200 mg/g maltodextrin, 476 mg/g sucrose and 34 mg/g yellow/caramel colourants) once per day for 90 days as a freeze-dried powder consumed in 200 mL of soup or warm water at lunch. LBW provided 10 mg/day goji berry-derived zeaxanthin, and 68.5 mg/day goji berry-derived vitamin C precursor. After 90 days, the LBW group showed significantly less macular hypopigmentation and fewer soft macular drusen than the control group. Plasma zeaxanthin (the carotenoid that composes the pre-retinal pigment and is abundant in goji berries) and antioxidant activity were significantly increased in the LBW group versus control. These findings suggest that milk-based goji formulations may protect against age-related macular degeneration by preventing hypopigmentation and soft drusen formation. Interestingly, no relationship was found between change in plasma zeaxanthin levels and changes in macular characteristics, therefore the mechanism of protection remains unclear (Bucheli et al 2011). It is worth noting that three of the authors are employees of the company that manufactures the milk-based goji berry formulation used in this study.

## OTHER USES

Goji is broadly marketed as a ‘functional food’ with significant health-promoting qualities. The high concentration of antioxidants, vitamins and minerals in the fruit makes it a nutritious substance; however, claims that it cures major diseases are not founded on sound clinical evidence.

The high concentration of zeaxanthin in the berries makes it a good dietary source of this carotenoid. As such, indications which respond to increased zeaxanthin intake may also respond to an equivalent dose from goji berries. (See Lutein and zeaxanthin monograph for further information.)

G

### Clinical note — Pesticide residues

Levels of pesticides pyridaben and imidacloprid, for which there are zero-tolerance levels, were found in commercial goji juice samples. Methomyl, a carbamate insecticide whose use is restricted due to its high toxicity in humans, was also found. Other pesticides were also found but these levels were below tolerance levels (Tran et al 2012). Practitioners should be aware of the source and quality of goji products.

### Practice points/Patient counselling

- Goji berries are a nutritious source of antioxidants, vitamins and minerals.
- The LBP in the fruit that are considered to be the most important for pharmacological activity are attracting research interest.
- Preliminary studies in test tubes and with animal models indicate the berry and/or polysaccharides enhance immune function, exert neuroprotective effects, reduce lipid and blood glucose levels in diabetic models and improve male fertility; however, human tests are not available to determine whether these effects are significant in humans.
- Use with caution in people taking warfarin.

## DOSAGE RANGE

Daily dose: 6–15 g daily.

Bioavailability of zeaxanthin from freeze-dried wolfberries can be greatly enhanced when consumed in hot skimmed milk compared to hot water or warm milk (Benzie et al 2006).

## ADVERSE REACTIONS

Cases of allergic reactions, including anaphylaxis after goji berry consumption, have been reported. Sensitivities to nuts, tomato, peach and *Artemisia* appear to be common in people sensitive to goji berries. Non-specific lipid transfer proteins seem to be the major allergens involved in sensitisation and cross-reactivity (Ballarin et al 2011, Carnes et al 2013, Larramendi et al 2012). One case study suggests that individuals with latex sensitivity may also be sensitive to goji berries (Gomez et al 2013).

One case of *L. barbarum*-induced photosensitivity has been reported in a 53-year-old male who presented with pruriginous eruptions on sun-exposed areas of 2-week duration. The man had been taking *L. barbarum* berries and *Uncaria tomentosa* infusions for 5 and 3 months, respectively. Photoprovocation tests with *L. barbarum* berries and *U. tomentosa* revealed that photosensitivity was not increased with *U. tomentosa*, but was increased with *L. barbarum* berries (Gomez-Bernal et al 2011).

One case of hepatotoxicity related to the consumption of *L. barbarum* has been reported. A 60-year-old woman was admitted to the hospital with a 24-hour history of asthenia, arthralgias, non-bloody diarrhoea and abdominal pain. The patient presented with mild jaundice and a generalised rash. She had been consuming a tea of goji berries three times daily for the previous 10 days and no other medication. Liver enzymes were raised, but no other abnormalities were detected in laboratory tests or abdominal ultrasound. Consumption of the tea was stopped, and liver enzymes returned to normal after 1 month (Arroyo-Martinez et al 2011). As it is unknown whether the tea was tested for authenticity and presence of contaminants, the causality cannot be established.

## SIGNIFICANT INTERACTIONS

### Warfarin

Three case reports exist in the literature suggesting that an interaction between warfarin and goji is possible. However causality remains unclear as it is unknown whether the suspected products were tested for authenticity and presence of contaminants.

One case was of an 80-year-old Chinese woman on a chronic stable dose of warfarin, who experienced two episodes of an elevated international normalised ratio (INR) after drinking herbal tea containing goji (Leung et al 2008). Another case describes a 61-year-old Chinese woman, previously stabilised on anticoagulation therapy (INR 2–3) who had an elevated INR of 4.1 as a result of drinking a concentrated Chinese herbal tea made from *L. barbarum* L. fruits (3–4 glasses daily). No changes in her other medications, lifestyle or dietary habits were revealed (Lam et al 2001). A third case describes a 71-year-old Ecuadorean-American woman who had been on warfarin for 3 months following knee surgery. The woman presented with epistaxis, bruising and rectal bleeding, and was found to have a markedly elevated INR. No changes in dietary habits or lifestyle were reported other than drinking goji juice for 4 days prior to hospitalisation (Rivera et al 2012). Until confirmation from controlled trials is available, caution is advised.

## CONTRAINDICATIONS AND PRECAUTIONS

Allergic reactions in sensitised individuals, especially those with sensitivities to nuts, tomato, peach, latex and *Artemisia*.

## PREGNANCY USE/PATIENT COUNSELLING

The fruit is likely to be safe when taken in typical dietary doses; however, the safety of higher doses is unknown.

## ! PATIENTS' FAQs

### What will this herb do for me?

Goji fruits are a nutritious source of vitamins, minerals and antioxidants. Preliminary tests show that it has multiple health-promoting effects, but little human research is available to confirm activity.

### When will it start to work?

As a concentrated source of nutrients, general benefits will start within several days.

### Are there any safety issues?

Three case reports suggest a possible interaction between warfarin and goji berry, but this remains to be confirmed.

## Goldenrod

**HISTORICAL NOTE** *Solidago virgaurea* (goldenrod) is a perennial herb that is common in Europe and found at lower altitudes (below 1500 m). It is recognisable by its elongated and branched golden yellow flower heads that bloom in summer (Laurençon et al 2013). Goldenrod has been used in European phytotherapy for over 700 years for the treatment of chronic nephritis, cystitis, urolithiasis, rheumatism (Apáti et al 2003) and wound healing. The name *Solidago* is from the Latin verb 'to make whole'. In 1934, reports from the US Department of Agriculture suggested that goldenrod was considered as a potential future source of commercially prepared rubber, although it was noted that domestication of the plant would be difficult as it is vulnerable to fungal infection and insect attack.

### COMMON NAME

Goldenrod

### OTHER NAMES

Aaron's rod, blue mountain tea, sweet goldenrod, woundwort

### BOTANICAL NAME/FAMILY

*Solidago canadensis* (Canadian goldenrod), *Solidago virgaurea* (European goldenrod) (family Asteraceae [Compositae]). There are numerous species of goldenrod.

### PLANT PARTS USED

Dried aerial parts — flowers and leaves.

### CHEMICAL COMPONENTS

Flavonoids, sesquiterpenes, diterpenes, triterpenes, saponins, phenolic glycosides (Zhang et al 2007), diterpenes (Starks et al 2010, Zhang et al 2007),

rutin, catechol tannins, phenolic acids, one essential oil, diterpene lactones and polysaccharides.

### MAIN ACTIONS

The pharmacology of goldenrod has not been significantly investigated; therefore, evidence of activity derives from traditional, in vitro and animal studies.

#### Diuretic

Goldenrod is considered an aquaretic medicine, as it promotes fluid loss without an associated disruption to electrolytes. Two animal studies have confirmed diuretic activity (Chodera et al 1991, Leuschner 1995). According to one study, excretion of calcium increases whereas excretion of potassium and sodium decreases (Chodera et al 1991). A review of herbal medicines for the urinary tract concluded that goldenrod is a major diuretic herb (Yarnell 2002).

### Antispasmodic and anti-inflammatory

High doses of a commercial preparation of *S. gigantea* extract have demonstrated anti-inflammatory activity in an animal model, comparable to those of the pharmaceutical anti-inflammatory medicine diclofenac (Leuschner 1995). Other tests with an extract of *S. virgaurea* have also produced similar results (el Ghazaly et al 1992).

The herbal combination consisting of *Populus tremula*, *S. virgaurea* and *Fraxinus excelsior* has demonstrated dose-dependent anti-inflammatory, analgesic and antipyretic effects comparable to those of non-steroidal anti-inflammatory drugs (NSAIDs) in several animal models (Okpanyi et al 1989). Although encouraging, the role of *Solidago* in this study is uncertain.

### OTHER ACTIONS

Traditionally believed to have an effect on the microarchitecture of the kidney.

### Antifungal

Inhibitory effects on human pathogenic yeasts such as *Candida* and *Cryptococcus* spp. have been demonstrated for triterpenoid glycosides isolated from *S. virgaurea* (Bader et al 1990). The saponins are considered chiefly responsible for the antimicrobial activity of *S. virgaurea* extract against *Candida albicans* hyphae formation. A study which isolated six triterpene saponins (virgaureasaponin 1–6) from the dried aerial parts of *S. virgaurea* found that four saponins showed an inhibition of *C. albicans* yeast–hyphal conversion, whereas fractions F1 and F2 were inactive. In contrast, fractions F3 and F4 showed significant inhibition of yeast–hyphal conversion (Laurençon et al 2013).

### Antibacterial

A moderate antibacterial activity in vitro against certain strains of bacteria, including species of *Bacillus*, *Proteus* and *Staphylococcus*, has been demonstrated from an extract of *Solidago virgaurea* (Thiem & Goslinska 2002). Clerodane diterpenes isolated from *S. virgaurea* were observed to have moderate antibacterial activity against *Staphylococcus aureus* (Starks et al 2010).

### Anticancer effects

An extract of *Solidago virgaurea* has demonstrated antineoplastic activity in vitro using a variety of cell lines, including prostate, breast, small-cell lung carcinoma and melanoma, and in vivo in a mouse model of prostate cancer (Gross et al 2002).

### Antiplatelet effects

Polyphenolic–polysaccharide conjugates from *S. virgaurea*, even at a concentration of 50 mcg/mL, could markedly reduce the level in nitrotyrosine in platelet proteins treated with ONOO<sup>-</sup>. The results indicated that the tested conjugates may protect platelet proteins against oxidation, leading to changed haemostatic function of platelets caused by

peroxynitrite or its intermediates (Saluk-Juszczak et al 2010). With this antiplatelet effect, goldenrod may have a potential use in cardiovascular disease, with further research expanding on the mechanism of action in the treatment of cardiovascular disease.

### Cardioprotective effects

A significant cardioprotective effect was observed in vivo against isoproterenol-induced cardiotoxicity when test rats were pretreated with *Solidago virgaurea* extract at a dose of 250 mg/kg once daily for 5 weeks. Without pretreatment, subcutaneous injections of isoproterenol led to a significant increase in serum lactate dehydrogenase, creatine phosphokinase, alanine transaminase, aspartate transaminase, angiotensin-converting enzyme activities, total cholesterol, triglycerides, free serum fatty acids, cardiac tissue malondialdehyde and nitric oxide levels ( $P < 0.05$ ). In addition, there was a significant decrease in levels of glutathione and superoxide dismutase in cardiac tissue as compared to the normal control group ( $P < 0.05$ ) (El-Tantawy 2014).

### CLINICAL USE

Goldenrod has not been significantly investigated under controlled study conditions, so most evidence is derived from traditional use, in vitro and animal studies.

### Cystitis

The most common use of goldenrod is in the treatment of bladder infections. Both the Commission E (Blumenthal et al 1998) and European Scientific Co-operative On Phytomedicine (ESCOP) (2003) have approved its use for irrigation of the urinary tract, with ESCOP also indicating usefulness as adjunctive treatment for bacterial urinary tract infections (UTIs).

### IN COMBINATION

Two clinical studies have been performed using a test combination which included *Solidago*, *Orthosiphon*, birch extract and cranberry (Cistimev Plus and Cistimev). One study involved people with indwelling catheters and the other women with recurrent UTIs; both produced encouraging results.

The first randomised study evaluated the efficacy of 1 × 600 mg Cistimev Plus tablet daily compared to no therapy in reducing microbial colonisation and biofilm development in patients with indwelling urinary catheters. After 30 days, a statistically significant reduction of microbial colonisation was found for the test group (10/43) vs the control group (16/30) ( $P = 0.013$ ) (Cai et al 2013).

The second study investigated the use of 3 months of antibiotic prophylaxis (prulifloxacin 600 mg, one tablet/week or phosphomycin one cachet/week) with and without the addition of Cistimev (one capsule/day) in 164 patients with UTI. The group using stand-alone antibiotics experienced a significantly greater UTI relapse risk (2.5 times greater) compared to the group taking combination therapy ( $P < 0.0001$ ). Of the group taking

both antibiotic prophylaxis plus Cistimev, 25% had no recurrence at 1 year, whereas all the patients receiving stand-alone antibiotic therapy experienced at least one recurrence within 1 year. In addition, the time to UTI recurrence was longer in the combination-therapy group (10.4 months) compared to antibiotics only (3.6 months;  $P < 0.0001$ ) (Frumenzio et al 2013).

### Arthritis (in combination)

The product Phytodolor contains alcoholic extracts of *Populus tremula*, *Fraxinus excelsior* and *Solidago virgaurea* and is standardised to 0.14 mg/mL of isofraxidine, 1 mg/mL salicine and 0.07 mg/mL of total flavonoids. As part of this combination, goldenrod has been investigated in patients with rheumatoid arthritis, osteoarthritis and back pain. Pain was significantly reduced by treatment with Phytodolor in a placebo-controlled study of 47 patients (Weiner & Ernst 2004). Symptom relief was equally effective amongst patients receiving half-strength, normal (60 drops three times daily) or double-strength treatment. A shorter placebo-controlled study of 2 weeks' duration found that Phytodolor reduced the need for conventional drug doses in subjects with 'at least one rheumatological diagnosis' (Weiner & Ernst 2004). Similarly, Phytodolor reduced requirements of diclofenac compared to placebo in a smaller study of 30 patients (Weiner & Ernst 2004). A 2-week placebo-controlled study of 30 subjects with osteoarthritis demonstrated that treatment with Phytodolor significantly reduced pain and improved grip strength (Weiner & Ernst 2004). A review found that Phytodolor may be a suitable alternative to NSAIDs and cyclooxygenase-2 inhibitors for the treatment of rheumatic disease (Gundermann & Muller 2007). The role of goldenrod in achieving these results is unclear.

### Inflammation of the nasopharynx with catarrh

Goldenrod is also used to relieve symptoms in this condition. The astringent activity of the tannin components provides a theoretical basis for its use.

### OTHER USES

In many countries, goldenrod is used to prevent urolithiasis and eliminate renal calculi (Skidmore-Roth 2001). Although only at the level of in vitro studies, goldenrod may be beneficial in reducing *Candida* overgrowth and in conditions associated with dry-mouth problems, without affecting the biofilm (Laurençon et al 2013). It is also used in children with otitis media and nasal catarrh.

### Traditional uses

Goldenrod is used both internally and externally for a variety of conditions. Internally it is used to treat upper respiratory tract catarrh, arthritis, menorrhagia and urological complaints, vomiting and dyspepsia, and externally it is used to support wound healing and as a mouth rinse for inflammatory conditions of the mouth and gums.

### DOSAGE RANGE

- Infusion of dried herb: 0.5–2 g in 150 mL of boiled water for at least 10 min.
- Fluid extract (1:1) (g/mL): 0.5–2 mL taken 2–4 times daily between meals.

### ADVERSE REACTIONS

Handling the plant has been associated with allergic reactions ranging from allergic rhinoconjunctivitis and asthma to urticaria. There is one study of a cohort predominantly comprising florists who had presented with complaints relating to the handling of plants; extensive cross-sensitisation to pollen of several members of the Asteraceae family (e.g. *Matricaria*, *Chrysanthemum* and *Solidago*) and to pollen of the Amaryllidaceae family (*Alstroemeria* and *Narcissus*) was found (de Jong et al 1998).

### SIGNIFICANT INTERACTIONS

None known.

#### Practice points/Patient counselling

- Goldenrod has a long history of use, but has not been tested in humans to any significant extent.
- Traditionally, it has been used internally to reduce upper respiratory catarrh, arthritis, menorrhagia, urological complaints and dyspepsia, and externally to promote wound healing and as a mouth rinse for inflammatory conditions of the mouth and gums.
- In Europe, goldenrod is a popular herb for treating lower UTIs and preventing kidney stones.
- When used as part of the commercial preparation Phytodolor, it provides effective symptom relief in rheumatoid arthritis and osteoarthritis, according to several clinical studies.
- It is considered an aquaretic herb: it induces diuresis but not potassium and sodium loss.
- Preliminary studies in animal models suggest anti-inflammatory activity comparable to that of NSAIDs, but human studies are not available to confirm the clinical significance of these findings.

### CONTRAINDICATIONS AND PRECAUTIONS

Commission E cautions against use as irrigation therapy when heart or kidney disease is also present (Blumenthal et al 1998).

People with known allergy to goldenrod or who are allergic to the Asteraceae (Compositae) family of plants should avoid this herb.

### PREGNANCY USE

From limited use in pregnant women, it appears that no increase in frequency of malformation or other harmful effects has been reported, although animal studies are lacking (Mills & Bone 2005).

## ! PATIENTS' FAQs

### What will this herb do for me?

Goldenrod has diuretic and anti-inflammatory activity, which may be useful in cases of bladder inflammation, although clinical testing has not yet been conducted to confirm this.

### When will it start to work?

This is unknown.

### Are there any safety issues?

People who are allergic to goldenrod or the Asteraceae family of plants should avoid taking this herb.

# Goldenseal

**HISTORICAL NOTE** Goldenseal is indigenous to North America and was traditionally used by the Cherokees and then by early American pioneers. Preparations of the root and rhizome were used for gastritis, diarrhoea, vaginitis, dropsy, menstrual abnormalities, eye and mouth inflammation and general ulceration. In addition to this, the plant was used for dyeing fabric and weapons. Practitioners of the eclectic school created a high demand for goldenseal around 1847. This ensured the herb's ongoing popularity in Western herbal medicine, but unfortunately led to it being named a threatened species in 1997. Today, most high-quality goldenseal is from cultivated sources.

### Clinical note — Isoquinoline alkaloids

Isoquinoline alkaloids are derived from phenylalanine or tyrosine and are most frequently found in the Ranunculaceae, Berberidaceae and Papaveraceae families (Pengelly 2004). This is a very large class of medicinally active compounds that include the morphinane alkaloids (morphine, thebaine and codeine), the ipecac alkaloids (emetine and cephaeline), the atropine alkaloid (boldine) and the protoberberines (berberine and hydrastine). Many other plants contain berberine, including *Berberis vulgaris* (barberry), *Mahonia aquifolium*/*Berberis aquifolium* (Oregon mountain grape), *Berberis aristata* (Indian barberry), *Coptis chinensis* (Chinese goldthread), *Coptis japonica* (Japanese goldthread) and *Thalictrum minus*.

### COMMON NAME

Goldenseal

### OTHER NAMES

Eye root, jaundice root, orange root, yellow root

### BOTANICAL NAME/FAMILY

*Hydrastis canadensis* (family Ranunculaceae)

### PLANT PARTS USED

Root and rhizome

### CHEMICAL COMPONENTS

Isoquinoline alkaloids, including hydrastine (1.5–5%), berberine (0.5–6%) and canadine (tetrahydroberberine, 0.5–1.0%). Other related alkaloids include canadine, hydrastidine, corypalmine and isohydrastidine.

There are significant seasonal variations in biomass yields and hydrastine contents of goldenseal roots, although rhizome yield are largely unaffected (Douglas et al 2010). Late summer or winter harvesting has been shown to provide the highest yield and alkaloid contents.

## MAIN ACTIONS

A wealth of empirical data exists for the medicinal use of goldenseal; however, much of the research has been conducted using the chief constituent berberine. It is recommended that goldenseal products be standardised to contain at least 8 mg/mL of berberine and 8 mg/mL of hydrastine (Bone 2003).

### Antimicrobial

In vitro testing has demonstrated antibacterial activity of both the whole extract of goldenseal and the major isolated alkaloids (berberine, beta-hydrastine, canadine and canadoline) against *Staphylococcus aureus*, *Streptococcus sanguis*, *Escherichia coli* and *Pseudomonas aeruginosa* (Scazzocchio et al 2001). In a study, two flavonoids isolated from goldenseal were shown to exhibit antibacterial activity against the oral pathogens *Streptococcus mutans* and *Fusobacterium nucleatum* (Hwang et al 2003). An added antimicrobial effect against *S. mutans* was noted with the addition of berberine. The synergistic effect of berberine with other goldenseal-derived alkaloids has been demonstrated against *Staphylococcus aureus*, whereby sideroxylin, 8-desmethyl-sideroxylin and 6-desmethyl-sideroxylin all enhanced the antimicrobial effect of berberine despite displaying no antimicrobial properties individually (Junio et al 2011). This effect was shown to be mediated through inhibition of the NorA multidrug-resistant pump.

Root and rhizome ethanolic extract of goldenseal has been shown to exhibit antibacterial activity against *Helicobacter pylori* and *Campylobacter jejuni* (Cwikla et al 2010). The methanolic extract of the rhizome inhibited the growth of 15 strains of *H. pylori* in vitro (Mahady et al 2003). The authors identified berberine and beta-hydrastine as the main active constituents.

Berberine alone, and in combination with both ampicillin and oxacillin, has demonstrated strong antibacterial activity against all strains of methicillin-resistant *Staphylococcus aureus* (MRSA) in vitro (Yu et al 2005); 90% inhibition was demonstrated with 64 microgram/mL or less of berberine. Berberine was also found to enhance the effectiveness of ampicillin and oxacillin against MRSA in vitro.

Many of the *Berberis* spp. contain the flavonolignan 5'-methoxyhydrnocarpin, which inhibits the expression of the multidrug-resistant efflux pumps (Musumeci et al 2003, Stermitz et al 2000a, 2000b); however, it is unknown whether goldenseal contains this compound.

Berberine inhibits the adherence of streptococci to host cells by aiding the release of an adhesin lipoteichoic acid (an acid that is responsible for the adhesion of the bacteria to the host tissue) from the streptococcal cell surface (Sun et al 1998). Berberine

is also able to dissolve lipoteichoic acid–fibronection complexes once they have been formed. Berberine displays well-defined antimicrobial properties against certain bacteria and such data suggest that it may also be able to prevent adherence and destroy already-formed complexes.

Berberine may also possess antifungal and antiviral properties. Antimycotic synergism between berberine and miconazole was observed against *Candida albicans* in both planktonic or biofilm growth phases (Wei et al 2011). When used alone, berberine was shown to destroy cell wall and sterol biosynthesis in *Candida* spp. in vitro (Park et al 1999).

The antiviral activities of goldenseal and its constituents have also been demonstrated in a number of studies. Ethanolic extracts of goldenseal, standardised to contain 25 microM berberine, were found to inhibit the growth of influenza A and the subsequent production of pro-inflammatory mediators TNF- $\alpha$  and PGE<sub>2</sub> after 24 hours exposure in RAW 264.7 cells (Cecil et al 2011). A study demonstrated the antiviral activity of berberine to be as effective as the DNA polymerase inhibitor ganciclovir in human cytomegalovirus (Hayashi et al 2007). It appeared to work via a different mechanism and may prove useful if used in conjunction to prevent tolerance and reduce toxicity.

### Antidiarrhoeal

Berberine decreases intestinal activity by activating alpha-2-adrenoceptors and reducing cyclic adenosine monophosphate (cAMP) (Hui et al 1991). Berberine also inhibits intestinal iron secretion and inhibits toxin formation from microbes (Birdsall & Kelly 1997).

Berberine has demonstrated efficacy in vitro for many bacteria that cause infective diarrhoea, including *E. coli*, *Shigella dysenteriae*, *Salmonella paratyphi*, *Clostridium perfringens* and *Bacillus subtilis* (Mahady & Chadwick 2001). It has also demonstrated activity in vitro against parasites that cause diarrhoea, including *Entamoeba histolytica*, *Giardia lamblia* and *Trichomonas vaginalis*. Berberine was effective against multiple strains of *Shigella* in vitro, with effects almost comparable to standard ciprofloxacin (Joshi et al 2011). An in vitro model of human intestinal epithelia found that berberine increased expression of the Na<sup>+</sup>/H<sup>+</sup> exchanger 3 and aquaporin 4 proteins in a model of induced diarrhoea, suggesting its actions may be mediated through enhancing sodium and water absorption (Zhang et al 2012). Further, in vivo studies have shown that berberine treatment delayed the onset of experimentally induced diarrhoea and number of diarrhoeal episodes in a dose-dependent manner. The effects of berberine on cholera toxin-induced water and electrolyte secretion were investigated in an experimental in vivo model (Swabb et al 1981). Secretions of water, sodium and chlorine were reduced 60–80 minutes after exposure to berberine. Berberine did not alter ileal water or electrolyte transport in the control model. It produced a significant reduction in fluid accumulation caused by

infection with *E. coli* in vivo (Khin-Maung & Nwe Nwe 1992). Oral doses of berberine before the toxin was introduced and intragastric injection after infection were both effective. Berberine was shown to inhibit by approximately 70% the secretory effects of *Vibrio cholerae* and *E. coli* in a rabbit ligated intestinal loop model (Sack & Froehlich 1982). As in the other study, the drug was effective when given either before or after enterotoxin binding. In an investigation using pig jejunum, berberine demonstrated a reduction in water and electrolyte secretion after intraluminal perfusion with *E. coli* (Zhu & Ahrens 1982).

Berberine significantly slowed small intestine transit time in an experimental in vivo model (Eaker & Sninsky 1989). Berberine inhibited myoelectric activity, which appears to be partially mediated by opioid and alpha-adrenergic receptors. The anti-diarrhoeal properties of berberine may be partially due to the constituents' ability to delay small intestinal transit time.

### Cardiovascular actions

Berberine may be effective for congestive heart failure and arrhythmia, as it has demonstrated positive inotropic, negative chronotropic, antiarrhythmic and vasodilator properties (Lau et al 2001).

In a 12-week rat model of hypercholesterolaemia and hyperglycaemia, berberine treatment (30 mg/kg/day) resulted in a 64% increase in cardiac output, 16% increase in left ventricular systolic pressure and a 121% decrease in left ventricular end diastolic pressure compared to no treatment (Dong et al 2011). Through analysis of cardiac biomarkers and protein expression, it was suggested these results were due to berberine's effects on alleviating cardiac lipid accumulation and promoting glucose transport.

In similar studies, after 8 weeks of treatment, oral doses of berberine (10 mg/kg) improved cardiac function and prevented development of left ventricular hypertrophy induced by pressure overload in rats (Hong et al 2002, 2003). Berberine was found to reduce left ventricular end-diastolic pressure, improve contraction and relaxation and decrease the amount of the atrophied heart muscle.

Berberine has also been found to increase cardiac output in dogs with left ventricular failure due to ischaemia (Huang et al 1992). Over 10 days, intravenous administration of berberine (1 mg/kg, within 3 minutes) followed by a constant infusion (0.2 mg/kg/min, 30 minutes) increased the cardiac output and decreased left ventricular end-diastolic pressure, diastolic blood pressure (DBP) and systemic vascular resistance, but did not affect heart rate. This study shows that berberine may be able to improve impaired left ventricular function by exerting positive inotropic effects and mild systemic vasodilatation. These results, although interesting, should be evaluated cautiously as the method of administration was intravenous. The hypotensive effects of the berberine derivative, 6-protuberberine (PTB-6), were studied in spontaneously hypertensive rats (Liu et al

1999). PTB-6 lowered systolic blood pressure (SBP) in a dose-dependent manner (5 mg/kg:  $-31.1 \pm 1.6$  mmHg; 10 mg/kg:  $-42.4 \pm 3.1$  mmHg). The berberine derivative also reduced cardiac output and heart rate. The authors conclude that the antihypertensive effect of PTB-6 is probably caused by a central sympatholytic effect.

### Hypocholesterolaemic/anti-atherogenic

Berberine upregulates the LDL receptor (LDLR) by stabilising the LDLR mRNA (Abidi et al 2005, Kong et al 2004). A follow-up study confirmed this and went on to demonstrate that the whole root preparation of goldenseal was more effective in up-regulating liver LDLR expression and reducing plasma cholesterol and LDL cholesterol in hyperlipidaemic hamsters than the pure berberine compound (Abidi et al 2006). The authors also noted that canadine effectively upregulated LDLR expression and unlike berberine was not affected by MDR1-mediated efflux from liver cells. In another study, hamsters fed a high-fat diet for 2 weeks, followed by treatment with oral doses of berberine (100 mg/kg) for 10 days, demonstrated a 40% reduction of cholesterol, including a 42% reduction in LDL cholesterol (Kong et al 2004). No effect on HDL cholesterol was noted.

The synergistic effects of berberine with plant stanols has been described in a number of studies. One study found that the supplementation of hamster diet ( $n = 17$ ) with 0.17% (100 mg/kg/day) berberine alone significantly reduced total cholesterol, HDL-cholesterol and non-HDL cholesterol compared to untreated control (Wang et al 2010). When co-administered with plant stanols, total cholesterol, non-HDL-cholesterol and triacylglycerols significantly decreased compared to untreated control, and both plant stanols and berberine alone. Conversely, the same research group found that in a rat model, berberine alone did not lower cholesterol, but when combined with plant stanols significantly reduced both total cholesterol and non-HDL cholesterol (Jia et al 2008). Rats being fed a high-sucrose, high-fat diet were given berberine (100 mg/kg), plant sterols (1% of total diet), a combination of both or a control mixture for 6 weeks. While berberine on its own made no appreciable difference, the combination reduced total cholesterol by 41% and non-HDL cholesterol by 59%. Berberine also reduced plasma triglycerides by 31%, which was of marginal statistical significance ( $P = 0.054$ ).

In combination with mevastatin, a HMG-CoA reductase inhibitor, berberine increased LDL receptor mRNA and protein levels and suppressed mRNA levels of PCSK9, a gene which down-regulated the LDL receptor (Cameron et al 2008). Further studies have been recommended to clarify the usefulness of berberine as an adjuvant therapy for patients receiving statins.

Berberine may have potential as an anti-atherosclerotic agent because of a demonstrated inhibition of lysophosphatidylcholine (lysoPC)-induced DNA synthesis and cell proliferation in

vascular smooth muscle cells (VSMCs) in vivo (Cho et al 2005). Berberine also inhibited the migration of lysoPC-stimulated VSMCs and the activity of extracellular signal-regulated kinases, reduced transcription factor AP-1 and intracellular reactive oxygen species. An in vitro study found that in PMA-induced macrophages, berberine inhibits the up-regulated expression of MMP-9 and EMMPRIN, both of which have been shown to contribute to plaque instability and rupture (Huang et al 2011). This suggests that berberine may be useful for the prevention and stabilisation of atherosclerosis.

### Antidiabetic

A glucose-lowering effect similar to metformin was observed in vitro for berberine; however, no effect was seen on insulin secretion (Yin et al 2002).

In high-fat diet-induced obese mice, the administration of 3 mg/kg/day berberine for 36 days resulted in significantly reduced food intake and blood glucose levels compared to untreated control (Hu & Davies 2010). A reduction in body weight and serum triglycerides was also seen at berberine concentrations of 0.75–3 mg/kg/day and a decrease in total serum cholesterol from 1.5–5 mg/kg/day. Results from this study suggest that berberine may be a useful adjunct in the prevention of obesity, although further tests are warranted.

Blood glucose, blood lipids, muscle triglycerides and insulin sensitivity were measured before and after the ingestion of berberine or metformin in rats fed a high-fat diet (Gao et al 1997). In this trial, berberine and metformin improved insulin resistance and liver glycogen levels, but had no effect on blood glucose, insulin, lipid and muscle triglyceride levels. The study was able to demonstrate that berberine was as effective as metformin for improving insulin sensitivity in the rats.

Similarly, fasting blood glucose, total cholesterol and triglyceride levels significantly decreased after 8 weeks of treatment with 187.5 or 562.5 mg/kg of berberine in an experimental model of glucose intolerance (Leng et al 2004). An additional in vitro study using insulin secreted from pancreatic cells, incubated with berberine for 12 hours, concluded that berberine increased insulin production. The relationship of these trials to oral doses in humans is unknown. In another in vivo test, diabetic rats were treated with berberine (100 or 200 mg/kg) via intragastric means for 21 days (Tang et al 2006). The researchers found that berberine demonstrated hypoglycaemic, hypolipidaemic and antioxidant effects.

Berberine inhibits alpha-glucosidase and therefore reduces the transport of glucose through the intestinal epithelium (Pan et al 2003). Berberine also appears to stimulate glucose uptake through the AMP-AMPK-p38 MAPK pathway, which may be at least partly responsible for its hypoglycaemic effects (Cheng et al 2006).

Berberine may be able to attenuate the renal complications of diabetes. Streptozotocin-induced diabetic rats were fed berberine (200 mg/kg) for 12

weeks in order to examine the effects on kidney function (Liu et al 2008). The results showed significant reductions in fasting blood glucose, blood urea nitrogen, protein and creatinine over 24 hours as compared to control animals.

### Anti-inflammatory

Rats treated long-term with golden seal (25,000 ppm in feed) over 2 years exhibited reduced lung and sinus inflammation as well as reduced neutrophil, macrophage and lymphocyte infiltration within both regions, indicative of reduced inflammatory mediation (Dunnick et al 2011).

Supplementation of berberine (50–500 mg/kg) over 14 weeks in non-obese diabetic mice was found to reduce the ratio of pro-/anti-inflammatory cytokines in the liver and kidney, as well as reduced the Th1/Th2 ratios in the spleen, thereby protecting these organs from spontaneous chronic inflammation (Chueh & Lin 2012).

Both in vitro and in vivo studies have found that berberine inhibits cyclo-oxygenase 2 (COX-2) transcriptional activity (Feng et al 2012, Fukuda et al 1999, Kuo et al 2005) and reduces prostaglandin (PG) synthesis (Kuo et al 2004). Berberine also inhibits kappa B-alpha phosphorylation and degradation, therefore reducing certain inflammatory mediators such as induced tumour necrosis factor (TNF)-alpha and interleukin (IL)-1beta productions in human lung cells (Lee et al 2007). The compound has also been found to reduce proliferation of human lymphocytes in vitro by inhibiting DNA synthesis in activated cells (Ckless et al 1995).

### Skin Ageing

Berberine inhibits basal and UV-induced matrix metalloproteinase (MMP)-1 activity, an interstitial collagenase, as well as increasing type I procollagen expression in primary human dermal fibroblasts (Kim & Chung 2008). The same group also demonstrated that berberine inhibited both basal and TPA-induced expression of MMP-9 and suppressed TPA-induced IL-6 expression in normal human keratinocytes (Kim et al 2008). These preliminary results suggest berberine may be of use in the prevention of skin damage associated with ageing and UV exposure, although further studies are recommended.

### Immune activity

Intragastric administration of the crude extract of goldenseal for 6 weeks increased the production of IgM in vivo (Rehman et al 1999). Berberine has also been found to induce IL-12 p40, a large subunit of IL-12, through the activation of p38 mitogen-activated protein kinase in mouse macrophages (Kang et al 2002). Interleukin-12 is crucial for the development of the Th1 immune response and thus may also have a therapeutic effect in reducing Th2 allergic disorders. A follow-up study demonstrated that pretreatment with berberine induced IL-12 production in stimulated macrophages and dendritic cells (Kim et al 2003). Macrophages pretreated with

berberine had an increased ability to induce interferon (IFN)-gamma and a reduced ability to induce IL-4 in antigen-primed CD4<sup>+</sup> T-cells. Increased levels of IL-12 appear to deviate CD4<sup>+</sup> T-cells from the Th2 to the Th1 pathway. This inhibition of type 2 cytokine responses indicates that berberine may be an effective anti-allergic compound.

The immunosuppressive effects of berberine were investigated in an induced autoimmune model in vivo (Marinova et al 2000). Berberine was administered daily (10 mg/kg) for 3 days before intravenous induction of tubulo-interstitial nephritis (TIN).

Significantly less damage and an increase in renal function were demonstrated in the animals pretreated with berberine as compared to controls after 2 months. Berberine decreased CD3, CD4 and CD8 lymphocytes in comparison with the non-treated animals. These results suggest that berberine may exert an immunosuppressive effect in a TIN model. Clinical trials in human kidney autoimmune diseases are warranted.

### Carcinogenic vs anticancer properties

A 2-year study by the National Toxicology Program investigated the effect of long-term administration of goldenseal (0–25,000 ppm in feed) in male and female rats and mice (Dunnick et al 2011). In both male and female rats, an increased incidence of hepatocellular adenoma was observed at doses of 25,000 ppm goldenseal. In male and female mice, significantly increased incidence of multiple hepatocellular adenoma was also observed from 9000 ppm. Further in vivo studies are recommended to determine whether use of goldenseal is likely to be safe and effective in a clinical setting (Tang et al 2009).

In contrast to this, there are a number of laboratory studies that have identified anticancer effects of berberine in the absence of other constituents of goldenseal (Tang et al 2009). Berberine has demonstrated cytotoxic activity in vitro against many strains of human cancer cells (Chen et al 2013, Hwang et al 2006, Kettmann et al 2004, Kuo et al 2005, Meeran et al 2008, Piyanuch et al 2007, Serafim et al 2008, Wang et al 2008). This is due in part to the reduction of COX-2 enzymes (Kuo et al 2005, Tai & Luo 2003), damage to the cytoplasmic membrane, DNA fragmentation (Letasiova et al 2005) and inhibition of topoisomerase II (Chen et al 2013). Pro-apoptotic activity of berberine through modulation of the HER2/PI3K/AKT signalling pathway and the mitochondrial apoptotic pathway have also been described (Tillhon et al 2012).

In an animal model of induced hepatocarcinoma, the combination of berberine and S-allyl-cysteine (SAC) inhibited Akt-mediated cellular proliferation, restored liver function and prevented morphological alterations in treated mice compared to control (Sengupta et al 2014). This study identified the inhibition of Akt-mediated pathways, inhibition of JNK and activation of PP2A may play a role in the underlying mechanisms of berberine and SAC in the induced hepatocarcinoma model. Similarly, another

in vivo study found the oral administration of berberine (50 mg/kg) reduced hepatocarcinogenesis through reductions in iNOS, hepatocyte proliferation and reduce cytochrome P450 activities (Zhao et al 2008).

The antitumour effects of berberine were investigated on malignant brain tumours in an in vitro and in vivo model (Zhang et al 1990). Berberine (150 mg/mL) demonstrated an ability to kill 91% of cells in six human malignant brain tumour cell lines and 10 mg/kg exhibited an 80.9% cell-kill rate against solid brain tumours in vivo. The addition of berberine to 1,3-bis(2-chloroethyl)-1-nitrosourea increased cytotoxicity.

### Neuroprotective

An in vivo study was designed to investigate the neuroprotective effects of berberine in ischaemic brain injury (Zhou et al 2008). Berberine (20 mg/kg) was intragastrically administered 30 minutes before and 1 day after middle cerebral artery occlusion (MCAO) was performed. After 48 hours, infarct size and neurological deficits were significantly reduced in the treatment group as compared to control. The authors were interested in discovering the mechanisms of action and designed a follow-up in vitro study. They found that berberine inhibited reactive oxygen species and protected PC12 cells against glucose and oxygen deprivation.

Berberine may also be effective in Alzheimer's disease according to early in vitro data (Asai et al 2007). Berberine significantly reduced extracellular amyloid-beta peptide levels by modulating amyloid precursor proteins in human neuroglioma H4 cells.

### Antidepressant

A number of in vivo studies have shown berberine to have antidepressant effects at doses up to 20 mg/kg (Kulkarni & Dhir 2008, Peng et al 2007). Within mouse models, berberine has been shown to inhibit both noradrenaline and serotonin uptake in mouse brain synaptosomes, an effect which may be mediated by human organic cation transporters hOCT2 and hOCT3 (Sun et al 2014).

Oral doses of berberine (10 and 20 mg/kg) were shown to possess antidepressant effects in both the forced swim and tail suspension tests (Peng et al 2007). It was found to be slightly weaker than the positive control desipramine, a tricyclic antidepressant. In the forced swim test, however, berberine was shown to have additive benefits when used with desipramine, fluoxetine (a selective 5-HT reuptake inhibitor) and moclobemide (a monoamine oxidase inhibitor). The authors also noted that noradrenaline and serotonin levels were increased in the frontal cortex and hippocampus of animals in the berberine group (20 mg/kg).

Another in vivo study used the same models and gave animals either 5, 10 or 20 mg/kg of berberine IP (Kulkarni & Dhir 2008). They also found that animals in the berberine group demonstrated a reduced immobility period. Berberine (5 mg/kg IP)

also improved the efficacy of subeffective doses of standard antidepressant medications in the forced swim test. The acute administration of berberine (5 mg/kg IP) increased noradrenaline (31%), serotonin (47%) and dopamine (31%) in the brain. The authors add that the mechanism may at least in part involve the nitric oxide pathway and/or sigma receptors.

### Antioxidant

It has been suggested that berberine's diverse range of biological activities may be a result of its antioxidant properties (Siow et al 2011). Berberine quenches superoxide radicals, peroxyxynitrite and nitric oxide (Choi et al 2001, Jung et al 2009, Shirwaikar et al 2006). The molecular mechanisms underlying these observations, as well as specific clinical links to disease states, remain unclear.

### Hepatoprotective

An *in vivo* study investigating the effects of oral goldenseal (300 mg/kg and 1000 mg/kg) on paracetamol-induced hepatotoxicity found that 300 mg/kg treatment attenuated increases in serum ALT and AST (Yamaura et al 2011). It was hypothesised by the authors that the inhibition of CYP2E1, which metabolises paracetamol to the hepatotoxic metabolite NAPQI, may be responsible for both observed effects.

In mice treated with carbon tetrachloride, berberine (5–10 mg/kg) was found to suppress the increase in serum ALT, AST, ALP, lipid peroxidation and the decrease in superoxide dismutase activity associated with induced hepatotoxicity (Domitrović et al 2011). This study also found that berberine treatment reduced the histopathological changes associated with CCl<sub>4</sub>-induced hepatotoxicity, possibly through the attenuation of pro-inflammatory cytokines TNF- $\alpha$  and COX-2, and antioxidant activity.

### Mitochondrial function

In an animal model of metabolic syndrome, rats fed high-fat diets who then received 100 mg/kg/day berberine treatment were found to have increased hepatic mitochondrial efficiency and back to levels seen in normal, untreated rats (Teodoro et al 2013). The recovery of mitochondrial function, including normalisation of mitochondrial membrane potential, by berberine was associated with an increased activity of the mitochondrial sirtuin 3 (SirT3).

### Urolithiasis

In a murine model of urolithiasis, berberine (10 mg/kg) prevented calcium oxalate crystal deposition in renal tubules and subsequent associated physical manifestations, including weight loss, impaired renal function and oxidative stress (Bashir & Gilani 2011).

### Periodontal disease

Data from *in vitro* and *in vivo* experimentation suggest that berberine may slow periodontal degradation through regulation of matrix-metalloproteinases

(Tu et al 2013). Berberine (0–100 microM) was added to LPS-treated human gingival fibroblast cultures and U-937 cultures, and was found to significantly decrease MMP activity in a dose-dependent manner. In periodontitic rats, berberine (75 mg/kg daily for 8 days) reduced gingival tissue degradation as assessed through micro-CT, histology and immunohistology, suggesting a possible role for berberine in periodontal disease.

### OTHER ACTIONS

Traditionally, goldenseal is described as having the following activities: antiscatarrhal, astringent, bitter, choleric, depurative, mucus membrane tonic, vulnerary and oxytocic.

### CLINICAL USE

Goldenseal has not been significantly investigated under clinical trial conditions, so evidence is derived from traditional, *in vitro* and animal studies. Many of these studies have been conducted on the primary alkaloids, in particular the isolated compound berberine. Although this compound appears to have various demonstrable therapeutic effects, extrapolation of these results to crude extracts of goldenseal is premature. It should also be noted that equivalent doses of the whole extract of goldenseal are exceptionally high.

### Diarrhoea

Diarrhoea and constipation are common clinical complaints that negatively affect quality of life. Unlike drugs that require systemic absorption to exert their effects, lumenally acting agents improve diarrhoea by altering intestinal and/or colonic motility, as well as mucosal absorption and secretion, through a variety of mechanisms. Berberine is an example of a lumenally acting agent for diarrhoea. Berberine from *Hydrastis canadensis* L., Chinese herb Huanglian, and also found in many other plants, is widely used in traditional Chinese medicine as an antimicrobial in the treatment of dysentery and infectious diarrhoea (Lau et al 2001).

In accordance with both *in vitro* and *in vivo* studies, human studies have shown that berberine treatment has anti-diarrhoeal activity.

A double-blind, placebo-controlled, randomised trial examined the effect of berberine alone (100 mg four times daily) and in combination with tetracycline for acute watery diarrhoea in 400 patients (Khin-Maung et al 1985). Patients were divided into four groups and given tetracycline, tetracycline plus berberine, berberine or placebo; 185 patients tested positive for cholera and those in the tetracycline and tetracycline plus berberine groups achieved a significant reduction in diarrhoea after 16 hours and up to 24 hours. The group given berberine alone showed a significant reduction in diarrhoea volume (1 L) and a 77% reduction in cAMP in stools. Noticeably, fewer patients in the tetracycline and tetracycline plus berberine groups excreted vibrios in their stool after 24 hours and interestingly no statistically significant improvements for patients

with non-cholera diarrhoea in the tetracycline or berberine group were shown. A later randomised, double-blind clinical trial compared 200 mg of berberine four times daily plus tetracycline with tetracycline alone in 74 patients with diarrhoea resulting from *V. cholerae* (Khin-Maung et al 1987). There were no statistically significant differences between the two groups.

An RCT evaluated the effect of berberine sulfate in 165 men with *E. coli*- or *V. cholerae*-induced diarrhoea as compared to tetracycline (Rabbani et al 1987). Patients with *E. coli* were given a single 400 mg dose and those with *V. cholerae* were given either a single 400 mg dose or 1200 mg (400 mg every 8 hours), combined with tetracycline. Berberine reduced mean stool volumes by 48% in the *E. coli* group as compared to control over 24 hours. Patients in the *V. cholerae* group who received 400 mg of berberine as a single dose also had a reduction in stool volume after 16 hours as compared to placebo. The combination of berberine and tetracycline did not show any statistical improvement over tetracycline alone in the *V. cholerae* group.

A follow-up randomised, placebo-controlled trial was designed to evaluate the antisecretory and antimicrobial potential of various antidiarrhoeal agents including berberine in patients with active diarrhoea due to *Vibrio cholerae* or enterotoxigenic *E. coli* (Rabbani 1996). Berberine at a lower dose of 200 mg resulted in a reduction in stool volume of between 30% and 50% without significant side effects. Berberine was again shown to be more effective in the treatment of diarrhoea resulting from *E. coli* than in cholera.

Small-intestinal transit time was evaluated in 30 healthy subjects in a controlled study (Yuan et al 1994). Transit time was significantly delayed from  $71.10 \pm 22.04$  minutes to  $98.25 \pm 29.03$  minutes after oral administration of 1.2 g of berberine. These results suggest that the antidiarrhoeal effect of berberine might be partially due to its ability to delay small-intestinal transit time.

### Giardiasis

Berberine may also be effective in the treatment of giardiasis. A comparison-controlled study of 359 children aged between 4 months and 14 years compared berberine (10 mg/kg/day) with metronidazole (20 mg/kg/day) for up to 10 days (Gupte 1975). Negative stool samples were evident in 90% of children receiving berberine after 10 days with 83% remaining negative after 1 month's duration. The results were comparative with the metronidazole (Flagyl) group (95% after 10 days and 90% after 1 month), without side effects. In a similar study, 40 children aged 1–10 years with giardiasis were given berberine (5 mg/kg/day), metronidazole (10 mg/kg/day) or placebo (vitamin B syrup) for 6 days (Choudry et al 1972). In the berberine group, 48% of children were symptom-free after 6 days and 68% had no giardia cysts on stool analysis as compared to the metronidazole group who experienced a 33% reduction in symptoms and a 100% clearance rate for cysts. These results show that

berberine may be more effective than Flagyl for symptom relief, but not as effective for clearing the organism from the gastrointestinal tract. The aforementioned study (Gupte 1975) used a higher dose of berberine (10 mg/kg/day), which produced better results; however, the equivalent amount of goldenseal for either dose would be exceedingly high based on an average berberine content of 5%, which would be inappropriate.

### Radiation-induced acute intestinal symptoms (RIAISs)

RIAISs are the most relevant complication of abdominal or pelvic radiation and have a negative impact on patients' daily activities. A RCT found that pretreatment with oral berberine significantly decreased the incidence and severity of RIAISs in patients with abdominal/pelvic radiotherapy when compared with the patients of the control group ( $P < 0.05$ ) (Li et al 2010, Menees et al 2010). Oral berberine also significantly postponed the occurrence of RIAISs in patients with abdominal or whole pelvic radiation. The study included 36 patients with seminoma or lymphomas who were randomised to receive berberine oral ( $n = 18$ ) or not ( $n = 18$ ) and an additional 42 patients with cervical cancer were randomised to a trial group ( $n = 21$ ) and control group ( $n = 21$ ). Active treatment consisted of 300-mg berberine taken orally three times daily. In addition, 8 patients with RIAISs were treated with 300-mg berberine three times daily from the third to the fifth week.

### Eye infection

A controlled clinical trial of 51 patients with ocular trachoma infections investigated the effectiveness of berberine over 3 weeks with a 1-year follow-up (Babbar et al 1982). Subjects who used the 0.2% berberine either by itself or combined with sulfacetamide demonstrated significant symptom improvement and tested negative for *Chlamydia trachomatis*, with no relapse after 1 year.

A later comparison-controlled clinical study also evaluated the effectiveness of the topical treatment of berberine for trachoma in 32 microbiologically confirmed patients (Khosla et al 1992). A 0.2% berberine solution (2 drops in each eye, three times daily) was found to be more effective than sulfacetamide (20%) in reducing both the course of the trachoma and the serum antibody titres against *C. trachomatis*. Berberine eyedrops were compared to berberine plus neomycin ointment, sulfacetamide and placebo in a double-blind, controlled clinical trial in 96 primary school children (Mohan et al 1982). Patients in the berberine group were asked to use 2 drops (0.2% berberine) of the solution in each eye, three times daily and to additionally apply a berberine ointment (0.2%) at night for 3 months. Children treated with only the berberine had an 87% clinical response rate, compared to 58% in the berberine and neomycin group; however, only 50% tested negative in follow-up microbiological tests.

A study addressed safety concerns about berberine eye products (Chignell et al 2007). They concluded that caution should be taken when eyes are exposed to strong sunlight.

### Hypercholesterolaemia

In an RCT, oral doses of 0.5 g of berberine, given twice daily for 3 months in 32 hypercholesterolaemic patients, resulted in a 29% reduction in serum cholesterol, a 35% reduction in triglycerides and a 25% reduction in LDL cholesterol (Kong et al 2004). HDL cholesterol levels remained unchanged. Berberine also significantly improved liver function, as noted by liver enzyme levels.

Use of berberine (500 mg three times daily) in newly diagnosed type 2 diabetics ( $n = 26$ ) compared to standard metformin therapy (500 mg three times daily) for 13 weeks resulted in significantly reduced total cholesterol (reduced by 0.57 mmol/L) and triglycerides levels (reduced by 0.24 mmol/L) in patients taking berberine compared to the metformin group ( $P = 0.05$ ) (Yin et al 2008). In the same study, the combination of standard metformin therapy with berberine treatment resulted in significantly lowered LDL cholesterol, total cholesterol and triglyceride levels compared to baseline after 13 weeks.

A 2008 trial compared berberine, simvastatin and a combination of both (Kong et al 2008). Patients ( $n = 63$ ) diagnosed with hypercholesterolaemia (total cholesterol over 5.2 mmol/L) were randomised into three groups and given either berberine (1 g/day), simvastatin (20 mg/day) or both. After 2 months of oral treatment, the results were as follows: mono-preparation of berberine reduced LDL cholesterol by 23.8% and triglycerides by 22.1%; simvastatin reduced LDL cholesterol by 14.3% and triglycerides by 11.4%; combination therapy reduced LDL cholesterol by 31.8% and triglycerides by 38.9%. Total cholesterol reductions were similar to LDL reductions and HDL cholesterol did not change significantly in any group. All preparations were found to be safe.

### Chronic congestive heart failure

The efficacy and safety of berberine in chronic congestive heart failure were studied in a randomised, double-blind, controlled study in 156 patients with chronic heart failure (Zeng et al 2003). All patients received conventional treatment and 79 patients in the treatment group also received 1.2–2.0 g/day of berberine for 8 weeks. Quality of life was greatly improved in the berberine group in comparison to controls, as measured by a significant increase in left ventricular ejection fraction, less fatigue and a greater capacity to exercise. A significant reduction in mortality was also noted during the 24-month follow-up (7 in the treatment group as compared to 13).

The acute cardiovascular effects of intravenous berberine (0.02 and 0.2 mg/kg/minute for 30 minutes) were studied in 12 patients with refractory congestive heart failure (Marrin-Neto et al 1988). At

the lower dose, a 14% reduction in heart rate was noted, whereas 0.2 mg/kg resulted in a 48% decrease in systemic vascular resistance and a 41% decrease in pulmonary vascular resistance. Right atrium and left ventricular end-diastolic pressures were reduced by 28% and 32%, respectively. Cardiac index, stroke index and left ventricular ejection fraction were also significantly enhanced.

### Diabetes

Despite a large amount of preclinical data, well designed clinical trials investigating the role of goldenseal or berberine in glucose metabolism are still lacking. Preliminary studies suggest that berberine may be effective in lowering fasting blood glucose and Haemoglobin A<sub>1C</sub> (HbA<sub>1C</sub>) in patients with type 2 diabetes, as well as patients with comorbidities such as chronic hepatitis (Zhang et al 2010).

A pilot study was designed to determine the safety and efficacy of berberine in patients with type 2 diabetes mellitus (Yin et al 2008). Eighty-four subjects were divided into two groups. Study A consisted of 36 newly-diagnosed type 2 diabetics who received either berberine (500 mg three times daily) or metformin (500 mg three times daily) for 13 weeks. The second group (study B) consisted of 48 diabetics who were poorly controlled on their current medication. They all stayed on their current regimen and half also received berberine (500 mg three times daily) for 13 weeks.

Results for study A: Participants in the berberine group had very similar results to the metformin group. HbA<sub>1C</sub> reduced by 2%, fasting blood glucose reduced by 3.8 mmol/L and postprandial blood glucose reduced by 8.8 mmol/L. Fasting insulin levels and postprandial insulin were also the same as the metformin group.

Results for study B: Participants in the combination group had reductions in haemoglobin A<sub>1C</sub> from 8.1% to 7.3% ( $P = 0.001$ ). Fasting blood glucose and postprandial blood glucose also improved significantly ( $P = 0.001$ ), and fasting insulin was also reduced by 29.0%.

### Polycystic ovary syndrome (PCOS) and IVF

An RCT involving 150 infertile women with PCOS found that 3 months of berberine treatment before ovarian stimulation produced greater reductions in total testosterone, free androgen index, fasting glucose, fasting insulin and HOMA-IR, compared with placebo (An et al 2014). The same study confirmed that berberine and metformin treatments prior to IVF improved the pregnancy outcome by normalising the clinical, endocrine and metabolic parameters in PCOS women but that berberine had a more pronounced therapeutic effect and achieved more live births with fewer side effects than metformin. Furthermore, treatment with berberine, in comparison with metformin, was associated with decreases in BMI, lipid parameters and total FSH requirement.

**Clinical note — Berberine absorption**

Berberine is poorly absorbed, with up to 5% bioavailability (Pan et al 2002). In vitro data have clearly demonstrated that berberine is a potent antibacterial; however, in vivo data have established low bioavailability. Berberine has been shown to upregulate the expression and function of the drug transporter P-glycoprotein (Pgp) (Lin et al 1999). Pgp belongs to the super family of ATP-binding cassette transporters that are responsible for the removal of unwanted toxins and metabolites from the cell (Glastonbury 2003). It appears that Pgp in normal intestinal epithelia greatly reduces the absorption of berberine in the gut. In vivo and in vitro methods have been used to determine the role of Pgp in berberine absorption by using the known Pgp inhibitor cyclosporin A (Pan et al 2002). Co-administration increased berberine absorption sixfold and clearly demonstrated the role of Pgp in absorption.

Increased expression of Pgp can lead to cells displaying multidrug resistance (Glastonbury 2003). As previously reported, a certain flavonolignan in many *Berberis* spp. has the ability to inhibit the expression of multidrug-resistant efflux pumps (Stermitz et al 2000a, 2000b), allowing berberine and certain antibiotics to be more effective.

**Radiation-induced lung injury (RILI)**

A prospective, randomised, placebo-controlled, double-blind trial was designed to determine whether berberine might reduce RILI in patients receiving radiation treatment for non-small cell lung cancer (Liu et al 2008). Ninety patients were randomised to receive either 20 mg/kg/day of berberine or placebo for 6 weeks during three-dimensional conformal radiation therapy. At 6 weeks, 45.2% of patients in the treatment group developed RILI as compared to 72.1% in the placebo group. At 6 months, 35.7% of patients in the berberine group experienced RILI as compared to 65.1% in the control group. Significant improvements in lung function were also demonstrated.

**Recurrent aphthous stomatitis**

A randomised, placebo-controlled trial ( $n = 84$ ) found that the application of a gelatin containing berberine (5 mg/g) four times a day for 5 days significantly reduced ulcer pain, ulcer size, exudate level and erythema level in patients diagnosed with minor recurrent aphthous stomatitis compared to gelatin vehicle alone (Jiang et al 2013). Despite this, it should be noted that reductions across all four end-points were also seen in the control group, suggesting that occlusion of the ulcer with gelatin alone exerted some beneficial action. The authors did not comment on the significance of this finding compared with normal progression of ulcer wound healing.

**OTHER USES**

Menorrhagia, dysmenorrhoea, peptic ulcer, gastritis, dyspepsia, skin disorders, sinusitis, chronic inflammation of mucous membranes and topically for ulceration and infection. Goldenseal is included in some remedies to treat allergic rhinitis, though evidence for this indication is lacking (Kushnir 2011).

Traditionally, it is used as a bitter digestive stimulant that improves bile flow and liver function.

**DOSAGE RANGE****Internal**

- Tincture (1:3): 2.0–4.5 mL/day or 15–30 mL/week (Bone 2003).
- Tincture (1:10): 6–12 mL/day (Mills & Bone 2005).
- Dried rhizome and root: 1.5–3 g/day by decoction (Mills & Bone 2005).

**External**

- Eyewash: 0.2% berberine solution, 2 drops in each eye, three times daily (Khosla et al 1992).

**ADVERSE REACTIONS**

Goldenseal is generally regarded as safe in recommended doses (Blumenthal 2003). Doses higher than 0.5 g of pure berberine may cause lethargy, dizziness, dyspnoea, skin and eye irritation, gastrointestinal irritation, nausea, vomiting, diarrhoea, nephritis and kidney irritation (Blumenthal et al 1998).

**SIGNIFICANT INTERACTIONS**

Because controlled studies are not available, interactions are currently speculative and based on evidence of pharmacological activity. Many studies have shown that extracts of goldenseal significantly inhibit cytochrome P450 enzymes (Budzinski et al 2000, 2007, Etheridge et al 2007, Gurley et al 2005, 2008a, 2008b, Raner et al 2007). Two studies in healthy volunteers demonstrated that CYP3A4 and CYP2D6 were significantly down-regulated following goldenseal treatment (Gurley et al 2008a, 2008b). The inhibitory effects of berberine on CYP1A1/2, CYP1B1, CYP2C8, CYP2D6, CYP2E1, CYP3A4/5/11 and CYP4A10/14 have been reported in vitro and in vivo with one study finding that CYP2D6 and CYP3A4/5 were each down-regulated by 40% (Chatuphonprasert et al 2012, Gurley et al 2005, 2008a, 2008b, Lo et al 2013). As such, a pharmacokinetic interaction is likely between drugs chiefly metabolised by CYP3A4 or CYP2D6 and goldenseal.

**Cyclosporin A**

Berberine increased the blood concentration of cyclosporin A in renal transplant patients in an RCT (Wu et al 2005): 52 patients received 0.2 g of berberine orally three times daily for 3 months. The final blood concentration in the berberine/cyclosporin A group was 29.3% higher than the

group given cyclosporin A only. The relevance of this to oral ingestion of goldenseal is unknown — caution advised.

### Digoxin

Twenty healthy volunteers took 3210 mg of goldenseal and 0.5 mg digoxin daily for 14 days (Gurley et al 2007). There was no change in the pharmacokinetics of digoxin suggesting that this dose of goldenseal is not a potent modulator of Pgp.

#### Practice points/Patient counselling

- Goldenseal has been used traditionally as an antidiarrhoeal agent and digestive stimulant.
- Most clinical evidence has been conducted using the chemical constituent berberine. These data have shown effectiveness against diarrhoea, congestive heart failure, infection, plasma glucose and cholesterol.
- It has been suggested that berberine may also possess immunosuppressive, antidepressant and hepatoprotective properties based on animal and in vitro studies, though studies in humans are yet to confirm this.
- Goldenseal inhibits two key cytochromes (3A4 and 2D6) and therefore caution should be exercised if co-administering drugs metabolised via these routes.
- Goldenseal is not to be used in pregnancy or during breastfeeding, or in patients with kidney disease.
- Use with caution in patients who have hypertension or taking cyclosporin.

#### CONTRAINDICATIONS AND PRECAUTIONS

Goldenseal is contraindicated in kidney disease because of inadequate excretion of the alkaloids (Blumenthal 2003). Berberine has been found to be a potent displacer of bilirubin (Chan 1993). A review published in 1996 stated that berberine can cause severe acute haemolysis and jaundice in babies with glucose-6-phosphate dehydrogenase deficiency (Ho 1996). Goldenseal is therefore not recommended in pregnancy, lactation or cases of neonatal jaundice. Goldenseal is also contraindicated in hypertension (BHMA 1983) as large amounts of hydrastine have been reported to restrict peripheral blood vessels and cause hypertension (Genest & Hughes 1969). The dose required to induce this effect is unknown and the ability to reach this threshold using the whole extract is unlikely; however, until this is clarified goldenseal is best avoided in hypertension.

#### PATIENTS' FAQs

##### What will this herb do for me?

Goldenseal may be used in the treatment of diarrhoea, dyspepsia, infection, diabetes and cholesterol. Most of the available research has been done on the alkaloid berberine. More clinical trials of the whole

#### PREGNANCY USE

Contraindicated in pregnancy and lactation.

In addition to the preceding concerns about bilirubin, berberine has caused uterine contractions in pregnant and non-pregnant experimental models (Mills & Bone 2005). An in vivo study using 65-fold the average human oral dose of goldenseal investigated effects on gestation and birth and found no increase in implantation loss or malformation (Yao et al 2005). The authors conclude that the low bioavailability of goldenseal from the gastrointestinal tract was likely to explain the differences between in vitro and in vivo effects in pregnancy. Hydrastine (0.5 g) has also been found to induce labour in pregnant women (Mills & Bone 2005). Until more pharmacokinetic studies are done, goldenseal is best avoided in pregnancy.

extract are needed to determine if the same effect will be seen.

##### When will it start to work?

Antibacterial and antidiarrhoeal activities should be apparent quite quickly. The lipid-lowering effects of goldenseal have been reported within 12 weeks.

##### Are there any safety issues?

The herb should not be taken during pregnancy or lactation and may interact with some medications.

# Grapeseed extract

G

**HISTORICAL NOTE** Since the time of Ancient Greece, grape leaves, fruit and sap have been used medicinally to treat a variety of ailments, such as skin and eye irritation, varicose veins, diarrhoea, bleeding and cancer. In the 1500s, a French expedition in North America found itself trapped in ice and forced to survive on salted meat and stale biscuits. After a time, the crew began to show signs of what we now recognise as scurvy. It is believed that the men survived because a Native American Indian showed them how to make a tea from the bark and needles of pine trees. The French explorer wrote of this encounter in a book that was subsequently read by researcher Jacques Masquelier, also a Frenchman, in the 20th century. Intrigued by the story, he began to investigate the chemistry and properties of pine bark and identified oligomeric proanthocyanidin complexes (OPCs). Several years later, he extracted OPCs from grapeseed extract, which is now considered the superior source of OPCs (Murray & Pizzorno 1999).

## COMMON NAME

Grapeseed extract

## BOTANICAL NAME/FAMILY

*Vitis vinifera*/Vitaceae

## PLANT PARTS USED

Seeds, grape skins

## CHEMICAL COMPONENTS

The skin of the grapeseed is a rich source of proanthocyanidins (PCs: also referred to as procyanidins). Mixtures of procyanidins are referred to as OPCs. Grapeseed extract contains OPCs made up of dimers or trimers of (+)-catechin and (–)-epicatechin (Fine 2000) and also trimers and polymers of PCs. *Vitis vinifera* also contains stilbenes (resveratrol and viniferins) (Bavaresco et al 1999); however, it is unclear whether significant amounts are present in the seeds.

## MAIN ACTIONS

Most evidence of activity derives from in vitro and animal studies for OPCs or grapeseed extract; however, some clinical studies are also available. The stilbene resveratrol (3,4',5 trihydroxystilbene) has also been the focus of much investigation and exhibits anti-inflammatory, antithrombotic, anticarcinogenic and antibacterial activities, but it is not clear whether significant amounts are present in the seeds and grapeseed extract (Fremont 2000).

## Antioxidant

Grapeseed PC extract has demonstrated excellent free radical-scavenging abilities, in both test tube and animal models, and provided significantly greater effects than vitamins C, E and beta-carotene (Bagchi et al 1997, 1998, 2000, 2001, Castillo et al 2000, Facino et al 1999, Fauconneau et al 1997, Maffei et al 1994, 1996). In vitro tests have further identified a vitamin E-sparing effect, in which PCs prevent vitamin E loss and cause alpha-tocopherol radicals to revert to their antioxidant form (Maffei et al 1998). Animal studies have also demonstrated

### Clinical note — Proanthocyanidins

PCs are a group of naturally occurring polyphenolic bioflavonoids that are present in many fruits (e.g. apples, pears, grapes and peaches), vegetables, nuts, beans (e.g. cocoa), seeds, flowers and bark (e.g. pine) (Bavaresco et al 1999). Grapeseeds are a particularly rich source of PCs, containing more than any other grape products, such as red, white or rosé wine or grape juice, and more than most commonly available foods (Rasmussen et al 2005). PCs are also found in many medicinal herbs, such as *Ginkgo biloba*, *Camellia sinensis*, *Hypericum perforatum* and *Crataegus monogyna*; however, grapeseed extract is considered the superior source. PCs demonstrate a wide range of biological actions according to various in vitro, in vivo and clinical studies. However, in recent years, bioavailability studies have demonstrated that not all orally ingested PCs are absorbed. In particular, PC polymers have negligible absorption from the gastrointestinal tract, whereas low-molecular-weight PCs (monomers, dimers and trimers) are absorbed (Rasmussen et al 2005). In addition, some PCs are degraded by microflora in the caecum and large intestine into low-molecular-weight phenolic acids, chiefly hydroxyphenylpropionic acid and 4-O-methylgallic acid (Ward et al 2004), which are likely to contribute to the biological effects. These findings have implications when interpreting in vitro data because this method of testing does not take into account the variations in bioavailability and metabolism in the body.

that grapeseed extract exerts significant improvements in antioxidant enzyme activity in obesity- and diet-related oxidative stress (Castrillejo et al 2011, Choi et al 2012). A recent randomised controlled trial (RCT) found that 400 mg/day of catechin-rich grapeseed extract for a period of 1 month resulted in a positive effect on oxidative markers in obese adults — better than resveratrol alone, and on par

with resveratrol triphosphate (a more stable resveratrol derivative) (De Groote et al 2012).

### Inhibits platelet aggregation

Grapeseed extract has been shown to inhibit platelet aggregation, and combining extracts of grapeseed and grape skin produces a far greater antiplatelet effect in test tube and ex vivo tests (Shanmuganayagam et al 2002). Inhibition of platelet function was confirmed more recently (Sano et al 2005, Vitseva et al 2005).

### Stabilises capillary walls and enhances dermal wound healing

In vivo studies have found that PCs stabilise the capillary wall and prevent increases in capillary permeability when chemically induced in tests, such as carrageenan-induced hindpaw oedema (Zafirov et al 1990) and dextran-induced oedema (Robert et al 1990). Components in grapeseed extract have the ability to cross-link collagen fibres, thereby strengthening the collagen matrix (Tixier et al 1984). Clinical studies confirm that grapeseed extract improves capillary resistance when used at a dose of 150 mg daily (Lagrué et al 1981). Not unexpectedly, research has also identified wound-healing properties.

A 2002 study in mice found that topical application of grapeseed PCs considerably accelerated wound contraction and closure and provided additional support during the wound-healing process (Khanna et al 2002). It has been shown that a grapeseed extract preparation containing 5000 ppm resveratrol facilitates oxidant-induced vascular endothelial growth factor expression in keratinocytes in vitro, which may account for its beneficial effects in promoting dermal wound healing and resolution of related skin disorders (Khanna et al 2001).

### Anticarcinogenic, antimutagenic

Most tests have been conducted with PCs from grapeseed extract and show significant activity.

A number of in vitro studies have demonstrated that PCs from *Vitis vinifera* strongly suppress tumour growth and have cytotoxic activity against a range of cancer cells, including breast, lung, prostate, colon and gastric adenoma cells (Bagchi et al 2000, Dinicola et al 2010, Engelbrecht et al 2007, Fernandez-Perez et al 2012, Joshi et al 2001, Kaur et al 2006, Tyagi et al 2003, Ye et al 1999). More specifically, PCs from grapeseeds exerted antitumour properties in several animal models (Kim et al 2004, Martinez Conesa et al 2005, Nomoto et al 2004, Raina et al 2007, Ray et al 2005, Tong et al 2011, Zhang et al 2005). One study also found that grapeseed PCs enhanced the growth and viability of human gastric mucosal cells at the same time (Ye et al 1999).

Tests with grapeseed extract showed that it induced apoptosis in acute myeloid leukaemic cells (Fernandez-Perez et al 2012, Hu & Qin 2006) and an in vitro study identified gallic acid within

grapeseed extract to be effective against human prostate carcinoma cells (Agarwal et al 2006). In breast cancer cells, its mechanism of action is to inhibit aromatase activity and expression (Kijima et al 2006).

PCs from grape stems have also demonstrated inhibitory action against liver and cervical cancer cell growth in vitro, comparable to PCs from grapeseeds, preventing reactive oxygen species-induced DNA damage (Apostolou et al 2013).

### Anti-inflammatory

In vitro evidence suggests that grapeseed extract has anti-inflammatory activity (Sen & Bagchi 2001). Two compounds isolated from *Vitis vinifera* exhibit non-specific inhibitory activity against cyclooxygenase-1 and -2 (Waffo-Teguo et al 2001). Inhibition of the proinflammatory 5-lipoxygenase is another mechanism identified recently for grapeseed extract (Leifert & Abeywardena 2008). Rats fed on a hyperlipidic diet and grapeseed extract had a reduction in pro-inflammatory markers such as C-reactive protein, interleukin-6 and tumour necrosis factor-alpha (Terra et al 2009). Mice subjected to immunological liver injury demonstrated a significant reduction in inflammatory cytokines when treated with grapeseed extract (Liu et al 2012).

### Cardioprotective effects

Considering that grapeseed extract demonstrates antioxidant, antiplatelet and anti-inflammatory actions, it may have a role in the prevention of cardiovascular disease. A number of researchers have investigated this issue further, mainly using animal models. One series of studies was conducted by Bagchi et al (2003) using a natural, standardised, water-ethanol extract made from California red grapeseeds, which contained approximately 75–80% oligomeric PCs and 3–5% monomeric PCs. According to in vivo research, treatment with grapeseed extract provided resistance to myocardial ischaemia-reperfusion injury, better postischaemic ventricular recovery and reduced incidence of reperfusion-induced ventricular fibrillation and ventricular tachycardia, as compared with corresponding control animals. Another study using a hamster atherosclerosis model found that 50 and 100 mg grapeseed extract/kg body weight led to a 49% and 63% reduction in foam cells, respectively. Additionally, cholesterol- and triglyceride-lowering activity has been reported (Yu et al 2002). One animal study identified that grapeseed extract significantly reduced total cholesterol by 42%, low-density lipoproteins (LDLs) by 56% and elevated high-density lipoprotein (HDL) cholesterol by 56% (El-Adawi et al 2006). This lipid-lowering action has been attributed to enhanced bile acid secretion (Jiao et al 2010). A study with hyperlipidaemic rabbits showed that grapeseed extract administered over 15 weeks produced a significant reduction in aortic atherosclerosis in males, although no effect was observed in females (Frederiksen et al 2007).

A small RCT ( $n = 50$ ) assessed the role of 1300 mg/day of oral grapeseed extract, for a period of 4 weeks, on vascular endothelial function in high-risk subjects. The study found that, while there was no improvement in endothelial function after 4 weeks' treatment, there was a significant increase in brachial diameter, demonstrating measurable vascular effect (Mellen et al 2010).

A more recent in vitro study demonstrated that PCs from grapeseed extract inhibited angiotensin-converting enzyme activity (Eriz et al 2011), a finding that should be confirmed in vivo.

### Cognition enhancer/neuroprotective

Grapeseed PC extract demonstrated neuroprotective effects in vivo and an increase in superoxide dismutase with the highest test dose (Devi et al 2006). Some in vivo studies have identified that grapeseed extract reduces age-related oxidative DNA damage and improves memory performance and cognitive enhancement, most likely achieved via an antioxidant mechanism (Balu et al 2005, 2006, Sarkaki et al 2007, Sreemantula et al 2005). Interestingly, along with grapeseed extract's antioxidant action, one study demonstrated a neurorescue effect when grapeseed extract was given to rats 3 hours after neurotoxic injury (Feng et al 2005, 2007).

The ability of grapeseed extract to protect critical proteins in the brain that are most affected in Alzheimer's disease suggests a potential clinical application (Kim et al 2005, 2006).

### Reducing drug-induced toxicity

Protection against chemically induced multiorgan toxicity has also been reported (Bagchi et al 2001). Hepatoprotection was demonstrated in studies where rats were exposed to a hepatotoxin. It is thought that this effect was due to inhibiting lipid peroxidation via antioxidant activity (Dulundu et al 2007, Jamshidzadeh et al 2008, Pan et al 2011). Grapeseed extract demonstrated potent antioxidant activity and protected kidneys from gentamicin-induced nephrotoxicity in an experimental model. The same study found that bone marrow chromosomes were also protected (El-Ashmawy et al 2006). Grapeseed extract was also protective in rats from toxicity due to radiation exposure (Enginar et al 2007, Saada et al 2009).

Grapeseed extract protected against the cardiotoxic side effects of the chemotherapy drug doxorubicin in vivo. It is thought that the antioxidant properties of grapeseed extract protecting cardiomyocytes was chiefly responsible (Du & Lou 2008). Protection against chemotherapy-induced small-intestine mucositis was observed in another animal study where rats were administered with 400 mg/kg of grapeseed extract before and during chemotherapy (Cheah et al 2008).

### Modulating insulin response

Animal studies have shown that catechin-rich grapeseed extract significantly affected body weight

development over 12 weeks, suppressing weight gain in mice fed a high-fat diet. Grapeseed extract supplementation also decreased blood glucose and plasma insulin, leptin, glutamic pyruvate transaminase and cholesterol, compared to control (Meepprom et al 2011, Ohyama et al 2011). PCs have also demonstrated a direct effect on insulin resistance in an animal model, lowering insulin response after 10 days' treatment of 25 mg/kg day. However, longer-term dosing of 30 days showed better maintenance of fasting glycaemia. This dose was also shown to reduce visceral adipose tissue (Montagut et al 2010).

A recent RCT involving 8 healthy adults showed that supplementation of between 100 mg and 300 mg grapeseed extract, ingested together with a high-carbohydrate meal, significantly reduced postprandial plasma glucose. This result was seen within 15 minutes of ingestion and lasted up to 2 hours (Sapwarabol et al 2012). Longer term, 4 weeks' treatment with 600 mg/day grapeseed extract significantly improved markers of inflammation and glycaemia in 32 obese adults with type 2 diabetes (Kar et al 2009).

### OTHER ACTIONS

There is preliminary evidence from many other studies indicating a range of pharmacological effects. Results from a clinical study suggest that grapeseed extract increases the rhodopsin content of the retina or accelerates its regeneration after exposure to bright light (Boissin et al 1988). Reduced incidence of cataract development and cataract progression was also observed in an experimental model using grapeseed PC extract (Durukan et al 2006). Grapeseed extract shows evidence of antibacterial and antifungal actions, specifically against *Candida albicans* (Furiga et al 2009, Han 2007). Grapeseed extract has also been shown in vitro to have an antivenom action against the saw-scaled viper (Mahadeswaraswamy et al 2008). Antinociceptive effects demonstrated in vivo for grapeseed extract show a reduction in pain and a potentiating effect of morphine (Uchida et al 2008). An animal study demonstrated antiageing potential due to grapeseed extract maintaining the erythrocyte membrane integrity that is often impaired in the elderly (Sangeetha et al 2005). In vitro, grapeseed extract has demonstrated antiallergenic potential via the inhibition of mast cell degranulation (Chen et al 2012).

### CLINICAL USE

Free radical damage has been strongly associated with virtually every chronic degenerative disease, including cardiovascular disease, arthritis and cancer. Due to the potent antioxidant activity of grapeseed and its myriad of other pharmacological effects, its therapeutic potential is quite broad. The majority of clinical studies have been conducted in Europe using a commercial product known as Endotelon. Due to the poor bioavailability of high-molecular-weight PCs, it is advised that products containing chiefly low-molecular-weight PCs be used in practice.

### Fluid retention, peripheral venous insufficiency and capillary resistance

There is good supportive evidence from clinical studies that have investigated the use of grapeseed extract in fluid retention, capillary resistance or venous insufficiency (Amsellem et al 1987, Costantini et al 1999, Delacroix 1981, Henriët 1993, Lagrue et al 1981).

Hormone replacement therapy and fluctuations in hormone levels can produce symptoms of venous insufficiency in some women. One large study involving 4729 subjects with peripheral venous insufficiency due to hormone replacement therapy showed that grapeseed extract decreased the sensation of heaviness in the legs in just over half the subjects by day 45, whereas 89.4% of subjects experienced an improvement by day 90 (Henriët 1993). According to an open multicentre study of women aged 18–50 years with oedema due to premenstrual syndrome, grapeseed extract (Endotelon) administered from day 14 to 28 improved various symptoms of fluid retention, such as abdominal swelling, weight gain and pelvic pain and also venous insufficiency (Amsellem et al 1987). The treatment was taken for four cycles, with most women (60.8%) responding after two cycles and 78.8% responding after four cycles.

An open study involving 24 patients with non-complicated chronic venous insufficiency found that over 80% of subjects receiving OPCs (100 mg/day) reported lessened or no symptoms after 10 days. Symptoms of itching and pain responded best, completely disappearing during the course of treatment in 80% and 53% of the patients, respectively (Costantini et al 1999). A double-blind study of 50 patients with symptoms of venous insufficiency found that grapeseed extract (Endotelon 150 mg daily) improved both subjective and objective markers of peripheral venous insufficiency, such as pain (Delacroix 1981).

In some pathological conditions, such as inflammation or diabetes, vascular permeability can be abnormally increased (Robert et al 1990). Two studies investigated the effects of grapeseed extract on capillary resistance in hypertensive and diabetic patients under both open and double-blind, placebo-controlled conditions, with treatment producing significant improvements in both groups (Lagrue et al 1981). The studies used a daily dose of 150 mg (Endotelon).

### Diabetes

#### Diabetic retinopathy

Grapeseed extract (Endotelon 150 mg) was found to stabilise diabetic retinopathy in 80% of subjects compared to 47% with placebo, under double-blind test conditions (Arne 1982). These results were obtained by measuring objective markers such as visual acuity, muscular tone and ocular tone.

### Diabetic nephropathy

Preliminary in vitro research indicates that grapeseed polyphenols have a protective effect against cell damage, including renal cell damage, caused by high glucose levels (Fujii et al 2006). Other in vitro research also points to possible therapeutic benefits in preventing and treating vascular problems and diabetic complications (Zhang et al 2007).

A study with diabetic rats given grapeseed PC extracts identified nephroprotection, which might be related to the free radical-scavenging activity of grapeseed PC extracts (Liu et al 2006). Further research would be required to confirm a clinical application.

### Metabolic syndrome and blood pressure reduction

A randomised trial in 27 adults with metabolic syndrome found that treatment with either 150 mg or 300 mg grapeseed extract/day resulted in a significant reduction of both systolic and diastolic blood pressures after 4 weeks' treatment. In the 300 mg/day group, there was also significant reduction of oxidative LDL and an increase of plasma catechin concentrations (Sivaprakasapillai et al 2009).

### Eye strain

A double-blind study involving 75 patients with eye strain caused by viewing a computer screen found that a 300 mg dose of grapeseed extract daily significantly improved objective and subjective measures (Bombardelli & Morrazzoni 1995). Grapeseed extract (Endotelon) has also been shown to significantly improve visual adaptation to and from bright light in a dual-centre study involving 100 volunteers (Boissin et al 1988, Corbe et al 1988). A dose of 200 mg daily over 5 weeks was used. It has been proposed that grapeseed extract increases rhodopsin content of the retina or accelerates its regeneration after exposure to bright light.

### Hyperlipidaemia/atherosclerosis

A single-blind, placebo-controlled study where 61 healthy subjects took 200 or 400 mg grapeseed extract over 12 weeks showed that active treatment significantly lowered oxidised LDL levels at the end of the test period. The group receiving the higher dose experienced results at the earlier 6-week point as well as at 12 weeks (Sano et al 2007). A randomised, double-blind study of 40 subjects with hypercholesterolaemia compared the effects of placebo, chromium polynicotinate (400 mcg/day), grapeseed extract (200 mg/day) or a combination of both. Over 2 months, the combination treatment decreased total cholesterol and LDL levels significantly but did not significantly alter homocysteine, HDL or blood pressure among the four groups (Preuss et al 2000). The role of grapeseed extract in achieving this result is unclear.

### Enhances dermal wound healing

A 2002 study in mice found that topical application of grapeseed PCs considerably accelerated wound contraction and closure and provided additional support during the wound-healing process (Khanna et al 2002).

### Chloasma

Chloasma is a condition characterised by hyperpigmentation and is generally considered recalcitrant to treatment. PC-rich grapeseed extract successfully reduced hyperpigmentation in women with chloasma after 6 months of oral treatment, according to an open study involving 12 subjects (Yamakoshi et al 2004). The study continued for another 6 months but failed to find any additional improvement with further use. The researchers suggested that a preventive effect may be possible with long-term oral grapeseed extract when used in the months prior to summer.

### Pancreatitis

It is believed that the oxygen-derived free radicals mediate tissue damage in acute and chronic pancreatitis. Therefore, antioxidant treatment is being investigated. A small, open study of three patients with difficult-to-treat chronic pancreatitis found that a commercially available IH636 grapeseed extract produced a reduction in the frequency and intensity of abdominal pain, as well as resolution of vomiting in one patient.

### Preventing reperfusion injury

Procyanidin administration reduced the adverse effects of myocardial ischaemia-reperfusion injury during cardiac surgery in several *in vivo* studies (Facino et al 1999, Maffei et al 1996). This appears to be positively associated with an increase in plasma antioxidant activity. An animal model also suggests that a PC-rich extract from grapeseed was protective against renal damage from ischaemia-reperfusion injury (Nakagawa et al 2005). Another animal model showed protection against hepatic ischaemia-reperfusion injury by regulating the release of inflammatory mediators and by its antioxidant action (Sehirli et al 2008).

### Reduces sunburn

Topical application of grapeseed extract has been shown to enhance sun protection factor in human volunteers (Bagchi et al 2000). A study, with a grapeseed extract supplement, topical cream and a topical lotion (both Anthogenol products), assessed 42 individuals randomised into two groups, with one group taking the dietary supplement. Ultraviolet radiation-induced erythema was treated and it was found that both the topical applications decreased erythema formation, with slightly better results for those volunteers also taking the oral supplements. Application of the topical lotion produced the best results (53% reduction) and the lotion plus

the grapeseed extract supplement added a further 13% reduction in skin inflammation, while all groups found improved skin hydration (Hughes-Formella et al 2007).

#### Practice points/Patient counselling

- Grapeseed extract has considerable antioxidant activity and appears to regenerate alpha-tocopherol radicals to their antioxidant form.
- Grapeseed extract also has anti-inflammatory actions, reduces capillary permeability, enhances dermal wound healing and reduces photodamage, inhibits platelet aggregation and may enhance rhodopsin regeneration or content in the retina.
- It is popular in Europe as a treatment for venous insufficiency and capillary fragility, both of which are supported by clinical evidence. It is also used to relieve eye strain and stabilise diabetic retinopathy and connective tissue disorders.
- Preliminary research has identified cardioprotective effects due to a variety of mechanisms. Possible benefits include pancreatitis and multiorgan protection against damage caused by several pharmaceutical drugs, including several chemotherapy drugs, and radiation. Anticarcinogenic activity has also been reported.
- It shows promise for neurodegenerative disorders in preliminary studies.
- Most clinical research has been conducted in Europe with a commercial grapeseed product known as Endotelon.
- Due to concerns with bioavailability, it is recommended that only preparations containing low-molecular-weight PCs be used.
- It provides protection against multiorgan drug and chemical toxicity.

The results from a number of *in vivo* studies have suggested that pre-exposure to grapeseed extract can provide multiorgan protection against damage caused by various drugs, such as paracetamol, amiodarone, doxorubicin, cadmium chloride and dimethylnitrosamine treatment (Bagchi et al 2000, 2001). This is most likely via an antioxidant mechanism.

### OTHER USES

Some preliminary *in vitro* research suggests a potential use for periodontal diseases and oral hygiene for prevention of periodontitis. This is due to grapeseed extract's antimicrobial effect against specific oral bacteria and its strong antioxidant action (Furiga et al 2009, Houde et al 2006).

An *in vitro* study suggests a promising use for grapeseed extract as active against *Candida albicans* and a possible synergistic action with the drug amphotericin B, which would enable this strong drug dose to be reduced by 75% when given in conjunction with grapeseed extract. Clinical studies are needed to confirm this potential use (Han 2007).

## DOSAGE RANGE

- Fluid extract 1:1 (g/mL): 20–40 mL per week.
- Solid-dose forms: 12,000 mg of grapeseed extract standardised to OPCs taken 2–3 times daily in order to provide 150–300 mg of OPCs daily. Due to the poor bioavailability of high-molecular-weight PCs, it is advised that products containing chiefly low-molecular-weight PCs be used in practice.

According to clinical studies:

- Chloasma: 162 mg/day grapeseed extract.
- Cardiovascular disease: 200–300 mg/day grapeseed extract.
- Hypercholesterolaemia: 200–400 mg/day grapeseed extract.
- Chronic pancreatitis: ActiVin 200–300 mg/day.
- Oedema due to premenstrual syndrome: grapeseed extract (Endotelon) 150–400 mg taken from day 14 to 28.
- Oedema due to injury or surgery: 200–400 mg/day grapeseed extract (Endotelon).
- Diabetic retinopathy: 150–400 mg/day grapeseed extract (Endotelon).
- Insulin resistance: 300 mg/day grapeseed extract.
- Vascular fragility: 150–400 mg/day grapeseed extract (Endotelon).
- Venous insufficiency and poor leg circulation: grapeseed extract (Endotelon) 150–300 mg/day.
- Vision problems: grapeseed extract (Endotelon) 200 mg/day.

## TOXICITY

Tests in animal models have found grapeseed extract to be extremely safe (Bentivegna & Whitney 2002).

## ADVERSE REACTIONS

Studies using doses of 150 mg/day have found it to be well tolerated. Side effects are generally limited to gastrointestinal disturbances, including nausea and indigestion.

## SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are theoretical and based on evidence of pharmacological activity.

### Antiplatelet drugs

Additive effect theoretically possible — observe patient.

### Anticoagulant drugs

Increased risk of bleeding theoretically possible — monitor patient for increased bruising or bleeding.

### Iron and iron-containing preparations

Decreased iron absorption. Tannins can bind to iron, forming insoluble complexes — separate doses by 2 hours.

## CONTRAINDICATIONS AND PRECAUTIONS

None known.

## PREGNANCY USE

Safety has not been scientifically established.

## PATIENTS' FAQs

### What will this herb do for me?

There is evidence that grapeseed extract is a useful treatment for venous insufficiency, poor leg circulation and capillary fragility and has considerable antioxidant activity. It may also assist with blood sugar regulation and hyperlipidaemia in overweight and high-risk individuals. Grapeseed extract is used to treat eye strain and diabetic retinopathy and enhance wound healing when applied locally.

### When will it start to work?

It appears to relieve symptoms of venous insufficiency within 10 days and eye strain within 5 weeks. Other uses may take longer before results are seen.

### Are there any safety issues?

Research suggests that it is well tolerated and generally safe; however, people taking anticoagulant medicines should refer to their healthcare professional before taking this substance.

## Green tea

**HISTORICAL NOTE** Tea has been a popular beverage for thousands of years and was originally grown in China, dating back 5000 years, where it has been used as part of various ceremonies and to maintain alertness. Green tea and the partially fermented oolong tea have remained popular beverages in Asia since that time, whereas black tea is the preferred beverage in many English-speaking countries. Tea was introduced to the Western culture in the sixth century by Turkish traders (Ulbricht & Basch 2005). Second to water, tea is now considered to be the world's most popular beverage.

### COMMON NAME

Green tea

### OTHER NAMES

Chinese tea, camellia tea, gruner tea, Matsu-cha, green Sencha tea, Japanese tea, Yame tea

### BOTANICAL NAME/FAMILY

*Camellia sinensis* (family Theaceae)

### PLANT PART USED

Leaf

### CHEMICAL COMPONENTS

The composition of green tea varies according to the growing and harvesting methods, but the most abundant components are polyphenols, which are predominantly flavonoids (e.g. catechin, epicatechin, epicatechin gallate, epigallocatechin gallate,

**Clinical note — The difference between teas**

Black, green and oolong tea are produced from the same plant (*Camellia sinensis*) but differ in polyphenol content according to the way the leaves are processed. Black tea is made from oxidised leaves, whereas oolong tea is made from partially oxidised leaves and green tea leaves are not oxidised at all. Because the oxidising process converts many polyphenolic compounds into others with less activity, green tea is considered to have the strongest therapeutic effects and the highest polyphenol content (Lin et al 2003). Caffeine concentrations also vary between the different teas: black tea > oolong tea > green tea > fresh tea leaf (Lin et al 2003). Variation in caffeine content is further influenced by growing conditions, manufacturing processes and size of the tea leaves (Astill et al 2001). The highest-quality leaves are the first spring leaf buds, called the 'first flush'. The next set of leaf buds produced is called the 'second flush' and considered to be of poorer quality. Tea varieties also reflect the area they are grown in (e.g. Darjeeling in India), the form produced (e.g. pekoe is cut, gunpowder is rolled) and processing method (black, oolong or green) (Ulbricht & Basch 2005).

proanthocyanidins). Caffeine content in green tea varies but is estimated at about 3%, along with very small amounts of the other common methylxanthines, theobromine and theophylline (Graham 1992). It also contains many other constituents, such as tannin, diphenylamine, oxalic acid, trace elements and vitamins.

Epigallocatechin gallate is one of the most abundant polyphenols in tea and is regarded as the most important pharmacologically active component.

**MAIN ACTIONS**

It is suspected that the polyphenol content is chiefly responsible for the chemoprotective, antiproliferative, antimicrobial and antioxidant activity of green tea. The caffeine content is predominantly responsible for central nervous system (CNS) activity and an interaction between both appears necessary for increasing thermogenesis.

**Antioxidant**

Green tea has consistently demonstrated strong antioxidant activity. A recent systematic review of 31 controlled intervention studies concluded that green tea reduced lipid peroxidation and increased antioxidant capacity when the beverage was consumed regularly (0.6–1.5 litres a day) (Ellinger et al 2011). In a controlled human trial, 24 healthy women consumed two cups of green tea (250 mg catechins/day) for 42 days (Erba et al 2005). The results showed a significant increase in plasma antioxidant status, reduced plasma peroxides and reduced

low-density lipoprotein (LDL) cholesterol when compared with controls. Several other in vitro animal and human studies have also demonstrated that green tea inhibits lipid peroxidation and scavenges hydroxyl and superoxide radicals (Leenen et al 2000, Rietveld & Wiseman 2003, Sung et al 2000).

**Antibacterial activity**

Green tea extract has moderate and wide-spectrum inhibitory effects on the growth of many types of pathogenic bacteria, according to in vitro tests, including seven strains of *Staphylococcus* spp., seven strains of *Streptococcus* spp., 26 strains of *Salmonella*, 19 strains of *Escherichia coli* spp. and one strain of *Corynebacterium suis* (Ishihara et al 2001). In one in vitro study green tea was effective against most of the 111 bacteria tested, including two genera of Gram-positive and seven genera of Gram-negative bacteria. It was also confirmed that in vivo it could protect against *Salmonella typhimurium* (Bandyopadhyay et al 2005).

Recent in vitro research is looking at a possible role for (–)(–)-epigallocatechin-3-gallate (EGCG) in fighting antibiotic-resistant bacteria. It has been shown to be effective against 21 clinical isolates of *Acinetobacter baumannii*, a common cause of infection in intensive-care units, and against the antibiotic resistant *Stenotrophomonas maltophilia* (Gordon & Wareham 2010, Osterburg et al 2009).

Green tea has also been found to inhibit *Helicobacter pylori* in animal models (Matsubara et al 2003, Stoicov et al 2009). According to one study, which compared the antibacterial activity of black, green and oolong tea, it seems that fermentation adversely affects antibacterial activity, as green tea exhibited the strongest effects, and black tea the weakest (Chou et al 1999). An in vitro study has demonstrated that green tea can significantly lower bacterial endotoxin-induced cytokine release and therefore may reduce mortality from sepsis. Part of the antibacterial activity may be a selective anti-adhesive effect, with green tea inhibiting pathogen adhesion to cells (Lee et al 2009).

**Oral pathogens**

In a recent randomised controlled trial (RCT), 66 healthy subjects rinsed with a green tea extract for 1 minute three times a week, and at the end of 4 and 7 days there was a significant reduction in *Streptococcus mutans* and lactobacilli in the green tea group (Ferrazzano et al 2011). Both in vitro and in vivo tests have identified strong antibacterial activity against a range of oral pathogens, such as *Streptococcus mutans*, *S. salivarius* and *E. coli* (Otake et al 1991, Rasheed & Haider 1998). The mechanism of action appears to involve antiadhesion effects, with the strongest activity associated with epigallocatechin gallate and epicatechin gallate. Green tea catechins (GTCs) have also showed an antibacterial effect against *Porphyromonas gingivalis* and *Prevotella* spp. in vitro (Araghizadeh et al 2013, Hirasawa et al 2002).

Furthermore, green tea polyphenols, especially epigallocatechin gallate, have been found to completely inhibit the growth and adherence of *Porphyromonas gingivalis* on buccal epithelial cells (Sakanaka et al 1996).

### Antiviral activity

A number of in vitro studies have shown that epigallocatechin gallate strongly inhibits HIV replication (Chang et al 1994, Fassina et al 2002, Liu et al 2005, Tao 1992, Williamson et al 2006) and inhibits attachment of HIV virus to T cells (Nance et al 2009). The theaflavins from black tea have shown even stronger anti-HIV activity than catechins in vitro by inhibiting viral entry into target cells (Liu et al 2005). Antiviral activity has also been identified against Epstein–Barr virus, herpes simplex virus 1, influenza A and B, rotavirus and enterovirus (Chang et al 2003, de Oliveira et al 2013, Imanishi et al 2002, Isaacs et al 2008, Mukoyama et al 1991, Tao 1992, Weber et al 2003). EGCG and epicatechin gallate show antiviral activity inhibiting influenza virus replication in vitro with differences in the strength of the antiviral activity depending on the strain of influenza (Song et al 2005). In vitro research shows green tea extract and EGCG inhibit human papillomavirus in human cervical cancer cells (Tang et al 2008). Antiviral activity seems to be attributable to interference with virus adsorption (Mukoyama et al 1991).

### Antimalarial

Antimalarial properties have been shown in vitro, with crude extract of green tea, EGCG and epicatechin gallate strongly inhibiting *Plasmodium falciparum* growth (Sannella et al 2007).

### Anticarcinogenic

Several in vitro studies have shown a dose-dependent decreased proliferation and/or increased apoptosis in a variety of cancer cell lines (lung, prostate, colon, stomach, pancreatic, bladder, oral, leukaemia, breast, cervical and bone) (Garcia et al 2006, Gupta et al 2003, Han et al 2009, Honicke et al 2012, Kavanagh et al 2001, Khan et al 2009a, Kinjo et al 2002, Qanungo et al 2005, Qin et al 2007, Sen & Chatterjee 2011, Shimizu et al 2005, Siddiqui et al 2011, Srinivasan et al 2008, Valcic et al 1996, Wang & Bachrach 2002, Yamauchi et al 2009, Yoo et al 2002, Zhang et al 2002, Zou et al 2010). Additionally, photochemopreventive effects for green tea and epigallocatechin gallate have been demonstrated in vitro, in vivo and on human skin for the prevention of skin cancer (Afaq et al 2003, Katiyar 2011) and apoptosis of skin tumour cells (Mantena et al 2005).

The mechanism of action by which tea polyphenols exert antimutagenic and antitumorogenic effects is still largely speculative. A review of research suggests there is increasing experimental evidence of multiple signalling pathways and reducing cancer metastasis (Khan & Mukhtar 2010, Thakur et al

2012). A systematic review of in vitro and in vivo studies on epithelial ovarian cancer cells concluded green tea components had an impact on cell signalling, cell motility, angiogenesis, apoptosis and inflammation (Trudel et al 2012). The following has been observed: inhibition of the large multicatalytic protease and metalloproteinases, which are involved in tumour survival and metastasis, respectively, and inhibition of many tumour-associated protein kinases, while not affecting kinase activity in normal cells (Kazi et al 2002, Wang & Bachrach 2002). Tea polyphenols have also been found to inhibit some cancer-related proteins that regulate DNA replication and transformation. There is increasing evidence that catechins possess antiangiogenic properties (Sachinidis & Hescheler 2002). Inhibition of angiogenic factors and antitumour immune reactivity, including an increase in cytotoxic T-lymphocyte cells, was found to be the mechanism of action in preventing photocarcinogenesis (Mantena et al 2005). Recent work suggests tea polyphenols may inhibit microsomal aromatase and 5 alpha-reductase, so suppressing prostate carcinogenesis. Tea catechins may work to suppress proteasomal activities, thereby inhibiting breast cancer cell proliferation (Ho et al 2009). Modification of oestrogen metabolism was found with both premenopausal and menopausal women, which may modify the risk of breast cancer (Fuhrman et al 2013).

### Adjunct in cancer treatment

There has been some exploratory in vitro research to study the combination of green tea and anticancer drugs, with findings suggesting that EGCG with cyclooxygenase-2 inhibitors increased apoptosis mediated through the MAPK signalling pathway and the combination of EGCG and tamoxifen increased the effectiveness in apoptosis more than tamoxifen alone (Suganuma et al 2011). In this cell culture research the issue of ovarian cancer cells developing resistance to chemotherapy was explored. They found EGCG and sulforaphane from cruciferous vegetables may offer a novel treatment in ovarian cancer. The combination of EGCG and sulforaphane increased apoptosis significantly after 6 days of treatment in cells that were resistant to paclitaxel and it may offer a solution for overcoming paclitaxel resistance in this disease (Chen et al 2013). This initial in vitro work may point the way to future research.

### Antihypertensive

Recent human studies have found antihypertensive benefit, with a small RCT reporting significant reduction in both systolic and diastolic blood pressure in obese patients with hypertension (Bogdanski et al 2012) and other studies reporting blood pressure-lowering effects (Brown et al 2009, Nantz et al 2009). In vitro experiments using green tea extracts have identified angiotensin-converting enzyme inhibition (Persson et al 2006). Animal experiments have also shown that a green tea extract

protected against arterial hypertension induced by angiotensin II (Antonello et al 2007).

### Cardioprotective

Studies on animals and humans find that green tea has multiple mechanisms that have an impact on the cardiovascular system, including lipid lowering, hypocholesterolaemic, anti-inflammatory, anti-thrombogenic, antioxidant, antihypertensive and antiatherosclerotic (Babu & Liu 2008, Neves et al 2008) and shows a beneficial effect on endothelial function in healthy volunteers (Alexopoulos et al 2008). The catechins in the green tea also have the ability to prevent atherosclerosis, as well as inhibiting thrombogenesis through a platelet aggregation action (Bhardwaj & Khanna 2013).

### Neuroprotective/neurorescue

Neuroprotective activity refers to the use of an agent before exposure to a neurotoxin which prevents toxicity. Neurorescue is a different term which refers to the use of an agent after exposure to a neurotoxin, which is able to reverse toxicity effects. In vitro and animal research indicates that EGCG found in green tea has the ability to act as both a neuroprotective and a neurorescue agent (Guo et al 2007, Hou et al 2008, Jeong et al 2007). In vitro tests reveal that EGCG reduces apoptosis of human neuroblastoma cells (Avramovich-Tirosh et al 2007). Additionally, in vivo studies have found a neuroprotective effect for EGCG on dopamine neurons, which is being further investigated as a potential preventive treatment in Parkinson's disease (Guo et al 2007, Jeong et al 2007). Animal research has found a number of neuroprotective benefits, such as reducing neuronal cell death, of EGCG in multiple sclerosis (Herges et al 2011), following a traumatic brain injury (Itoh et al 2011) and protecting the retina against neurodegeneration in a rat diabetic retinopathy model (Silva et al 2013). In vitro epicatechin and EGCG have been shown to have a neuroprotective effect which may be suitable for the neurological complications associated with HIV infection (Nath et al 2012).

Two animal studies found that EGCG reduced beta-amyloid deposition — one study reported 60% reduction in the frontal cortex and 52% in the hippocampus over the 3 months of the study (Li et al 2006, Rezai-Zadeh et al 2008). This may have implications in the development and progression of Alzheimer's dementia and is being further investigated in other models. Beta-amyloid deposition impacts on mitochondrial function and recent in vitro and in vivo research suggests EGCG can restore and protect brain mitochondrial function and integrity (Dragicevic et al 2011).

Numerous in vitro and animal models suggest several different mechanisms of action appear to be responsible for neuroprotective and neurorescue activity, including antioxidant, iron chelating, anti-inflammatory, cell apoptosis, signal transduction, gene regulation and an effect on amyloid precursor

protein (Assuncao et al 2010, Biasibetti et al 2013, Mandel et al 2006, Ostrowska et al 2007). These actions taken together make green tea polyphenols a promising agent in reversing age-related neuronal decline (Andrade & Assuncao 2012). A rat model found improvement in spatial learning and memory over long-term treatment, with green tea protecting against oxidative damage in the rat hippocampal region (Assuncao et al 2011). In an aged rat model improved cognitive function after EGCG might be due to its impact on neurotransmitters, with a positive effect found for dopamine, acetylcholine and serotonin (Srividhya et al 2012).

### Iron chelation

EGCG has been shown to chelate metals such as iron, zinc and copper (Guo et al 1996, Kumamoto et al 2001). Since the accumulation of iron has been implicated in the aetiology of both Alzheimer's dementia and Parkinson's disease and in vivo research shows EGCG's iron-chelating effect penetrates the brain barrier, it may offer neuroprotective and neurorescue effects in these diseases. EGCG has further been shown to reduce amyloid precursor protein and beta-amyloid peptide, most likely due to its iron-chelating activity (Reznichenko et al 2006). It is possible that iron chelation effects enabling iron to be removed from the brain may provide a novel therapy to prevent progression in neurodegenerative diseases (Mandel et al 2007).

### Thermogenic activity

Although the thermogenic activity of green tea is often attributed to its caffeine content, an in vivo study has shown that stimulation of brown adipose tissue thermogenesis occurs to a greater extent than would be expected from the caffeine content alone (Dulloo et al 2000). The interaction between catechin polyphenols and caffeine on stimulating noradrenaline release and reducing noradrenaline catabolism may be responsible. Clinical investigation has produced similar results, with green tea consumption significantly increasing 24-hour energy expenditure and urinary noradrenaline excretion, whereas an equivalent concentration of caffeine had no effect on these measures (Dulloo et al 2000).

### OTHER ACTIONS

Green tea exhibits a variety of other pharmacological actions, such as anti-inflammatory activity, CNS stimulation, inhibition of platelet aggregation, stimulation of gastric acid secretion and diuresis, increased mental alertness, relaxation of extracerebral vascular and bronchial smooth muscle, and reduced cholesterol, triglyceride and leptin levels (Fassina et al 2002, Sayama et al 2000). Recent in vitro and animal models suggest potential as a therapeutic agent for T-cell-mediated autoimmune conditions (Pae & Wu 2013). A significant genoprotective effect was found with an in vitro study and a small human trial using a biomarker of oxidative stress (Han et al 2011).

Some animal studies suggest that EGCG activates gamma-aminobutyric acid (GABA)-A receptors, causing sedative and hypnotic effects (Adachi et al 2006, Vignes et al 2006). A number of rat experiments have shown memory improvement in older animals. Improved spatial cognition learning ability in rats was demonstrated after the administration of long-term GTCs (Haque et al 2006). Significant improvement in memory and learning was found in older rats administered with green tea extract over 8 weeks (Kaur et al 2008).

### Hepatoprotective

Preliminary evidence from in vitro experiments demonstrates hepatoprotective activity with GTCs improving insulin sensitivity, decreasing lipids and through their antioxidant and anti-inflammatory actions (Masterjohn & Bruno 2012, Ueno et al 2009).

### Antithyroid

In vitro research and a recent rat model has found catechins have an antithyroid action, decreasing the activities of thyroid peroxidase and the synthesis of thyroid hormone (Chandra & De 2013). An action preventing autoimmune inflammation in an animal model suggests EGCG may delay or manage autoimmune disorders such as Sjögren's syndrome (Gillespie et al 2008). Another recent animal model of multiple sclerosis reported a protection against autoimmune expression by inhibiting immune cell infiltration and modulating proautoimmune cells and antiautoimmune cells (Meydani 2011). In vitro and in vivo studies and some preclinical research suggests an antiarthritic and antirheumatic activity for EGCG (Ahmed 2010).

### CLINICAL USE

Evidence is largely based on epidemiological studies, with few clinical studies available.

### Cancer prevention

It is still unclear whether green tea consumption reduces the incidence of all cancers or has any effect on mortality; however, studies of individual cancers show some protective effects. Supportive evidence is most consistent for breast, ovarian, endometrial and prostate cancers, with some supportive evidence for colorectal, pancreatic cancers and leukaemia and less consistent evidence for lung, liver, bladder, oesophageal and gastric cancers.

#### All cancers

A Cochrane review concluded that there was conflicting evidence regarding an inverse association between green tea drinking and cancer risk and suggests it remains unproven as a cancer intervention (Boehm et al 2009). Other systematic reviews and meta-analyses have suggested a trend towards protection in breast and prostate cancers and improved survival rates in epithelial ovarian cancer (Clement 2009, Johnson et al 2012). Another

review concluded that green tea was associated with a reduced risk of upper gastrointestinal tract cancers and had a beneficial role in breast cancer. However they suggested results on overall cancer prevention were inconclusive (Yuan et al 2011). A 2003 study using 13-year follow-up data found increased green tea consumption was associated with an apparent delay of cancer onset and death, and all-cause deaths (Nakachi et al 2003).

The conflicting results from different studies and reviewers may be due to confounding factors in different populations, dosages and differences in the EGCG content of green teas.

### Breast cancer

There appears to be a benefit of green tea drinking of three or more cups daily with reduction in the risk of breast cancer. Some recent studies are suggesting the aromatase-inhibiting action may be more effective for women drinking green tea premenopause, which may delay onset of breast cancer later in life. A meta-analysis of three cohort studies from Japan and one population case-control study from the United States concluded that green tea consumption reduced the risk of breast cancer (Sun et al 2006). Similar protective effects were observed in a case-control study in China, which found that regular drinking of green tea reduced breast cancer risk (Zhang et al 2007a). In a meta-analysis of nine studies — seven studies on the incidence and two on the recurrence of breast cancer — consumption of three or more cups of green tea daily was associated with reduced recurrence (pooled relative risk [RR] = 0.73, 95% confidence interval [CI]: 0.56–0.96). No association was found in the cohort studies for reduced incidence of breast cancer; however the case-control studies did find an inverse association with incidence (pooled RR 0.81, 95% CI: 0.75–0.88) (Ogunleye et al 2010). In this review it is suggested that the difference in numbers of pre- or postmenopausal women in the case-controlled or cohort studies may explain the conflicting results. One review examining data from the Shanghai Women's Health Study ( $n = 74,942$  Chinese women) considered the hypothesis that, because of the difference in oestrogens pre- and postmenopause, and green tea's aromatase-inhibiting action, tea-drinking protection might depend on menopausal status. Their analysis found that regularly drinking green tea from 25 years of age may delay the onset of breast cancer, suggesting a largely beneficial effect in premenopausal women (Dai et al 2010). This hypothesis may explain in part some of the conflicting evidence from studies, but larger studies and RCTs are required to confirm findings.

### Ovarian cancer

A recent meta-analysis included six case-control and cohort studies with a total of 9113 subjects (3842 cases and 5271 controls) reporting that green tea drinking can significantly decrease the risk of ovarian cancer (odds ratio [OR] 0.81; 95% CI: 0.73–0.89;

$P < 0.0001$ ). More research is suggested to assess different teas and dosages, and how different subgroups are affected (Gao et al 2013). The case-control Australian Ovarian Cancer Study conducted over 3.5 years (1368 patients and 1416 controls) reported a significant inverse association between green tea drinking (four or more cups) and ovarian cancer. They found no difference between green and black tea consumption and there was no dose-response effect. The same authors conducted a meta-analysis (which included 17 studies) and found a trend towards green tea drinking and ovarian cancer prevention (Nagle et al 2010). A 2011 review of the literature found only four case-control studies (Goodman 2003, Nagle et al 2010, Song et al 2008, Zhang et al 2002) of green tea and ovarian cancer and a meta-analysis of these studies found evidence of a combined inverse association (OR 0.66; 95% CI: 0.54–0.80) between green tea drinking and ovarian cancer, with a 32% reduction in risk for green tea drinkers. Both prospective and retrospective observational analysis found an inverse association; however the authors suggested caution in interpretation of the results, with very different levels of tea drunk in the studies and lack of prospective cohort results (Butler & Wu 2011). A systematic review of *in vitro*, *in vivo* and epidemiological studies on epithelial ovarian cancer included four case-control studies and concluded that it was difficult to extrapolate data as the catechins in the green tea varied, there were different cup sizes and various definitions of high tea intake. Despite these factors it did appear that green tea consumption was associated with a decreased ovarian cancer risk and better prognosis of the disease (Trudel et al 2012).

### Endometrial cancer

Green tea drinking was found to be mildly protective against endometrial cancer risk in a population-based case-control study in China where 995 cases were interviewed. This protective effect might be limited to premenopausal women (Gao et al 2005). A total of two cohort and five case-control studies were included in a meta-analysis that reported a significant reduction in risk of endometrial cancer for green tea drinkers, with an increase of two cups a day associated with a reduction in risk of endometrial cancer by 25% (Tang et al 2009b). A more recent review and meta-analysis of six observational studies confirmed a dose-dependent protective role of green tea drinking and endometrial cancer risk, suggesting a 23% reduction in risk for regular green tea drinkers (OR 0.78; 95% CI: 0.62–0.98). However the authors suggest caution in interpreting the results because of the differences in green teas and the amount of tea consumed (Butler & Wu 2011).

### Prostate cancer

Although evidence is inconclusive, there is a mounting body of research showing a preventive role for reducing the risk of prostate cancer with a

therapeutic dose of five or more cups of green tea a day. A Cochrane review included five studies and reported that in the higher-quality observational studies and in the only RCT there was a decreased risk of prostate cancer with high consumption of green tea (Boehm et al 2009). A case-control study in China with 130 prostate cancer patients found that green tea was protective against prostate cancer, with lower risk associated with an increase in the frequency, duration and quantity of green tea consumed (Jian et al 2004). Drinking green tea was also associated with a reduction in the risk of advanced prostate cancer in 49,920 men aged 40–69 years who completed questionnaires over a 10-year period in the Japan Public Health Center-based Prospective Study. The effect was dose-dependent and strongest for men drinking five or more cups/day compared with less than 1 cup/day (Kurahashi et al 2008). The more recent evidence appears to be inconclusive, with mixed results from a number of clinical trials and population studies (Henning et al 2011, Khan et al 2009a, Lee & Pasalich 2013). A meta-analysis of observational studies included seven studies with green tea and reported a borderline significant decrease (38%) in prostate cancer risk for Asian populations with high green tea consumption (Zheng et al 2011a). One of the plausible reasons for the conflicting evidence is that some studies include low tea consumption, which may skew the results, as it appears that dosage is important in cancer protection.

### Colorectal cancer

A recent meta-analysis of 13 case-control studies found a weak, non-statistically-significant reduction in colorectal cancer risk for those drinking high doses of green tea (Wang et al 2012c). This benefit did not seem to extend to US and European populations. More research would be required to confirm these findings. A meta-analysis of six prospective cohort studies (including 1675 cases of colorectal cancer) reported that in Shanghai populations there was an inverse risk between green tea consumption and the incidence of colon and colorectal cancers. The results overall were insufficient to suggest green tea may protect against colorectal cancer (Wang et al 2012e).

### Pancreatic cancer

A recent Chinese population-based case-control study (908 patients with pancreatic cancer and 1067 healthy controls) found that women had a 32% less risk of pancreatic cancer with regular low-temperature green tea consumption, especially drinking higher amounts and with long-term use. Drinking more than 150 g of dry tea leaves per month (also lower-temperature tea) resulted in a reduction in risk by 43% (OR 0.56, 95% CI 0.32–0.98) for women compared with non-tea drinkers. With men there was only an association between pancreatic cancer risk and tea for regular tea drinkers consuming luke-warm and cool tea compared to hot tea (Wang et al 2012b).

### Leukaemia

Leukaemia risk may be reduced with drinking sufficient amounts of green tea. The protective effect was significant in the 16–29-year age range with higher amounts of green tea consumption; there was no significant relationship to green tea drinking and leukaemia risk in younger people in the 0–15-year age range. These findings were from a population-based study in Taiwan (Kuo et al 2009). A hospital-based case-control study (107 patients) in China found that there was a reduction of risk in adult leukaemia with high green tea consumption (Zhang et al 2007b).

### Lung cancer

A systematic review of epidemiological studies on the risk of lung cancer and tea drinking found a significant reduction in risk for the high-level tea drinkers in only four out of 20 studies. Overall the review found a small benefit for green tea drinking in reducing the risk of lung cancer, which was especially noticeable in those who had never smoked (Arts 2008). A meta-analysis including 22 studies (12 studies on green tea only) also reported a borderline significant association with a 22% reduction in the risk of developing lung cancer for the highest green tea drinkers. Increasing green tea by two cups a day was shown to reduce lung cancer risk by 18% (Tang et al 2009a). This was confirmed in a dose-response analysis of six studies where a significant non-linear relationship between green tea and risk of lung cancer was reported. This beneficial effect was especially strong in those drinking more than seven cups a day (Wang et al 2012d). It appears that green tea may have a small beneficial effect in reducing lung cancer risk but, as a recent systematic review suggests, more well-designed studies are needed (Fritz et al 2013).

### Liver cancer

The protective effect of green tea drinking to reduce liver cancer risk appears to be stronger for high-risk patients with hepatitis B or C and also for long-term green tea drinkers. A recent meta-analysis included 13 epidemiological studies (six case-control and seven prospective cohort studies) and reported borderline significance showing green tea was preventive (for both men and women) in reducing the risk of developing primary liver cancer (Fon Sing et al 2011). Evidence is conflicting and one analysis of data from a Japanese Public Health Cohort study with 18,815 subjects found no association with green tea drinking and liver cancer risk (Inoue et al 2009a). However another larger Japanese cohort study (Ohsaki Cohort Study, following 41,761 subjects over 9 years) found a significant reduction in risk for liver cancer and green tea for men and women drinking five or more cups of green tea a day (Ui et al 2009). The differences in reporting

data may be linked to quantity of tea drunk, number of years of green tea drinking and also whether the group had a high- or low-risk cohort. A recent case-control study of 204 hepatocellular carcinoma (HCC) patients and 415 healthy controls found that drinking high amounts of green tea for longer periods of time resulted in a protective effect, with those drinking green tea for over 30 years having the lowest risk. In the subgroup of patients with chronic hepatitis infection, the risk of HCC in non-green tea drinkers was twice that of those consuming green tea. Further research in this subgroup of people with a higher HCC risk may be warranted (Li et al 2011). According to a placebo-controlled, randomised study, green tea polyphenols may reduce the incidence of HCC in high-risk patients (Yu et al 2006). The study involved 1209 males, who tested positive for hepatitis B virus and then were allocated to the control group or active treatment with green tea polyphenols (two capsules daily of 500 mg). The trial lasted 3 years, with a further 2-year follow-up period. Ten cases of HCC were reported in the green tea group and 18 cases in the placebo group.

### Bladder/kidney cancer

A recent meta-analysis included five case-control or cohort studies specifically for green tea and bladder cancer and no association was found between bladder cancer risk and green tea consumption (Wu et al 2013), although a meta-analysis in the same year suggested that Asian people drinking green tea may benefit and a protective effect on bladder cancer was found in this subgroup (Wang et al 2013). More research is indicated to confirm this finding and to discover why the benefit may be only for Asian populations, but the type of green tea may be a possible reason.

A hospital-based case-control study was undertaken in China, in which 250 patients diagnosed with clear cell renal cell carcinoma were compared with healthy controls. The research found green tea consumption of 500 mL or more a day was inversely associated with clear cell renal cell carcinoma risk (Wang et al 2012a).

### Oesophageal cancer

Ten epidemiological studies (eight case-control and two cohort studies;  $n = 33,731$ ) were included in a meta-analysis of green tea consumption and oesophageal cancer risk. There was no association with low or high green tea consumption and oesophageal cancer, except in a subgroup analysis, where the authors reported a protective effect of any level of green tea drinking and oesophageal cancer for women (high green tea consumption: RR/OR = 0.32, 95% CI: 0.10–0.54; medium consumption: RR/OR = 0.43, 95% CI: 0.21–0.66; low consumption: RR/OR = 0.45, 95% CI: 0.10–0.79) (Zheng et al 2012). Another systematic review and

meta-analysis of green tea, black tea and coffee and oesophageal cancer risk included 13 green tea studies (one cohort and the 12 case-controls) and the authors reported a significant association for the highest green tea drinkers in the case-control studies (OR = 0.70; 95% CI: 0.51–0.96,  $P < 0.001$ ) and for the Chinese studies (OR = 0.64; 95% CI: 0.44–0.95,  $P < 0.001$ ) and a more pronounced inverse association for women (Zheng et al 2013a). It is recommended that further studies with control of dose and the temperature of the tea be undertaken.

### Gastric cancer

There is conflicting research on the benefit of green tea in reducing gastric cancer risk according to a Cochrane review on green tea and cancer (Boehm et al 2009). However, there may be a trend towards significance for higher green tea consumption (five or more cups per day) and this is especially noted in women and in Chinese populations. A recent review of epidemiological evidence included 17 Japanese and Chinese studies (10 case-control and seven cohort studies). This review concluded that the evidence was insufficient to suggest that green tea reduces the risk of gastric cancer. They found seven studies with no association, eight with an inverse association and one study showing a positive association; however, they do suggest that *Helicobacter pylori* infection may be a confounding factor and that future research should include this subgroup (Hou et al 2013). A pooled analysis of six Japanese cohort studies (total of 219,080 individuals) reported no significant association of green tea drinking and reduction in gastric cancer risk for men; however, women drinking five or more cups a day had a significant reduction in risk of distal gastric cancer (with no significant effect seen on proximal gastric cancer) (Inoue et al 2009b). A later systematic review of epidemiological studies in Japan agreed with this finding, reporting a protective effect for women reducing gastric cancer risk. They included eight cohort studies and three case-control studies and, when analysing only the case-control studies, they found a weak association with gastric cancer reduction and green tea but not in the cohort studies (Sasazuki et al 2012). This difference in results reported from case-control and cohort studies was also found in an earlier meta-analysis (Myung et al 2009). One meta-analysis (seven cohort, 10 case-control and one population-based nested case-control study) reported a statistically significant 14% reduced risk of stomach cancer for people drinking five or more cups of green tea. The five Chinese studies showed a stronger stomach cancer risk reduction than the Japanese studies. The authors recommend further research confined to higher green tea drinkers to confirm the findings (Kang et al 2010). A note of caution from a population-based case-control study ( $n = 200$ ) found that drinking tea at a very hot temperature might be associated with an increased risk of gastric cancer (Mao et al 2011).

### Cancer treatment

Studies have been conducted with various doses of green tea and GTCs in different cancers, producing mixed results.

Overall, the current evidence does not support the use of green tea as a cancer treatment; however, there are some exceptions, which suggest an adjunctive role.

#### Epithelial ovarian cancer

Green tea increased the survival rate of patients with epithelial ovarian cancer in a cohort of 309 Chinese women (Zhang et al 2004). Most (77.9%) of the women in the treatment group were alive at the 3-year follow-up, as compared with 47.9% of the control group.

#### Cervical cancer

In an RCT, 90 patients with cervical lesions infected with human papillomavirus were given either a capsule containing 200 mg EGCG and/or an ointment containing 200 mg Polyphenon E, to be applied daily (Ahn et al 2003). There was a 69% response rate (35 out of 51 patients) for those on treatment when compared with a 10% response rate for controls ( $P < 0.05$ ), with the ointment showing the best effects.

#### Colorectal cancer

A pilot study was undertaken with 136 patients with colorectal adenomas, which are considered to be a precursor to colorectal cancers. This randomised trial in Japan increased green tea intake from an average of six cups a day to the equivalent of 10 cups a day by supplementing with green tea extract tablets. This involved supplementing the treatment group with 1.5 g of green tea extract per day for 12 months while both placebo and treatment group continued their green tea drinking. At the end of the intervention metachronous adenomas were evident in 31% (20 of 65) of the control and 15% (9 of 60) of the green tea extract group (RR 0.49; 95% CI, 0.24–0.99;  $P < 0.05$ ) and the size of the relapsed adenomas was smaller in the treated group, illustrating a potential chemopreventive role for green tea extract (Shimizu et al 2008).

#### Oral premalignant lesions

A phase II RCT with 39 patients with oral premalignant lesions gave the treatment group of patients 500, 750 or 1000 mg of green tea extract three times a day for 12 weeks. On biopsy the green tea extract group had improved histology, especially at the two higher doses, although this was not statistically significant. During the follow-up (median time of 27.5 months) 15 of the patients developed oral cancer and there was no difference between oral cancer-free survival between the placebo and green tea extract groups. It is thought that the green tea extract may act through stromal vascular endothelial growth factor and the research suggests that longer-term trials are needed (Tsao et al 2009).

### Prostate cancer

Several studies have been conducted in men with established prostate cancer. GTCs may have a role in arresting disease development in prostate cancer according to a double-blind, placebo-controlled study (Bettuzzi et al 2008). Sixty volunteers with high-grade prostate intraepithelial neoplasia and therefore at high risk of prostate cancer were treated with GTCs (three capsules of 200 mg/day) or placebo over 12 months. Of the 30 men in the GTC group, only one tumour was diagnosed, as opposed to nine cases in the placebo group. The GTC group also scored higher on the quality-of-life scores and had reduced lower urinary tract symptoms and no side effects were detected (Bettuzzi et al 2006). An update for this trial was undertaken 2 years later to see if the prostate cancer was merely delayed rather than prevented in the green tea group. Half the original subjects (equal numbers from placebo and green tea cohorts) agreed to further investigations, which detected one more tumour in the GTC group and two more in the placebo group. These results suggest that GTC given for a year may offer long-term protection within this at-risk group and might be useful as first-line preventive therapy. More recently, a small open-label study of 26 men (aged 41–68 years) with a recent diagnosis of prostate cancer (stage I, II or III) were given 800 mg EGCG (Polyphenon E) daily in the time between biopsy and radical prostatectomy and serum levels of prostate-specific antigen, hepatocyte growth factor, insulin-like growth factor-1 and vascular endothelial growth factor all decreased significantly with the median dosing period of 34.5 days. The authors also noted that there were no adverse effects on the liver observed during the study (McLarty et al 2009). This same trend was found in a RCT of 50 diagnosed prostate cancer patients given Polyphenon E or placebo for 3–6 weeks prior to surgery. Although not significant, biomarkers did show some chemopreventive potential with decreased prostate-specific antigen and insulin-like growth factors. However, it was found that apoptosis and angiogenesis did not differ in either group and the bioavailability of the polyphenols in the prostate tissue was low (Nguyen et al 2012). The authors suggested that longer term and larger controlled trials would be useful to verify findings.

In contrast, a small study testing green tea (6 g/day) in patients with pre-existing androgen-independent prostate cancer found little effect on PSA levels (Jatoi et al 2003). Similar results were obtained in a small study of 19 patients with hormone-refractory prostate cancer given a lower dose of 250 mg capsules of green tea twice a day (Choan et al 2005). It is likely that both these studies did not use a green tea treatment with sufficient concentrations of catechins or a high enough dose.

### Leukaemia

A clinical trial with 42 patients with Rai stage 0–II early stage of chronic lymphocytic leukaemia, who were asymptomatic and not eligible to begin chemotherapy, were given Polyphenon E (2000 mg twice daily) for up to 6 months and found declines in the absolute lymphocyte count and lymphadenopathy in the majority of patients (Shanafelt et al 2013). This is a possible novel use as a low-toxicity early intervention, but randomised trials are needed to affirm these findings.

### Adjunct in breast cancer treatment

Ten radiotherapy patients with non-inflammatory breast cancer (locally advanced) in a small 8-week study were randomly assigned to radiotherapy plus EGCG (400 mg three times daily) or radiotherapy plus placebo. The green tea treatment group showed serum changes, including suppression of cell proliferation and invasion, a reduction in metalloproteinase-9 and metalloproteinase-2 expression and lower serum vascular endothelial growth factor. This additive apoptotic effect with the radiation treatment suggests that green tea polyphenols have potential as an adjunctive treatment in breast cancer (Zhang et al 2012a).

### Reducing cancer drug side effects

An animal study has suggested a possible novel use of green tea to protect against nephrotoxicity caused by the use of cisplatin, a chemotherapy drug used to treat a variety of cancers (Khan et al 2009b).

Some recent research has experimented with nanochemoprevention with encapsulated EGCG which enhanced the bioavailability of the EGCG by 10-fold. In the future this nanoparticle-mediated delivery could be used to reduce toxicity side effects of chemotherapy drugs (Siddiqui et al 2009).

### Cardiovascular protection

Epidemiological studies suggest that green tea consumption is associated with a reduced risk of cardiovascular disease (CVD) (Kuriyama 2008, Maeda et al 2003). Its antioxidant effects may explain some of the CVD benefits and a recent systematic review of 31 RCTs found 0.6–1.5 L/day of green tea increased antioxidant capacity and reduced lipid peroxidation (Ellinger et al 2011). A systematic review of literature reported that observational studies indicated protection against stroke, atherosclerosis and hypertension for green tea drinkers (Clement 2009) and a recent review included four systematic reviews (Hooper et al 2008, Kim et al 2011, Wang et al 2011, Zheng et al 2011b) and meta-analysis, suggesting that, although evidence is not robust for a reduction in coronary artery disease (CAD), some RCTs do indicate that green tea may be effective in reducing LDLs and total cholesterol (Johnson et al 2012). This is confirmed by a recent Cochrane review reporting on 11 RCTs ( $n = 821$ ),

with seven of these trials on green tea alone (five on green tea tablets or capsules and two with tea drinking). The authors concluded that total cholesterol, LDL-cholesterol and blood pressure were significantly reduced with green tea consumption. They recommend caution in interpreting these results, as there were only a small number of studies in this analysis (Hartley et al 2013).

A 2000 prospective cohort study of 8552 people in Japan found that those consuming more than 10 cups a day, compared with those consuming fewer than three cups, had a decreased relative risk of death from CVD (Nakachi et al 2000). The Ohsaki National Health Insurance Cohort Study was a population-based study in Japan, spanning 11 years (1995–2005) with 40,530 Japanese adults aged 40–79 years. At baseline, no participants had cancer or coronary heart disease. The study identified an inverse association between green tea consumption and mortality due to CVD (especially mortality due to stroke) as well as all other causes. A significant protective effect was shown at a dose of five cups or more daily for men and three or more cups daily for women. Overall, the protective effects were greatest for women compared to men (Kuriyama et al 2006b). The investigators suggested higher smoking levels in men may have reduced potential benefits in this group (Cheng 2007).

Some 76,979 subjects from another Japanese study (Japan Collaborative Cohort Study for Evaluation of Cancer Risk) were included in a prospective study assessing tea drinking and mortality from CVD. The individuals did not have coronary heart disease nor had they had a stroke at the onset of the study. There were 1362 deaths from strokes and 650 deaths from CVD over the 13.1-year follow-up. The analysis found that a moderate intake of green tea was associated with lower CVD mortality. For coronary heart disease this benefit was more for women, who drank six or more cups of green tea a day (a 38% lower risk of mortality) (Mineharu et al 2011). Similarly, analysis from the Japan Public Health Center-Based Study, with a slightly larger cohort of 82,369, found that higher green tea drinkers had an inverse association with strokes (especially intracerebral haemorrhage) and CVD in the general population. The participants completed self-administered food frequency questionnaires over a 13-year period (Kokubo et al 2013).

Elderly people in a Japanese population-based study of 14,001 were followed for 6 years and drinking seven or more cups a day exerted a reduced risk of cardiovascular mortality (Suzuki et al 2009). A meta-analysis that included data from nine epidemiological studies with 4378 stroke incidences found a 21% lower risk of stroke among green or black tea drinkers if they consumed three or more cups a day (Arab et al 2009). These benefits of green tea drinking were not confirmed in a Dutch population study using a validated food frequency questionnaire ( $n = 37,514$ ) over 13 years, where they found no correlation with tea drinking and

stroke. The difference in findings with other population studies may be because most of the tea was black and not green tea (de Koning Gans et al 2010). Well-designed RCTs would be helpful to establish a benefit in reducing risk of stroke. However, this same large Dutch cohort of healthy men and women did appear to benefit from a reduction in coronary heart disease mortality by drinking three to six cups of tea a day (some green tea but mainly black tea). Relatively few people died from either stroke or coronary heart disease during the study, making associations with tea drinking difficult to evaluate (de Koning Gans et al 2010). In a later meta-analysis (13 studies on black tea and five studies with green tea), green but not black tea showed a significant association with reducing risk for the highest green tea drinkers. Including an additional cup of green tea per day was associated with a 10% decrease in CAD risk. This inverse association between green tea and CAD was found in the case-control studies, which may not be strong evidence given problems with recall or selection bias in retrospective studies. Thus the authors suggest the protective role of green tea is tentative and large prospective cohort studies are needed (Wang et al 2011). It may be that the catechins in green tea provide protection in CAD, whereas black tea benefits are more associated with heart disease (Di Castelnuovo et al 2012).

### Lipid lowering

An increasing body of research suggests that green tea given to patients with hypercholesterolaemia may lower total and LDL-cholesterol levels but there is less robust evidence that triglycerides or high-density lipoproteins (HDLs) are impacted.

A recent Cochrane review included evidence from seven RCTs on green tea with varied doses (five studies with 375–600 mg daily of green tea extract and two studies on green tea beverages). The review reported a statistically significant reduction in total cholesterol (MD  $-0.62$  mmol/L, 95% CI  $-0.77$  to  $-0.46$ ) and LDL-cholesterol (MD  $-0.64$  mmol/L, 95% CI  $-0.77$  to  $-0.52$ ) compared to placebo, with a trend towards a reduction in triglycerides (Hartley et al 2013). A meta-analysis including 20 trials found that total and LDL-cholesterol levels were lowered with green tea but no effect was found on HDL-cholesterol or triglycerides. Subgroup analysis suggested that people with normal cholesterol levels found no benefit and there appeared to be no significant effect with green tea capsules. The heterogeneity of the studies limits the meta-analysis. It appears that higher-dose catechins may be more effective and further studies on dose and duration of green tea drinking are needed (Kim et al 2011). Another meta-analysis in the same year included 14 RCTs ( $n = 1136$ ) and confirmed that green tea reduced both total and LDL-cholesterol but exerted no effect on HDLs, although these researchers found both green tea drinking and extracts were beneficial (Zheng et al 2011b).

A significant reduction in LDL-cholesterol and triglycerides and marked increase in HDL-cholesterol was also found for green tea consumption (400 mg given three times daily) in a double-blind, placebo, RCT of 78 obese women conducted over 12 weeks (Hsu et al 2008). Similar results were obtained in an early cross-sectional study involving 1371 men aged over 40 years (Imai & Nakachi 1995). The study showed that increased green tea consumption was associated with decreased serum concentrations of total cholesterol and triglyceride and an increase in HDL, together with a decrease in LDL and very-low-density lipoprotein cholesterols. Fifty-six obese hypertensive patients entered a randomised, double-blind, placebo-controlled trial and green tea supplementation did increase HDL-cholesterol as well as lower total and LDL-cholesterol. The treated group were given a green tea extract capsule (379 mg) daily for 3 months (Bogdanski et al 2012). Other studies have found no significant HDL effect which may be limited to patient subgroups.

In contrast, the inclusion of 3 g/day (145 mg of EGCG in 500 mL water daily) of green tea to a cholesterol-lowering diet provided no further lipid-lowering effects according to a study of 100 hypercholesterolaemic patients (Bertipaglia de Santana et al 2008). While green tea increased antioxidant potential, there was no significant reduction in any cholesterol parameters. This result may be explained by the low dose compared to other studies.

### Hypertension

Research is now beginning to find antihypertensive benefits for green tea and large, longer-term, well-designed studies are needed. A recent Cochrane review included three trials which measured blood pressure (Bogdanski et al 2012, Nantz et al 2009) and on analysis found a statistically significant reduction in both systolic (MD -3.18 mmHg, 95% CI -5.25 to -1.11) and diastolic blood pressure (MD -3.42, 95% CI -4.54 to -2.30) (Hartley et al 2013). Blood pressure was significantly reduced in an RCT of 56 obese, hypertensive patients taking one capsule a day of 379 mg of a green tea extract (with 208 mg of EGCG from Olimp Labs, Debica, Poland) for over 3 months. At the end of the trial both systolic and diastolic blood pressure had reduced significantly, tumour necrosis factor- $\alpha$  and C-reactive protein were significantly reduced, fasting glucose and insulin levels had lowered, along with a reduction in LDL and total cholesterol and an increase in HDL-cholesterol. This small study shows promise for a multifaceted benefit for obese patients with hypertension (Bogdanski et al 2012). Another small trial with 46 obese male patients found a reduction in diastolic blood pressure (by a modest 2.5 mmHg) but no other metabolic effects were observed. The intervention was a 400 mg capsule twice a day for 8 weeks (Teavigo with 97% pure EGCG) (Brown et al 2009). In a randomised, double-blind placebo study of 111 healthy volunteers a green tea extract (200 mg decaffeinated catechin green tea extract

Cardio Guard) was given twice daily. There was a reduction in systolic (5 mmHg) and diastolic (4 mmHg) blood pressure after only 3 weeks and after 3 months systolic blood pressure remained significantly lower. Other cardiovascular markers, including total and LDL-cholesterol-lowering effects, were also noted and there was a 42% reduction in serum amyloid- $\alpha$  (a marker of chronic inflammation) (Nantz et al 2009).

### Weight loss

Animal studies have found that green tea consumption reduces food intake, decreases leptin levels and body weight and increases thermogenesis.

Clinical studies investigating the effects of green tea on weight loss have produced mixed results; however green tea in some studies suggests moderate weight loss, reduction in waist circumference and improvement in metabolic parameters and may be helpful when combined with an exercise program. The wide disparity in green teas, green tea extracts and dosage protocols hampers the pooling of results, in meta-analyses, in a meaningful way.

A recent Cochrane review included RCTs of overweight adults with trials of at least 12 weeks. They included six studies outside Japan; a small, non-significant reduction in weight, waist circumference and body mass index (BMI) was found which was unlikely to be clinically relevant. The data from the eight Japanese studies could not be pooled and again some small non-significant improvements in weight loss were seen in some studies. There was no significant benefit on weight maintenance (Jurgens et al 2012). A meta-analysis including 11 studies suggests that green tea has a small beneficial effect on weight loss and weight maintenance (Hursel et al 2009). A systematic review and meta-analysis comparing GTC benefits with and without caffeine found, of the 15 studies included, that the GTCs alone did not show anthropometric benefit; however GTCs with caffeine showed modest benefit with reduced weight, BMI and waist circumference compared with caffeine alone (Phung et al 2010).

One open study found that a green tea extract AR25 (80% ethanolic dry extract standardised at 25% catechins) taken by moderately obese patients resulted in a 4.6% decrease in body weight and 4.5% decrease in waist circumference after 3 months' treatment (Chantre & Lairon 2002). Both groups lost the same amount of weight and displayed similar metabolic parameters at the end of the study period. An RCT study in Thailand was undertaken over 12 weeks with 60 obese individuals all given a similar diet of three meals a day with 65% carbohydrates, 15% protein and 20% fat. There was no significant difference in weight loss at week 4 but at weeks 8 and 12 weight reduction was significantly greater in the green tea group than the placebo group. The difference in weight loss between the groups was 2.70 kg at 4 weeks, 5.10 kg at 8 weeks and 3.3 kg

at 12 weeks. Researchers suggested the effects were due to changes in resting energy expenditure and fat oxidation (Auvichayapat et al 2008). However, two other studies produced negative findings. One double-blind, placebo-controlled parallel trial, with 46 women attempting a weight-loss program over 87 days, showed no difference between the green tea group and the placebo group (Diepvens et al 2005). Another double-blind, placebo RCT, with 78 obese women, also showed no significant difference in body weight, BMI or waist circumference after taking a green tea extract capsule of 400 mg three times a day for 12 weeks (Hsu et al 2008). An RCT ( $n = 104$ ) of Chinese participants with high levels of visceral fat found a significant reduction in abdominal visceral fat and body weight by drinking a catechin-enriched green tea (609.3 mg catechins and 68.7 mg caffeine) daily for 12 weeks (Zhang et al 2012b).

A randomised clinical trial using a highly bioavailable form of green tea (Monoselect Camellia containing GreenSelect Phytosome) was used in a study with 100 overweight participants who were all assigned low-calorie diets and half of them given the green tea extract. After 90 days the diet-only group lost 5 kg in weight while the diet plus green tea group lost 14 kg. Males in the study also experienced a significant reduction in waistline measurement by 14% compared to 7% in the diet-only group. Other metabolic parameters were improved in both groups, including LDL, HDL-cholesterol, triglycerides, growth hormone, insulin and cortisol. This particular green tea extract appears to potentiate weight loss in combination with a calorie-controlled diet (Di Pierro et al 2009). More research is needed to confirm the findings of this bioavailable form of green tea.

There is some emerging research on benefit for obese patients with metabolic syndrome due to the effect green tea has on weight loss, lowering of lipids, improving blood glucose regulation and cardiovascular health (Thielecke & Boschmann 2009). A randomised, controlled prospective trial with 35 participants with obesity and metabolic syndrome were assigned placebo, four cups of green tea (equivalent of 440 mg EGCG) or green tea extract (two capsules a day totalling 460 mg EGCG). After 8 weeks a significant reduction in body weight and BMI was reported in both the green tea groups. Biomarkers of oxidative stress and lipid peroxidation including LDL-cholesterol also had a modest reduction. In this subgroup green tea may have potential, and further research would be recommended to confirm the findings (Basu et al 2010).

A small intervention study of elderly patients with metabolic syndrome found that drinking three cups of green tea a day for 60 days significantly reduced weight, waist circumference and BMI compared to placebo. There were no changes in biochemical parameters (Vieira Senger et al 2012). In a recent RCT with 46 obese participants given green tea extract (379 mg a day) or placebo over 3

months, the supplemented group had a reduction in BMI, waist circumference, total and LDL-cholesterol, triglycerides and glucose. The green tea extract group also saw an increase in antioxidant levels and zinc, HDL-cholesterol and magnesium, although iron levels were lower than the placebo group. This study shows potential for multieffect benefits for obese patients taking green tea extract (Suliburska et al 2012).

### Combination of green tea with exercise for weight loss

Some small trials have shown additional benefits when dietary changes and exercise have been included in the studies. A recent double-blind, placebo-controlled trial with 36 overweight or obese women included dietary changes and resistance training over a 4-week period. They reported significant increases in resting metabolic rate, lean body mass and strength and significant reduction in waist circumference, body fat and triglycerides when combining green tea with resistance training compared with placebo and resistance training only (Cardoso et al 2013). Another study ( $n = 107$ ) of overweight or obese participants over 12 weeks randomly assigned a green tea drink (625 mg catechins and 39 mg caffeine) or control drink (39 mg caffeine) and all participants were asked to do 180 minutes of moderate-intensity exercise each week. The trend (non-significant) was towards a reduction in weight, subcutaneous abdominal fat and triglycerides in the catechin group (Maki et al 2009). Further research is needed to see if green tea enhances the weight loss benefits of an exercise training program.

### Diabetes

Animal studies have identified that green tea polyphenols reduce serum glucose levels and improve kidney function in diabetes (Rhee et al 2002, Sabu et al 2002) and may be helpful in preventing diabetic nephropathy (Kang et al 2012). Evidence from human trials has been contradictory and it may be that green tea is beneficial for some subgroups. A recent meta-analysis of 17 trials (including seven high-quality trials with the remainder low-quality) reported significant lowering of fasting glucose concentrations ( $-0.09$  mmol/L; 95% CI:  $-0.15$  to  $-0.03$  mmol/L;  $P < 0.01$ ) compared with controls and with HbA<sub>1c</sub> ( $-0.30\%$ ; 95% CI:  $-0.37$ ,  $-0.22\%$ ;  $P \leq 0.01$ ). There was no significant change in fasting insulin or homeostatic model assessment of insulin resistance (HOMA-IR) values. Interestingly, subgroup analysis found that green tea lowered fasting glucose in those at risk of metabolic syndrome but not in healthy subjects and a high dose of catechins was more effective. In further analysis the higher-quality trials also showed green tea significantly reduced fasting insulin (Liu et al 2013). Another meta-analysis in the same year included 22 RCTs with 1584 participants and found a significant decrease in fasting blood glucose

with GTCs (with or without caffeine) ( $-1.48$  mg/dL; 95% CI:  $-2.57$ ,  $-0.40$  mg/dL) over a 12-week time period, but not in the shorter treatment protocols under 12 weeks. No significant effect was found with fasting blood insulin, HbA<sub>1c</sub> or insulin resistance (HOMA-IR), but this could be because only a small number of the trials actually reported on these parameters. The trials included in this meta-analysis were pooled studies with diabetic, obese, metabolic syndrome and healthy patients; therefore outcome for diabetic patients alone may differ. The authors report conflicting results on dose of green tea consumption for the glucose metabolism effect and suggest further research is needed on the dose-response relationship and also to understand more about postprandial glycaemic variables (Zheng et al 2013b). One double-blind RCT with 49 individuals with type 2 diabetes mellitus found no significant hypoglycaemic effects for green tea given at 375 mg or 750 mg/day (MacKenzie et al 2007). Another RCT of 66 diabetic patients found 500 mg/day of green tea polyphenols had no clear effect on blood glucose or insulin resistance markers (Fukino et al 2005). A more recent randomised, double-blind and placebo-controlled trial with 68 obese type 2 diabetics found no significant difference in diabetic markers over 16 weeks with a decaffeinated green tea extract (500 mg three times daily 30 minutes after meals). However, some within-group comparisons did find significant reduction in HbA<sub>1c</sub>, waist circumference, HOMA-IR index and insulin levels and increase in the appetite-regulating hormone ghrelin (Hsu et al 2011). A cross-over RCT with 60 borderline diabetic patients reported a significant reduction in HbA<sub>1c</sub> levels and a borderline significant reduction in diastolic blood pressure after 2 months of green tea extract powder (456 mg catechins) daily. No changes were noted for weight, BMI, systolic blood pressure, lipids or fasting serum glucose levels (Fukino et al 2008). The bioavailability of some green tea extracts may vary and in some studies serum EGCG was detected in only half the subjects after early-morning testing, which could explain why some researchers report significant changes to diabetic markers and others non-significant changes. It appears that taking the green tea extract for at least 12 weeks is more beneficial and in most studies some of the diabetic markers are positively impacted, even if modestly so.

An epidemiological study of 542 men and women, aged over 65 years, from the Mediterranean islands found that tea consumption (green and black) was associated with reduced levels of fasting glucose but this was only in the non-obese subjects (Polychronopoulos et al 2008). The same MEDIS study in the Mediterranean islands evaluated 300 elderly men and women and found that long-term tea drinking (green and black) was associated with a reduction of risk of type 2 diabetes (Panagiotakos et al 2009).

## Dental caries and gingivitis

Green tea extract tablets, gels, mouthwash and chewable oral preparations have been investigated for effects on dental plaque formation and gingival health under RCT conditions, overall producing favourable results (Liu & Chi 2000). Recent research also suggests potential for preventing caries.

A double-blind study investigated the effects of GTCs and polyphenols on the gingiva when used in the form of chewable oral sweets (Krahwinkel & Willershausen 2000). Compared with placebo, the green tea product chewed eight times a day significantly decreased gingival inflammation and improved periodontal structures before the 21-day test period was complete.

Another study investigated Chinese green tea polyphenol tablets for effects on plaque formation in 150 volunteers (Liu & Chi 2000). The randomised, controlled crossover study showed that green tea polyphenol tablets used for 2 weeks were able to reduce the plaque index compared with placebo treatment. Thirty chronic periodontitis patients were included in an RCT, with the treated group using a thermo-reversible sustained-release green tea gel. At the end of the 4-week trial the green tea group had a significant reduction in oral pocket depth and gingival index, showing a benefit and reduction in inflammation in these periodontitis patients (Chava & Vedula 2013).

A recent pilot study in a dental clinic concluded that rinsing with a green tea solution strongly inhibited *Streptococcus mutans* growth in saliva and plaque and reduced the gingival bleeding index score. The authors suggested further research to find out if a green tea mouthwash can reduce the prevalence of dental caries (Awadalla et al 2011). Another single-blinded RCT gave 25 high school female students, with gingivitis, a green tea mouthwash twice a day. They reported improvements on all periodontal indices over the 5-week study, although these improvements were not statistically significant (Jenabian et al 2012). In an RCT with 60 children a green tea mouthwash was as effective as sodium fluoride in reducing oral *S. mutans* and lactobacillus indicating a potential use for reduction in caries (Tehrani et al 2011).

Green tea drinking, in a study with 940 Japanese men, has also been found to have a small inverse association with periodontal disease (Kushiyama et al 2009).

## Genital warts

A number of recent trials have shown good effectiveness for a topical treatment (Polyphenon E, Medigene EU) containing a fixed amount of GTCs in the treatment of genital warts. The product is marketed as Veregen in the United States. It is thought the mechanism of action is a combination of immune enhancement, cell apoptosis and inhibition of human papillomavirus (Stockfleth & Meyer 2012).

A systematic review and meta-analysis included three RCTs of Polyphenon E (Gross 2008, Stockfleth et al 2008, Tatti et al 2008) with a total of 660 men and 587 women. It reported a significantly higher chance of complete clearance with the green tea product and very low recurrence rates with both the 10% ointment cream and 15% ointment. There was good tolerability, although some side effects were noted of erythema and localised skin itching (Tzellos et al 2011). Healing of genital warts occurred in 54.9% of patients using Polyphenon E ointment compared with 35.4% of patients receiving placebo in three placebo-controlled clinical studies ( $n = 1400$ ) (Gross 2008). Another trial with the same Polyphenon E topical treatment evaluated 503 patients, with external genital and perianal warts, who were randomised to be treated with a 15% or 10% ointment or placebo. Treatment was applied three times a day for up to 16 weeks. After follow-up, 12 weeks later, 53% of patients with the 15% strength ointment had complete clearance, 51% for the 10% ointment and 37% for the control vehicle. A greater number of women experienced total clearance of all warts (with the Polyphenon E treatment compared to men, 60% compared to 45%; Stockfleth et al 2008). Another double-blind, placebo-controlled RCT of 502 patients with genital and perianal warts used a topical treatment of sin catechins (a defined green tea extract), which was found to be effective and well tolerated. The findings were significant at weeks 4 and 6 and at subsequent visits over the 16-week trial. Complete clearance of warts was obtained in 57% of patients compared with only 33% with the control group (Tatti et al 2008).

## Infections

### Influenza

A potential novel use of green tea has been studied preventing influenza infection. A randomised, double-blind, placebo-controlled trial found the green tea group had significantly lower incidence of flu, a lower incidence of viral antigen measured in the laboratory and a significantly longer time free from the influenza infection from the start of the green tea intervention. This 5-month RCT with 200 health workers during the flu season administered six capsules of green tea extract a day (total catechins 378 mg/day and theanine 210 mg/day) or placebo. Larger trials are needed but this study may demonstrate a potential use as a prophylactic agent for influenza (Matsumoto et al 2011).

An observational study of 2663 schoolchildren in Japan gained information from questionnaires during the flu season and found an inverse association between drinking 1–5 cups a day of green tea and influenza infection (Park et al 2011).

### Pneumonia

The Ohsaki cohort study in Japan followed up 19,079 men and 21,493 women (aged 40–79 years)

and found 406 reported deaths from pneumonia and, although no significant association was found for men drinking green tea, it was found that green tea consumption for women did reduce the risk of dying from pneumonia (Watanabe et al 2009).

## Tuberculosis

A study of 200 newly diagnosed patients with acid-fast bacilli-positive pulmonary tuberculosis were randomly assigned to receive catechin (500 mcg) or placebo. Patients were undergoing conventional treatment and after 1 and 4 months the patients with the green tea extract had a reduction in oxidative stress (Agarwal et al 2010). With further studies there may be a role for green tea extract as an adjuvant therapy in tuberculosis patients.

## Sunburn protection and skin ageing

More than 150 *in vitro* and *in vivo* studies have reported the benefits of green tea for the skin (Hsu 2005). Many mechanisms appear to be responsible: green tea protects against ultraviolet and psoralen + ultraviolet A-induced carcinogenesis and DNA damage and is a potent antioxidant, anti-inflammatory, anticarcinogenic and vulnerary (Hsu 2005). Research with human volunteers has found that topical application of green tea to skin half an hour before ultraviolet exposure protects against the development of sunburn and epidermal damage (Elmets et al 2001). The effect is dose-dependent and strongest for the EGCG and epicatechin gallate polyphenols.

A 2-year, double-blind randomised placebo-controlled trial of oral supplementation of green tea reported significant improvement at 6 months in solar damage and improvement at 12 months in erythema and telangiectasias, although these improvements were not sustained to the 2-year end of the trial. At the end of 2 years there was no significant improvement in photoageing of the skin. The trial included 56 women who were randomised to take 250 mg of green tea polyphenols twice a day or placebo. This was a low dose of green tea extract and further research may be useful to confirm findings (Janjua et al 2009).

## Liver disease

A recent meta-analysis reported borderline significance showing green tea was preventive (for both men and women) in reducing the risk of developing primary liver cancer (Fon Sing et al 2011). A systematic review of 10 studies showed that increased green tea consumption is associated with a reduced risk of liver disease. The studies were published between the years 1995 and 2005, with numbers of subjects ranging from 52 to 29,090. Of the 10 studies, four were RCTs, two cohort, one case-control and three cross-sectional studies. Among them, eight studies were conducted in China, one in Japan and the other in the United States. Most of the studies used adjustments such as age, sex, smoking and drinking to control potential

confounders and the study periods varied from less than 6 months to more than 6 years. Eight studies yielded statistically significant results, showing a protective role of green tea against liver disease, whereas two studies only showed a partial tendency. Also, four studies showed a positive association between green tea intake and attenuation of liver disease. When considering the protective effects of green tea against subgroups of liver diseases, it seems that they are more effective in fatty liver disease and liver disorders (Jin et al 2008); The protective effect of green tea drinking to reduce liver cancer risk appears to be stronger for high-risk patients with hepatitis B or C and also for long-term green tea drinkers. Despite these promising results, more rigorous double-blind studies are still required to confirm the results as the studies used in the review were heterogeneous and differed in the design, outcome, tea dosage and other aspects.

### OTHER USES

Green tea has many other uses, based on results of animal or in vitro tests or on the known pharmacological activity of constituents such as tannin and caffeine. Some of these other uses are treatment of diarrhoea, Crohn's disease, dyspepsia and other digestive symptoms, promoting alertness and cognitive performance, reducing symptoms of headache and promoting diuresis.

### Allergic rhinitis

A novel study suggests drinking tea may provide benefits for seasonal allergic rhinitis. The trial was an open-label, single-dose, randomised study of 38 subjects in Japan. Half the participants drank the benifuuki green tea (34 mg *O*-methylated catechin) daily for 1.5 months before the cedar pollen season while the other group commenced at the start of the pollen season. The symptoms of throat pain, nose blowing and disturbance in daily life were significantly lower in the group taking the tea for the longer period pre-pollen season. This same group of researchers had previously reported that benifuuki green tea containing *O*-methylated catechin had reduced perennial or seasonal rhinitis whereas the placebo green tea did not. It may be the *O*-methylated catechins are required for this effect and more studies are warranted (Maeda-Yamamoto et al 2009).

### Ulcerative colitis

Animal studies have shown anti-inflammatory activity in colitis (Varilek et al 2001, Westphal et al 2008). A double-blinded pilot study of 20 patients with mild to moderate ulcerative colitis achieved a 53% remission rate compared with 0% for placebo after daily doses of Polyphenon E (400 mg or 800 mg of EGCG daily) for 56 days. The remission results were based on the ulcerative colitis disease activity index and the inflammatory bowel disease questionnaire and 10 of the 15 patients in the

Polyphenon E group responded to treatment. The authors suggest Polyphenon E may offer a novel therapy for mild to moderate ulcerative colitis (Dryden et al 2013).

### Dementia/cognitive impairment

Several in vivo studies have demonstrated memory improvement in older animals for green tea extract and improvements in spatial cognition learning ability after long-term administration of GTCs (Haque et al 2006, Kaur et al 2008). In healthy adults a small RCT with 27 participants found a significant improvement in cerebral blood flow with the lower dose of 135 mg of EGCG (and not with the higher dose of 270 mg). These doses were given on two separate days and no significant improvement was found with mood or cognitive performance (Wightman et al 2012). A community-based self-administered questionnaire of 1003 Japanese geriatric people found that greater ingestion of green tea was associated with lower cognitive impairment (Kuriyama et al 2006a). Green tea intake was significantly associated with better cognitive performance in a 2-year follow-up study of Japanese elderly (Hasegawa et al 2005).

### Depression

Novel research in Japan with 537 men and women in a cross-sectional study, using a validated dietary questionnaire, found a 51% lower prevalence of depression in those drinking four or more cups of green tea a day compared to one cup (Pham et al 2013).

### Beta-thalassaemia

In vitro research shows green tea (tannins) chelates iron, which could prove useful in patients with conditions such as beta-thalassaemia (Srichairatanakool et al 2006). Beta-thalassaemic mice (with iron overload due to transfusions) were fed green tea extract and a reduction in liver iron content resulted. This may prove to be a novel therapy to chelate liver iron overload in beta-thalassaemia patients (Saewong et al 2010).

### Amyloid light-chain amyloidosis

This rare disease, causing amyloid deposits in different organs, can affect the heart. Green tea's cardiac benefits may be useful in this condition when there is cardiac involvement. In a small longitudinal observational study of 59 patients with amyloid light-chain amyloidosis with cardiac involvement it was found that green tea polyphenol EGCG produced a significant reduction in left ventricular wall thickness. A reduction of 2 mm of wall thickness occurred in 11 patients; heart functionality was also improved, as was left ventricular ejection fraction. The patients either drank 1.5–2 L of green tea daily or consumed green tea extracts of 600–800 mg EGCG over a 6-month time period (Mereles et al 2010). This novel study requires more research to confirm findings.

### Renal failure

Green tea extract blocks the development of cardiac hypertrophy in experimental renal failure and reduces oxidative stress, according to the results of investigation with animal models (Priyadarshi et al 2003, Yokozawa et al 1996).

### Urinary stones

Two in vivo and in vitro studies have shown that green tea's antioxidant action may inhibit kidney stone formation (Itoh et al 2005, Jeong et al 2006).

### Osteoporosis

There are several in vitro and animal studies as well as emerging human epidemiological research showing promise for green tea in improving bone health. Its mechanism of action is thought to be enhancing osteoblast activity, reducing osteoclasts plus osteoprotection through anti-inflammatory and antioxidant action, leading to a reduction in bone loss (Shen et al 2009, 2011, Tokuda et al 2008). Clinical studies are needed to confirm these findings and to assess if green tea results in fracture reduction. In a study, 150 postmenopausal women with osteopenia were randomised to have green tea supplement (500 mg daily) and/or tai chi exercise over 6 months. Muscle strength and bone formation biomarkers were improved by both green tea and tai chi exercise (Shen et al 2012).

### DOSAGE RANGE

The dose varies depending on the indication it is being used for. Some research suggests 8–10 cups of green tea/day are required for effects whereas others indicate only 3–5 cups of green tea/day are required. It is likely that the dose also depends on the quality of the green tea and the concentration of GTCs in the preparation. When used as a green tea extract in capsule form in high doses for long periods, green tea may have the potential to have adverse effects (Schonthal 2011).

- For external genital and perianal warts: Polyphenon E 10–15% strength ointment applied three times daily.
- For reduced risk of cancers: five or more cups daily.
- For CVD protection: 3–10 cups daily.
- For treatment for periodontal disease: use of gel, chewable tablets or mouthwash twice daily for 2–4 weeks.

### ADVERSE REACTIONS

Due to the caffeine content of the herb, CNS stimulation and diuresis are possible when consumed in large amounts. Teeth staining is also possible due to the tannin content of the herb.

One clinical study found an absence of any severe adverse effects when 15 green tea tablets were taken daily (2.25 g green tea extracts, 337.5 mg EGCG and 135 mg caffeine) for 6 months (Fujiki et al 1999). One trial with high-dose green tea

(600 mg/day) reported adverse effects in 69% of the patients with a range of adverse effects, including insomnia, fatigue, nausea, vomiting, diarrhoea, abdominal pain and confusion (Jatoi et al 2003).

There are rare, idiosyncratic reports of altered liver function with the consumption of green tea. A review of green tea and hepatic reactions found 34 cases of hepatitis with a positive rechallenge in 29 cases. There was one reported death (where there were other confounding factors, such as drugs and alcohol) and a positive rechallenge in seven cases. The authors suggest a causal association between green tea and liver damage which could be related to particular conditions and concomitant medications may be part of the picture (Mazzanti et al 2009). Frequently the green tea products were not fully analysed and others contained a herbal combination, making it difficult to definitively establish a causal relationship between green tea extracts and hepatotoxicity (Schonthal 2011). The US pharmacopeia similarly reports 27 cases where green tea is a possible causality and seven cases as a probable causality of liver damage. They reported that liver issues may be worse if the extract is taken under fasting conditions or on an empty stomach. This committee concluded that, when dietary supplements are formulated and manufactured appropriately, there are no significant safety issues with green tea but there should be caution with use (Sarma et al 2008). Another case report of acute hepatitis occurred in 2009 after consuming a green tea supplement; other causes were excluded and there was a rapid recovery after cessation of the supplement. However other studies have demonstrated no hepatotoxic effects, such as the placebo-controlled parallel study with healthy men taking six capsules of green tea extract daily (714 mg/day green tea polyphenols) for 3 weeks, where no significant changes in biomarkers of liver function or cardiovascular risk markers were found (Frank et al 2009). This was only a small study of 17 and so had no statistical power. Other studies have shown green tea to be effective in reducing liver disease (Jin et al 2008) and liver cancer (Ui et al 2009) and one trial using 1.3 g daily of GTCs reported no abnormalities in liver function tests when used for the duration of around 34 days (McLarty et al 2009).

There is one case report of thrombotic thrombocytopenic purpura after a 38-year-old woman consumed a weight loss product containing green tea extract (200 mg) for 2 months. After being hospitalised for 20 days and treated, her neurological symptoms reduced and platelet count and haematocrit levels normalised. The green tea preparation has been classed as a 'possible' cause of this condition developing in this woman and, as there are no other reported cases, it has been suggested that this could be an idiosyncratic drug reaction. The authors suggest that doctors be aware of this rare condition developing after ingesting green tea (Liatsos et al 2010).

When used over a 16-week period for genital warts, erythema and localised skin itching may occur (Tzellos et al 2011).

## SIGNIFICANT INTERACTIONS

Few controlled studies are available for green tea, so interactions are speculative and based on evidence of pharmacological activity or known actions of key constituents such as caffeine and tannins.

### Anticoagulants

Antagonistic interaction — a case of excessive consumption (2.25–4.5 L of green tea/day) was reported to inhibit warfarin activity and decrease the international normalised ratio (Taylor & Wilt 1999). Whether this is an exceptional case or representative of an expected interaction remains to be determined.

### Hypoglycaemic agents

Caffeine-containing beverages can increase blood sugar levels when used in sufficient quantity (200 mg of caffeine); however, hypoglycaemic activity has been reported for green tea, which could theoretically negate this effect (Ulbricht & Basch 2005) — the outcome of this combination is uncertain, therefore observe the patient.

### Iron

Tannins found in herbs such as *Camellia sinensis* can bind to iron and reduce its absorption — separate doses by at least 2 hours. Protein and iron have also been found to interact with tea polyphenols and decrease their antioxidant effects in vitro (Alexandropoulou et al 2006). The clinical significance of this is as yet unknown.

### CNS stimulants

Based on the caffeine content of the herb, high intakes of green tea can theoretically increase the CNS stimulation effects of drugs such as nicotine and beta-adrenergic agonists (e.g. salbutamol); however, the clinical significance of this is unknown — observe patient.

### CNS depressants

Based on the caffeine content of the herb, high intakes of green tea can theoretically decrease the CNS-depressant effects of drugs such as benzodiazepines; however, the clinical significance of this is unknown — observe patient.

### Antidepressants

Based on theoretical considerations, caution is advised when using highly concentrated supplements with monoamine oxidase inhibitors or dopaminergic drugs because catechins are metabolised by catechol-*O*-methyltransferase (Shord et al 2009).

### Bortezomib (BZM) and other boronic acid-based proteasome inhibitors

EGCG was tested in vitro and in vivo to investigate whether combining it with the proteasome inhibitor BZM, commonly used in the treatment of multiple myeloma, would result in an increase in the drug's

antitumour activity (Golden et al 2009). Green tea extract almost completely blocked the effects of BZM both in vitro and in vivo — avoid.

### Diuretics

Based on the caffeine content of the herb, high intakes of green tea can theoretically increase the diuretic effects of drugs such as frusemide; however, the clinical significance of this is unknown — observe patient.

### Drugs metabolised by cytochrome P450 system

The inhibitory effect of caffeine on CYP1A2 may cause other interactions, but this is speculative for green tea. In vitro and animal research has shown that green tea inhibits CYP3A4 metabolism and a probable inhibition of intestinal CYP3A4, but clinical relevance is unknown (Engdal & Nilsen 2009, Fukuda et al 2009). A small trial with 42 volunteers giving 800 mg of green tea a day suggested that drugs metabolised by the CYP enzymes were unlikely to be significantly affected (Chow et al 2006).

## CONTRAINDICATIONS AND PRECAUTIONS

Excessive intake will increase the likelihood of adverse effects due to the caffeine content and therefore is not recommended for people with hypertension, cardiac arrhythmias, severe liver disease, anxiety or psychiatric disorders or insomnia. It is considered safe when consumed as a tea in moderate amounts but should not be consumed to excess and is generally better on a full rather than empty stomach. However, if taken too close to meals, the tannin content of green tea will inhibit iron absorption.

## PREGNANCY USE

Usual dietary intakes appear safe; however, excessive use is not recommended due to the caffeine content of green tea. It may also be prudent to avoid or drink small quantities of green tea in pregnancy due to its potential to chelate iron and a recent study linking high green tea intake with lower levels of folate in pregnant women (Shiraishi et al 2010).

## PATIENTS' FAQs

### What will this herb do for me?

Green tea has strong antioxidant effects and some population studies suggest that regular consumption may reduce the risk of cancer and CVD. Early research has found it may be useful for sunburn protection, reducing dental plaque formation, colitis,

### Practice points/Patient counselling

- Green tea is made from the same plant as black tea, but it contains greater amounts of polyphenols and generally less caffeine.
- Green tea has been found to have significant antioxidant activity and protects against sunburn when applied topically.
- It has antibacterial activity and is used in oral preparations to reduce plaque and improve gingival health.
- Several in vitro and animal studies have shown anticarcinogenic activity for a range of cancers and some epidemiological evidence further suggests cancer-protective effects may occur, especially for reducing the risk of breast, prostate, endometrial, ovarian, colorectal and pancreatic cancers and leukaemia; however, further research is required. Patients with a high risk of prostate or liver cancer (due to hepatitis B) may benefit from regular green tea drinking.
- Epidemiological evidence suggests green tea may reduce CVD, especially stroke risk. Some clinical trials have demonstrated a reduction in LDL-cholesterol and antihypertensive effect.
- Preliminary evidence from animal studies has shown that it increases thermogenesis, decreases appetite, reduces inflammation in colitis, reduces glucose levels in diabetes, may be useful in renal failure and has the potential to improve cognitive function in the elderly and be used in Alzheimer's and Parkinson's diseases. Early clinical trials have shown specific green teas (benifuuki tea) may be preventive for allergic rhinitis and green tea drinking may reduce depression.
- Some clinical studies show inconsistent, but possibly modest, benefits in diabetes treatment.
- It is not known whether the use will promote weight loss in humans as research results are inconsistent; however, it may assist with modest weight reduction, especially when combined with exercise.
- A proprietary ointment made from a fixed concentration of GTCs is effective in the treatment of genital warts.

diabetes, flu prevention, renal disease, improving memory and cognition and as an antiseptic. However, further research is required.

#### When will it start to work?

This will depend on the reason it is being used. Preventive health benefits are likely to take several years of regular daily tea consumption. Effects on oral health care appear to develop more quickly, within 2 weeks.

#### Are there any safety issues?

Research suggests that green tea is a safe substance when used in usual dietary doses, but excessive consumption may produce side effects, chiefly because of the caffeine content.

## Guarana

**HISTORICAL NOTE** Guarana has been used by the Amazonian Indians of South America for centuries to enhance energy levels, suppress appetite, increase libido and protect them from malaria. More recently, hot and cold guarana beverages have been adopted by the greater population as a tonic to enhance wellbeing, in much the same way coffee is consumed in Australia.

### COMMON NAME

Guarana

### OTHER NAMES

Brazilian cocoa, guarana gum, guarana paste, qarana, quarane, uabano, uaranzeiro, zoom

### BOTANICAL NAME/FAMILY

*Paullinia cupana* (family Sapindaceae)

### PLANT PART USED

Seeds

### CHEMICAL COMPONENTS

Guarana seeds are a rich source of caffeine, containing 3–6% on a dry-weight basis (Saldana et al 2002). Other major compounds include theobromine, theophylline, tannins, resins, protein, fat and saponins (Duke 2003).

### MAIN ACTIONS

A review of the scientific literature reveals that guarana itself has only recently been the subject of clinical studies. As such, studies pertaining to caffeine are sometimes used to explain the herb's action, an approach that presupposes the other constituents are either inactive or of such weak effect they need not be recognised. Although this approach is convenient and provides us with some understanding of the herb's pharmacological effects, the results of clinical studies suggest that guarana's effects on cognitive function are due to more than its caffeine content. It has also been suggested that the effects of guarana are longer lasting than caffeine, possibly due to the saponin and tannin content (Babu et al 2008).

#### Central nervous system (CNS) stimulant

Although guarana has not been clinically investigated for its effects on the CNS, there is a great deal of evidence to show that caffeine is an antagonist of the adenosine receptor, which produces a net increase in CNS activity because the inhibitory

action of adenosine is blocked (Smith 2002). This results in the release of a variety of neurotransmitters (e.g. noradrenaline, acetylcholine, dopamine, and the gamma-aminobutyric acid/benzodiazepine system).

### OTHER ACTIONS

#### Inhibits platelet aggregation

Guarana inhibits platelet aggregation both in vitro and in vivo (Bydlowski et al 1988, 1991). Decreased thromboxane synthesis may in part explain this activity.

#### Gastric effects

Guarana may increase gastric acid secretion and delay gastric emptying. This has been demonstrated in a clinical study using a herbal combination known as YGD, which contains yerba mate (leaves of *Ilex paraguayensis*), guarana (seeds of *Paullinia cupana*) and damiana (leaves of *Turnera diffusa* var. *aphrodisiaca*) (Andersen & Fogh 2001). Whether stand-alone treatment with guarana will produce similar effects is unknown.

#### Chemoprotective

Guarana has been shown to be chemoprotective in a mouse hepatocarcinogenesis model (Fukumasu et al 2005). The herb was found to reduce the cellular proliferation of preneoplastic cells. It has also been demonstrated that guarana is protective against chemically-induced DNA damage in mouse liver. This effect was attributed to the tannin content of the herb (Fukumasu et al 2006). A later mouse experiment observed a decrease in proliferation and an increase in apoptosis of melanoma lung metastases, resulting in a reduction in tumour size (Fukumasu et al 2008).

#### Antibacterial

In vitro data have demonstrated the antibacterial and antioxidant effects of the ethanolic extract of guarana, thought to be due to the phenolic compounds (Basile et al 2005). Guarana was shown to

be effective against many pathogens of the digestive tract, including *Escherichia coli*, *Salmonella typhimurium* and *Staphylococcus aureus*. This adds weight to the traditional use of guarana for diarrhoea. More recently in vitro research has demonstrated antibacterial activity against *Streptococcus mutans*, which could have applications in preventing dental plaque (Yamaguti-Sasaki et al 2007). Antimicrobial activity was further confirmed in vitro when testing guarana seed extracts against food-borne fungi and bacteria. This may have applications in food preservation (Majhenic et al 2007).

### Antioxidant

A strong antioxidant activity has been demonstrated in vitro for guarana seeds (Majhenic et al 2007). This has been attributed to several processes, including an inhibitory effect on lipid peroxidation (Portella 2013) and nitric oxide metabolism (Bittencourt et al 2013).

### Cardiovascular disease prevention

A recent observational study reported a lower prevalence of hypertension, obesity and metabolic syndrome in elderly individuals who habitually consumed guarana, compared to those who never ingested the herb. The guarana group also presented with lower cholesterol (total and low-density lipoprotein) and advanced oxidative protein product levels (Portella 2013).

### Other actions relating to caffeine content

Although these have not been tested for guarana directly, the caffeine content, which is well absorbed from the herb, may cause mild dilation of the blood vessels; an increase in blood pressure, renin and catecholamine release, urine output, metabolic rate, lipolysis, respiration and intestinal peristalsis; and inhibition of CYP1A2. Caffeine also possesses thermogenic properties (Astrup 2000).

## CLINICAL USE

### Mood enhancing

For several years anecdotal evidence has suggested that guarana produces similar effects to caffeine on subjective feelings of wellbeing, energy, motivation and self-confidence (Mumford et al 1994). Tests with animal models indicate guarana exerts a mild antidepressant effect, thereby providing some support for the observed mood-elevating effects (Campos et al 2005, Otobone et al 2007).

Mood elevation was further demonstrated in a recent double-blind, placebo-controlled, multidose clinical study involving 26 volunteers which tested a low caffeine-containing guarana extract (PC-102) (Haskell et al 2007). Four strengths were investigated (37.5 mg, 75 mg, 150 mg and 300 mg). Treatment at each dose level produced a significant effect on mood. As there were low levels of caffeine measured in the guarana extract, mood elevation cannot be explained by the caffeine content alone.

### Enhanced cognitive function and alertness

A growing number of clinical studies have been conducted to investigate whether guarana affects cognitive function, producing mixed results thus far. Four double-blind studies report that guarana has significant effects on cognitive function and provides evidence that these effects are not just mediated by the herb's caffeine content (Haskell et al 2005, 2007, Kennedy et al 2004, 2008). In contrast, two earlier double-blind studies failed to identify significant effects for guarana on cognitive function (Galduroz & Carlini 1994, 1996). Whether this is due to differences in the chemical profile and caffeine content of the tested extracts appears likely, but remains to be confirmed. Some studies have tested guarana in combination with other herbs or nutritional agents.

One double-blind, placebo-controlled study assessed the effects of four different doses of guarana (37.5 mg, 75 mg, 150 mg and 300 mg) in 22 subjects (Haskell et al 2005). Cognitive performance and mood were assessed at baseline and again 1, 3 and 6 hours after each dose using the Cognitive Drug Research computerised assessment battery, serial subtraction tasks, a sentence verification task and visual analogue mood scales. All doses improved picture and word recognition, results on the Bond-Lader visual analogue scales and caffeine research visual analogue scales showing improvements in alertness and reduced ratings of headache. The two lower doses produced better results than the two higher doses, which were associated with impaired accuracy of choice reaction and one of the subtraction tests. Several observations suggest that these effects were not due to caffeine alone. Firstly, effects were still apparent 6 hours after administration and secondly, better results were obtained with a dose of 37.5 mg than 300 mg with a caffeine content of less than 5 mg in the lowest dose. The study was replicated 2 years later, with a double-blind, counterbalanced, placebo-controlled study (Haskell et al 2007). In this study, 26 participants were given the same four doses of a standardised guarana extract. All doses improved mood; however, cognitive improvements were greatest for the two lower doses, with the 75 mg dose most effective. As there was only 9 mg of caffeine in this dose it is unlikely that the effects can be attributed solely to the caffeine content.

Another double-blind, placebo-controlled study investigated the effects of a single dose of guarana (75 mg) on cognition, in combination with and in comparison to ginseng (*Panax ginseng* 200 mg) in 28 healthy volunteers (Kennedy et al 2004). Guarana was shown to produce comparable effects to ginseng in improved task performance, with all three treatments better than placebo. However, guarana was superior to ginseng in improving the speed of performed tasks. Once again, given the low caffeine content (9 mg) of the guarana extract used in this study, the effects are unlikely to be attributable to its caffeine content alone, particularly as the dose

was shown to be as effective as a 16-fold dose of pure caffeine. A later double-blind, randomised, placebo-controlled study of 129 adults tested a multivitamin and mineral supplement with added guarana (Berocca Boost with 222 mg guarana containing 40 mg caffeine) and found it supported the previous findings that guarana improves cognitive performance. A single dose of the supplement also reduced mental fatigue after sustained mental effort (Kennedy et al 2008).

Two other randomised, double-blind studies have investigated the effects of guarana on cognitive function (Galduroz & Carlini 1994, 1996). One study involving 45 healthy elderly volunteers found that guarana treatment was ineffective (Galduroz & Carlini 1996), which confirmed the findings of a previous study conducted with younger subjects. Guarana 500 mg (12.5 mg caffeine) was given twice daily (Galduroz & Carlini 1994). Studies in some animal models have produced positive results for both single-dose and long-term administration of guarana, observing a positive effect on memory acquisition and memory maintenance (Espinola et al 1997).

A more recent double-blind randomised controlled trial of 129 volunteers found that treatment with an acute dose of a guarana and multivitamin mineral supplement increased speed and accuracy on a cognitive demand battery test and reduced the subjective feeling of fatigue (Scholey 2008). The study used Berocca Boost which contains caffeine (40 mg) derived from guarana (222 mg). As a combination supplement was used in this trial, the effects cannot be attributed to guarana alone.

### Chemotherapy-related fatigue

Guarana has also been assessed in breast cancer patients experiencing fatigue during chemotherapy treatment. The randomised study involving 32 patients found a daily dose of 50 mg guarana taken over 21 days produced a significant reduction in fatigue during this period when compared to placebo and was not associated with toxicity or adverse effects (de Oliveira Campos 2011). Brief Fatigue Inventory (BFI) significantly improved after treatment with an oral purified dry extract of *P. cupana* (PC-18; 37.5 mg twice daily) given one week after starting chemotherapy. The study of 40 people with solid tumours found BFI fatigue scores improved or stabilised in 36 out of the 40 patients (mean BFI score difference = 2.503;  $P = .0002$ ) (del Giglio et al 2013). Interestingly, the benefits continued for several weeks after ceasing guarana treatment.

### Ergogenic aid

Guarana is also used as an ergogenic aid by some athletes, most likely because caffeine and theophylline have been used in this way, to improve performance in training and competition (Graham 2001). No human studies testing guarana for effects on physical performance could be located. Referring to caffeine studies, it appears that ergogenic effects are observed under some conditions but not under

others (Doherty et al 2002, Hunter et al 2002, Ryu et al 2001). Testing guarana in several animal models has also produced contradictory results. Significant increases in physical capacity have been observed with a dose of 0.3 mg/mL of a guarana suspension after 100 and 200 days' treatment. However, the same effect was not seen with a concentration of 3.0 mg/mL nor with a solution of caffeine 0.1 mg/mL (Espinola et al 1997).

### Appetite suppressant and weight-loss aid

Weight-loss products often contain guarana, in the belief that it suppresses appetite and may have thermogenic and diuretic activities. An animal study designed to evaluate the effects of guarana and decaffeinated guarana found that only the caffeinated herb was effective for weight loss (Lima et al 2005).

To date, most clinical studies have investigated the effects of guarana in combination with other herbs.

### IN COMBINATION

A double-blind randomised controlled trial testing a combination of yerba mate (leaves of *Ilex paraguayensis*), guarana (seeds of *Paullinia cupana*) and damiana (leaves of *Turnera diffusa* var. *aphrodisiaca*) found that the preparation significantly delayed gastric emptying, reduced the time to perceived gastric fullness and induced significant weight loss over 45 days in overweight patients (Andersen & Fogh 2001). The same herbal combination (Zotrim) was tested in an open study of 73 overweight health professionals over 6 weeks. Active treatment resulted in a significant reduction in self-reported weight and waist and hip measurements, and increased satiety after meals. Significant weight loss was reported by 22% of volunteers.

Another randomised double-blind placebo-controlled trial evaluated the effects of guarana in combination with ma huang (*Ephedra* spp.) and concluded that the formula was effective for weight loss in overweight men after 8 weeks of treatment (Boozer et al 2001). A more recent double-blind, placebo-controlled, randomised study tested a multicomponent herbal combination containing extracts from asparagus, green tea, black tea, guarana, mate, kidney beans, *Garcinia cambogia* and chromium yeast and found that over a 12-week period there was a significant change in the Body Composition Improvement Index and decreased body fat compared to placebo (Opala et al 2006). The formula was more effective for those participants who were undertaking an exercise program at the same time than for those who remained sedentary.

A short-lived increase in metabolic rate was observed in a small double-blind, placebo-controlled, crossover study of 16 healthy subjects (Roberts et al 2005). A product containing primarily black tea (*Camellia sinensis*) and guarana extract providing 36% caffeine (plus vitamin C and some other trace nutrients and herbs) increased metabolic rate after 1 hour with no significant difference at the 2-hour check.

Although encouraging, the effects of guarana as a stand-alone treatment need to be confirmed.

**Clinical note — Popular energy drinks and caffeine content**

Adolescents in particular are high consumers of energy drinks, with a reported 30–50% of teens and young adults consuming these drinks in the United States alone (Seifert et al 2011). In the most recent American Drug Abuse Warning Network report, the number of emergency room visits associated with energy drinks doubled from just over 10,000 in 2007 to just over 20,000 in 2011 (SAMHSA 2013). In Australia, there also appears to be an increasing trend of adverse events associated with energy drink consumption (Gunja & Brown 2012). These drinks often contain a mixture of caffeine, guarana, taurine and other herbs and vitamins. According to product labels and websites, the following drinks contain varying amounts of caffeine:

• Coca Cola	34 mg per 355 mL can
• Diet Coke	45.6 mg per 355 mL
• Diet Pepsi	36 mg per 355 mL
• Diet Pepsi Max	69 mg per 355 mL
• Red Bull	151 mg per 475 mL can
• Mother	80 mg per 250 mL
• V	78 mg per 250 mL
• Brewed coffee	60–120 mg per cup

A large intake of these drinks can produce adverse effects based on their caffeine content such as headache, agitation, insomnia, anxiety, tremor, restlessness, seizures, tachycardia and nausea and other gastrointestinal disturbances. Four independent cases associating high consumption of energy drinks with seizures have been reported (Iyadurai & Chung 2007), and in 2009 a caffeine-related death from energy drinks was reported (Berger & Alford 2009). A prudent suggestion is to avoid a high intake of these drinks. There has been one reported case of intractable ventricular fibrillation in a young woman with a pre-existing mitral valve prolapse. This occurred after consuming an energy drink with guarana and high caffeine content (Cannon et al 2001).

**OTHER USES**

Traditionally, guarana has been used as an aphrodisiac, a treatment for diarrhoea, a diuretic and as a beverage in some cultures.

**DOSAGE RANGE****According to clinical trials**

- Cognition, alertness and mood: doses between 37.5 and 75 mg are sufficient to provide effects for at least 6 hours. However, doses of up to 300 mg have been used with varying concentrations of naturally present caffeine.

- For other indications, guarana has not been significantly researched. Based on its caffeine content, it is advised that doses should not exceed that amount that will provide approximately 250 mg of caffeine daily. This is equivalent to 2.5–4 g guarana/day, depending on the caffeine content of the preparation.

**Clinical note — Is caffeine safe in pregnancy?**

There have been numerous studies investigating the effects of caffeine in pregnancy, with inconsistent results. A meta-analysis of 32 case-control or cohort design studies found that there was a small, statistically significant increase in the risk of spontaneous abortion and of low-birth-weight babies where the pregnant mother consumed more than 150 mg of caffeine per day (equivalent to about 1.5 cups of freshly brewed coffee) (Fernandes et al 1998). Confounders such as maternal age, smoking and alcohol use could not be excluded. More recent studies have produced varying results, with one cohort study in Denmark concluding that high levels of coffee consumption were associated with a higher risk of fetal death, especially after 20 weeks (Bech et al 2005). A population-based case-control study in Uruguay also showed a significantly increased risk of fetal death when more than 300 mg caffeine per day is consumed (Matijasevich et al 2006). An increased risk of repeated miscarriage with high caffeine intake was reported in a Swedish study (George et al 2006) and a more recent study found an increased miscarriage risk even allowing for pregnancy-related symptoms (Weng et al 2008). The risk of small-for-gestational-age (SGA), especially for boys, was nearly doubled for mothers with high rather than low caffeine intake in the third trimester (Vik et al 2003). A UK study of 2643 women found that women whose pregnancies resulted in late miscarriage and stillbirth consumed more than 145 mg/day caffeine through the first trimester (Greenwood et al 2010).

In contradiction to these findings, other studies showed caffeine consumption was unlikely to be a major risk factor for SGA or low-birth-weight babies (Infante-Rivard 2007), and a systematic review showed no association between moderate caffeine consumption and fetal growth (Pacheco et al 2007). Another large prospective study confirmed no clinical importance was demonstrated looking at fetal growth, except for women consuming 600 mg caffeine daily (Bracken et al 2003).

It therefore seems prudent that caffeine intake should be avoided or limited throughout pregnancy and that the caffeine content of guarana products should be checked before use.

**Practice points/Patient counselling**

- Guarana has mild CNS-stimulant properties and increases alertness, cognitive function and mood.
- Current evidence is inconclusive as to whether guarana also enhances physical stamina.
- It has been used in combination with other herbs as a weight-loss aid with some degree of success. However, it is unknown what role guarana played in achieving these results.
- In some sensitive individuals, guarana may produce CNS-stimulant-related side effects, such as elevated heart rate and blood pressure, tremor, restlessness and excitability.

**TOXICITY**

Animal tests have shown that high doses of 1000–2000 mg/kg (intraperitoneal and oral) do not induce significant alterations in parameters for toxicological screening, suggesting an absence of toxicity (Mattei et al 1998). This has also been demonstrated with longer-term use (Antonelli-Ushirobira 2010).

**ADVERSE REACTIONS**

Due to a lack of clinical studies testing guarana as a stand-alone treatment, it is difficult to determine what adverse reactions may exist.

Based on caffeine content, the following adverse effects may theoretically occur at high doses: agitation, tremor, anxiety, restlessness, headache, seizures, hypertension, tachycardia and premature ventricular contractions, diarrhoea, gastrointestinal cramping, nausea and vomiting and diuresis.

**SIGNIFICANT INTERACTIONS**

Controlled studies are not available, therefore interactions are theoretical and based on evidence of pharmacological activity with uncertain clinical significance.

**CNS stimulants**

Additive stimulant activity is theoretically possible, so use with caution.

**CNS sedatives**

Antagonistic effects are theoretically possible due to the herb's CNS stimulant activity. However, one in vivo study found no interaction with pentobarbitone. Observe patients taking this combination.

**Diuretics**

Additive diuretic effects are theoretically possible — use this combination with caution.

**Anticoagulants**

Increased bleeding is theoretically possible, as in vitro and in vivo research has identified antiplatelet activity for guarana. Use this combination with caution.

**CONTRAINDICATIONS AND PRECAUTIONS**

Contraindicated in moderate to severe hypertension and cardiac arrhythmias.

Use with caution in anxiety states, hypertension, diabetes, gastric ulcers and chronic headache. Adverse reactions may be dose dependent. Suspend use of concentrated extracts 1 week before major surgery.

Under the World Anti-Doping Code 2007 Prohibited List, caffeine is not classified as a prohibited stimulant, unless specified by particular sports. Therefore athletes are recommended to check with their own sports federation about the status of caffeine-containing substances.

**PREGNANCY USE**

The use of caffeine-containing preparations should be limited during pregnancy and breastfeeding as it has the ability to cross the placenta and can be found in breast milk. Caffeine clearance is also delayed in the second and third trimesters, with the half-life of caffeine increasing to 10.5 hours from 2.5–4.5 hours in a non-pregnant woman. It also appears that the fetus has a reduced capacity to metabolise caffeine.

**Antiplatelet drugs**

Additive effects are theoretically possible as in vitro and in vivo research has identified antiplatelet activity for guarana. Observe patients taking this combination.

**Digoxin**

Long-term use of high-dose supplements can result in reduced potassium levels, which lowers the threshold for drug toxicity. Avoid long-term use of high-dose guarana preparations.

**Drugs metabolised by CYP1A2**

The inhibitory effect of caffeine on CYP1A2 may cause other interactions, but this is highly speculative for guarana.

**PATIENTS' FAQs****What will this herb do for me?**

Guarana is a herbal stimulant that increases alertness, cognitive function and possibly mood.

**How quickly does it start working?**

Effects are expected 1–2 hours after ingestion, although this will vary depending on the individual and the current level of wakefulness.

**Are there any safety issues to be aware of?**

Used in small amounts, it is likely to have a degree of stimulant activity and decrease fatigue; however, as with all stimulants, excessive use or long-term use can be detrimental to health. Guarana should be

used with caution in people with hypertension, anxiety states, gastric ulcers, diabetes and some types of cardiovascular disease. It may also interact with a variety of medicines and therefore it is recommended to consult your healthcare professional if you are currently taking pharmaceutical medication.

# Gymnema sylvestre

**HISTORICAL NOTE** *Gymnema* is a traditional Ayurvedic medicine used in India for over 2000 years. It has been called the sugar destroyer because the leaf demonstrates the ability to suppress sweet taste recognition on the tongue. It has been used to treat diabetes, as well as to aid metabolic control when combined with other herbal medicines. The first biological investigations were reported in 1930 where blood glucose lowering activity was observed for the leaves in animals with pancreatic function, thereby confirming traditional use (Shanmugasundaram et al. 1990).

## COMMON NAME

Gymnema

## OTHER NAMES

*Asclepias geminate*, gurmar (sugar destroyer), *gymnema melicida*, gokhru, gulmaro, gummara, gurmarbooti, kar-e-khask, kharak, merasingi, meshasringi, masabedda, *Periploca sylvestris*, sirukurinjan

## BOTANICAL NAME/FAMILY

*Gymnema sylvestre* (family Asclepiadaceae)

## PLANT PART USED

Leaf

## CHEMICAL COMPONENTS

*Gymnema* contains gymnemasaponins, gymnemasides, gymnemic acids and gypenosides (Duke 2003), oleanane-type triterpenic acid (Peng et al 2005), flavonol glycosides (Liu et al 2004) and phenolic compounds (Kang et al 2012), as well as a range of nutrients, including ascorbic acid, beta-carotene, chromium, iron, magnesium and potassium. The main active chemical components appear to be the gymnemic acids, gymnemasaponins and the polypeptide gumarin.

## MAIN ACTIONS

### Sweet-taste suppression

It appears that gymnema possesses a number of taste-suppressive substances, some of which are effective in certain animal species and not others. For example, in rats and mice, the constituent gumarin inhibits the ability to taste sweetness (Harada & Kasahara 2000, Kurihara 1969, 1992) but not in humans (Sigoillot et al 2012). In contrast, gymnemic acid, a triterpenoid saponin, increases sweet taste suppression in humans and chimpanzees (Hellekant et al 1996, 1985) but not in rodents (Hellekant et al 1976).

### Antidiabetic

Extensive preclinical research has been conducted with gymnema and several of its isolated constituents in numerous diabetic models. Gymnema's antidiabetic activity appears to be due to a

combination of mechanisms, including reduction of intestinal absorption of glucose (Shimizu et al 2001), inhibition of active glucose transport in the small intestine (Yoshioka 1986), suppression of glucose-mediated release of gastric inhibitory peptide (Fushiki et al 1992), increased activity of the enzymes responsible for glucose uptake and use (Shanmugasundaram et al 1983), stimulation of insulin secretion (Persaud et al 1999, Sugihara et al 2000) and increasing the number of islets of Langerhans and number of pancreatic beta cells (Prakash et al 1986, Shanmugasundaram et al 1990). *Gymnema montanum* (a related species) has also been shown to have antidiabetic, antiperoxidative and antioxidant effects in diabetic rats (Ananthan et al 2003) and antioxidant activity evident in the liver, kidney (Ananthan et al 2004) and brain tissues (Ramkumar et al 2004).

Animal studies suggest that gymnema will reduce blood glucose levels in response to a glucose load in streptozotocin-induced mildly diabetic rats (Okabayashi et al 1990) and alloxan-induced diabetic rats (Shanmugasundaram et al 1983, Srivastava et al 1985), but will not affect blood glucose levels in normal or spontaneously hypertensive rats (Preuss et al 1998). *Gymnema* extract has been found to return blood sugar and insulin levels to normal in streptozotocin-induced diabetic rats after 20–60 days and to double the number of pancreatic islet and beta cells (Shanmugasundaram et al 1990), as well as maintain stable blood glucose levels in rats given beryllium nitrate (Prakash et al 1986). One experimental rat model using streptozotocin to induce type 1 diabetes found that a standardised extract of gymnema, containing 70% of gymnemic acids, produced a significant decrease in blood glucose levels progressing for each of the 3 weeks of the experiment (Jain et al 2006).

In contrast, there are two in vivo studies that have not demonstrated efficacy in diabetic models. One study using a dose of 120 mg/kg/day oral gymnema did not find improvements in insulin resistance in insulin-resistant, streptozotocin-induced diabetic rats (Tominaga et al 1995) and the other study, from Brazil using dried powdered leaves of gymnema, found no effect on blood glucose, body weight or food or water consumption in non-diabetic and alloxan-diabetic rats (Galletto et al

2004). The concentration of gymnemic acids used in these studies is unknown.

Gymnemic acids have demonstrated hypoglycaemic activity in dexamethasone-induced hyperglycaemic mice (Gholap & Kar 2005) and gymnema, together with other Ayurvedic herbs, has been shown to have hypoglycaemic activity in streptozotocin-induced diabetic mice (Mutalik et al 2005) and rats (Babu & Prince 2004). *Gymnema* has also been shown to protect the lens against sugar-induced cataract by multiple mechanisms (Moghaddam et al 2005) and protect against the adverse effects of lipid peroxidation on brain and retinal cholinesterases, suggesting a use in preventing the cholinergic neural and retinal complications of hyperglycaemia in diabetes (Ramkumar et al 2005). In diabetic rats, gymnema extract decreased the activity of glutathione peroxidase in the liver and glutamate pyruvate transaminase in serum to normal levels and decreased lipid peroxidation levels in serum (31.7%), the liver (9.9%) and the kidney (9.1%). Phenolic compounds were thought to be responsible for this activity (Kang et al 2012).

#### Used in combination

A combination of gymnema, *Acacia catechu* and *Pterocarpus marsupium* was found to significantly elevate serum insulin levels in an animal model (Wadood et al 2007). The effect was thought to be due to beta cell regeneration. A polyformula of 18 herbs (Diabegon), including gymnema, was administered to rats resulting in improvement in insulin resistance and dyslipidaemia (Yadav et al 2007). Another polyherbal formula (Diakyur) also demonstrated significant hypoglycaemic activity and antilipid peroxidative effect (Joshi et al 2007). While these studies demonstrate the success of these specific herbal formulas, it is unclear what role gymnema had in producing these results.

#### Lipid lowering and weight loss activity

*Gymnema* extract reduces fat digestibility and increases faecal excretion of cholesterol, neutral sterols and acid steroids, as well as reducing serum cholesterol and triglyceride levels, according to animal studies (Nakamura et al 1999, Shigematsu et al 2001). A saponin-rich aqueous leaf extract of *Gymnema sylvestre* was studied in obese rats fed a high-fat diet for 8 weeks. An oral dose of 100 mg/kg of body weight was administered once a day to the treatment group (Reddy et al 2012). It significantly decreased food consumption, body weight and visceral organ weight and improved lipid profiles (decreased triglycerides, total cholesterol, low-density lipoproteins, very low-density lipoproteins, atherogenic index and increased levels of high-density lipoproteins). Another study in obese rats induced by a high-fat diet displayed similar findings. Rats fed a high fat diet for 28 days were treated with a standardised ethanolic extract of gymnema (200 mg/kg). The treatment group demonstrated a significant decrease in BMI, weight gain, organ

weights and food intake, serum lipids (decreased total cholesterol, triglycerides, LDL-cholesterol, VLDL-cholesterol, apolipoprotein-B, atherogenic index and increased HDL-cholesterol and apolipoprotein-A1) and haemodynamic parameters (systolic, diastolic, mean arterial BP and heart rate). Other findings included significantly decreased serum leptin, insulin, glucose and lactate dehydrogenase (LDH), as well as decreased oxidative stress and prevention of myocardial apoptosis by decreasing cardiac caspase-3 levels, cardiac DNA fragmentation and increasing the cardiac Na-K ATPase levels (Kumar et al 2012).

#### Antimicrobial, antibacterial, antiviral and larvicidal

The ethanolic extract of *Gymnema sylvestre* leaves demonstrated antimicrobial activity against *Bacillus pumilis*, *B. subtilis*, *Pseudomonas aeruginosa* and *Staphylococcus aureus*, but was found inactive against *Proteus vulgaris* and *Escherichia coli* (Satdive et al 2003). This finding was confirmed in a later in vitro study which found that gymnemic acid extract exerted strong antibacterial activity against *Bacillus subtilis*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa* and *Salmonella typhi* (Poonkothai et al 2005). Unlike the study by Satdive et al (2003), this study did identify activity against *Escherichia coli*. Antiviral activity has also been reported (Porchezian & Dobriyal 2003). A larvicidal effect has been demonstrated for a 5% concentration of aqueous extract of *Gymnema sylvestre* leaves against *Culex quinquefasciatus* larvae (Gopiesh 2007). The treatment was 100% effective.

#### OTHER ACTIONS

*Gymnema* contains a constituent with ATPase inhibitor activity, which has been shown to block the effect of ATPase from snake venom (Manjunatha & Veerabappa 1982). A significant anti-inflammatory activity was discovered for an aqueous extract of gymnema leaves, which was comparable to that of the drug phenylbutazone in a carrageenan-induced paw oedema animal model (Malik 2008).

#### CLINICAL USE

Several different gymnema extracts have been tested in clinical studies. An ethanolic acid-precipitated extract from gymnema, known as GS4, has been used in several human trials and been patented as the product ProBeta. Most commercial preparations are standardised for gymnemic acids.

#### Sweet-taste suppression and weight loss

A controlled trial of normal volunteers found that an aqueous gymnema extract with concentrated gymnemic acid reduced sweetness perception by 50%, resulting in reduced caloric consumption 1.5 hours after the sweetness-numbing effect stopped (Brala & Hagen 1983).

### IN COMBINATION

In a 6-week randomised, double-blind, placebo-controlled study, a multiherbal formula that included gymnema was found to significantly reduce body weight and fat loss in obese adults after 6 weeks (Woodgate & Conquer 2003); however, the role of gymnema in achieving these results is unknown. A double-blind, placebo-controlled, RCT compared (–)-hydroxycitric acid (HCA-SX) with HCA plus a combination of chromium and *Gymnema sylvestre* extract. In this study, a group of 29 volunteers, in the obese BMI range, were divided into three groups and given the supplements or placebo for 8 weeks and all subjects were provided with a 2000 kcal diet per day and a supervised 30-minute walk for 5 days each week. The study combined data from two previous double-blind, placebo-controlled RCTs and reported that both the HCA-SX group and, to a greater degree, the group with the added chromium and gymnema experienced weight loss, decreased appetite, improvement in blood lipids, higher serum leptin and serotonin levels plus an increase in fat oxidation (Preuss et al 2005). This result supports the findings of several animal studies.

### Type 1 and type 2 diabetes

Orally, gymnema leaf is used to treat both type 1 and type 2 diabetes and hyperglycaemia. There are several clinical trials that suggest that gymnema may be useful in reducing blood glucose levels in both type 1 and type 2 diabetes.

Early clinical research was conducted in the 1980s, starting in India. In 1981, Shanmugasundaram et al showed that oral administration of the dried leaves of *G. sylvestre* (GS4) decreased blood glucose and raised serum insulin levels, during an oral glucose tolerance test in alloxan diabetic rabbits and in healthy human volunteers. Administration of dried leaves for a period of 10 days lowered blood glucose and increased the glucose-triggered rise in serum insulin levels in a single case of maturity onset diabetes, suggesting possible repair or regeneration of the *beta* cells in the Islets of Langerhans (Shanmugasundaram et al 1981).

This was followed by a second clinical study of 27 patients with type 1 diabetes who were treated with an aqueous extract of gymnema leaves (GS4 200 mg taken after breakfast and again after dinner) in addition to insulin and compared to 37 controls receiving insulin alone. Active treatment was for a minimum of 6 months. Over time, the groups receiving gymnema started to develop hypoglycaemia and insulin doses were reduced by 10 units at a time, ending at a dose nearly half the initial dose. Treatment also significantly reduced HbA<sub>1c</sub> level in the first 6–8 months of therapy ( $P < 0.001$ ) and reductions were also observed for glycosylated plasma protein levels, cholesterol, triglycerides and serum amylase. It was suggested that gymnema treatment enhanced endogenous insulin, possibly by regeneration/revitalisation of the residual *beta* cells as higher levels of serum C-peptide were found (Shanmugasundaram et al 1990).

In one study, the ability of the GS4 extract (400 mg/day) to supplement the use of conventional oral hypoglycaemic agents (glibenclamide or tolbutamide) was studied in 22 patients with type 2 diabetes over 18–20 months. Treatment resulted in a significant reduction in fasting blood glucose ( $174 \pm 7$  vs  $124 \pm 5$  mg/dL), HbA<sub>1c</sub> ( $11.91 \pm 0.3$  vs  $8.48 \pm 0.13\%$ ) and glycosylated plasma protein levels ( $3.74 \pm 0.07$  vs  $2.46 \pm 0.05$  microgram hexose/mg protein) and raised insulin levels, whereas no changes were observed in the control group. This allowed for a decrease in conventional drug dosage and in five cases, blood glucose homeostasis was maintained with GS4 alone, suggesting that *beta*-cell function may have been restored (Baskaran et al 1990).

Recently, a novel high molecular weight gymnema extract (Om Santal Adivasi (OSA) was tested for effects on plasma insulin in 11 patients with type 2 diabetes (Al-Romaiyan et al 2010). In 10 of 11 patients, oral treatment with OSA (1 g/day, 60 days) was associated with a reduction in fasting blood glucose levels with a mean reduction from  $162 \pm 23$  to  $119 \pm 17$  mg/dL ( $P < 0.005$ ). Postprandial blood glucose levels also showed significant reductions in 10 patients, with a reduction from  $291 \pm 10$  to  $236 \pm 30$  mg/dL ( $P < 0.02$ ) and there was a mean increase in serum insulin from  $24 \pm 9$  to  $32 \pm 6$  U/mL ( $P < 0.001$ ). Improvements in glycaemic control were associated with increased levels of insulin and/or C-peptide in all patients from  $298 \pm 42$  to  $447 \pm 48$  pmol/L ( $P < 0.05$ ).

### IN COMBINATION

A small, double-blind, randomised, placebo-controlled trial of a multiherbal Ayurvedic formula containing gymnema showed significantly improved glucose control and reduced HbA<sub>1c</sub> levels in patients with type 2 diabetes within the 3-month test period (Hsia et al 2004).

#### Clinical note — Herbs and diabetes

Diabetes has been recognised since ancient times, and as early as 700–200 BC two types of diabetes were recorded in India, one of which was diet related and the other was described as genetic. Diabetes has also been recognised in China for thousands of years, where it is attributed to yin deficiency and treated with an integrated approach that involves more than lowering blood glucose. At least 30 different herbal medicines are used in the management of diabetes and its complications, with several of these having outstanding beneficial potential.

### Hypercholesterolaemia and hypertriglyceridaemia

Short-term animal studies have shown that gymnema extracts are able to reduce serum cholesterol and triglyceride levels in experimentally induced hyperlipidaemic rats (Bishayee & Chatterjee 1994) and in

spontaneously hypertensive rats (Preuss et al 1998), as well as in humans with type 2 diabetes (Shanmugasundaram et al 1990). These results have not yet been established by long-term studies. A recent rat experiment demonstrated reduced hyperlipidaemia and weight loss without rebound effect after the treatment was withdrawn for 3 weeks (Luo et al 2007).

## OTHER USES

Gymnema has been used as a snakebite cure because it inhibits venom ATPase (Manjunatha & Veerasappa 1982), and has also been used as a leaf paste to treat toe mycosis.

An insecticide against mosquitos may be another use due to its larvicidal properties.

In Ayurvedic medicine, gymnema is used as an antimalarial, digestive stimulant, laxative and diuretic and as a treatment for cough, fever, urinary conditions and diabetes.

## DOSAGE RANGE

The typical therapeutic dose of an extract, standardised to contain 24% gymnemic acids, is 400–600 mg/day. When used to regulate blood sugar, gymnema may best be administered in divided doses with meals.

### Diabetes

- Liquid extract (1:1): 25–75 mL/week or 3.6–11.0 mL/day.
- 6–60 g/day of dried leaf infusion.

### Sweet craving and reducing sweet perception

- Liquid extract (1:1): 1–2 mL dropped onto the tongue and rinsed off — repeat every 2–3 hours as required.

## ADVERSE REACTIONS

No clinically significant side effects have been reported in clinical trials lasting up to 3 years. At higher doses, gastric irritation can occur because of the saponin content. In this event, the dose should be decreased, or administered after eating. Gymnema liquid extracts will affect sweet-taste suppression of all foods, not just sugars. If gymnema is not being used as a sweet taste suppressor, it may be administered after eating to avoid decreasing the palatability of food.

### Hepatotoxicity

There are two case reports of hepatotoxicity resulting from the consumption of a weight-loss formula containing gymnema and other herbs, including *Garcinia cambogia*, willow bark, glucomannan, green tea and guarana. Whether gymnema was the main causative factor remains unclear. There has been one case report in the literature linking gymnema to hepatotoxicity. A 60-year-old type 2 diabetic female with a BMI of 33 presented with fatigue, weakness, jaundice, anorexia and weight loss. Seventeen days prior she had started taking a *Gymnema sylvestre* tea

(dose unknown, consumed three times per day). Her symptoms appeared on the seventh day and she discontinued use on the tenth day. The patient had also been taking acetazolamide for the past 2 years. Investigations found elevated bilirubin and transaminases; a minimally enlarged liver with steatosis on abdominal ultrasound and steatosis and inflammation on biopsy. The patient was prescribed prednisone and a proton-pump inhibitor. After monthly monitoring, bilirubin and transaminases returned to normal after 6 months. The gymnema was not re-challenged and was not tested to rule out adulteration, contamination or substitution (Shiyovich et al 2010).

## SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

### Hypoglycaemic agents and insulin

Gymnema may enhance the blood glucose-lowering effects of insulin and hypoglycaemic agents, and so should be used with caution. In practice, the interaction may be useful, as a reduction in the drug dose could theoretically be achieved under professional supervision.

### Contraindications and precautions

Blood glucose levels should be monitored closely when used in conjunction with insulin and hypoglycaemic agents.

### PREGNANCY USE

There is insufficient reliable information available about the safety of gymnema in pregnancy.

### Practice points/Patient counselling

- Gymnema liquid extracts suppress the ability to taste sweet on the tongue.
- It may be useful as a weight-loss aid, according to preliminary research.
- Clinical studies have shown that gymnema may be useful to help control blood sugar levels in diabetes and also reduce lipid levels.
- When used with hypoglycaemic medications, blood sugar levels need to be monitored to prevent hypoglycaemia.
- Preliminary research suggests that it may also have a role in elevated cholesterol and triglyceride levels.

### PATIENTS' FAQs

#### What will this herb do for me?

Gymnema has the ability to reduce the tongue's perception of sweetness. It may also improve blood glucose handling in diabetics, reduce lipid levels and possibly aid in weight loss.

**When will it start to work?**

Liquid extracts reduce the taste of sweetness rapidly, lasting for several hours, but effects on blood sugar regulation develop with long-term use.

**Are there any safety issues?**

Diabetic patients on medication should carefully monitor their blood sugar levels when taking this herb to avoid hypoglycemia.

# Hawthorn

**HISTORICAL NOTE** The name ‘hawthorn’ comes from ‘hedgethorn’, after its use as a living fence in much of Europe. Dioscorides and Paracelsus praised hawthorn for its heart-strengthening properties and it is also known in traditional Chinese medicine. It has since been shown to have many different positive effects on the heart and is a popular prescription medicine in Germany for heart failure (Rigelsky & Sweet 2002).

H

## COMMON NAME

Hawthorn

## OTHER NAMES

Aubepine, bianco spino, crataegi (azarolus, flos, folium, folium cum flore [flowering top], fructus [berry], nigra, pentagyna, sinaica boiss), English hawthorn, Chinese hawthorn, fructus oxyacanthae, fructus spinae albae, hagedorn, hedgethorn, maybush, maythorn, meidorn, oneseed hawthorn, shanzha, weissdorn, whitehorn

## BOTANICAL NAME/FAMILY

*Crataegus laevigata*, *C. cuneata*, *C. oxyacantha*, *C. monogyna*, *C. pinnatifida* (family Rosaceae [Rose])

## PLANT PARTS USED

Extracts of the leaf and flower are most commonly used, although the fruit (berries) may also be used.

## CHEMICAL COMPONENTS

Leaves and flowers contain about 1% flavonoids, such as rutin, quercetin, vitexin, hyperoside, 1–3% oligomeric procyanidins, including catechin and epicatechin, triterpenes, sterols, polyphenols, coumarins, tannins (Blumenthal et al 2000). Although the therapeutic actions cannot be attributed to single compounds, the herb has been standardised to flavonoid content (hyperoside as marker) and procyanidins (epicatechin as marker). For example, RP WS 1442 is a hydroalcoholic extract of hawthorn prepared from leaves and blossoms and standardised to 18.75% oligomeric procyanidins. It has been found that bioequivalent extracts, as determined by noradrenaline-induced contraction of isolated guinea pig aorta rings, can be obtained using 40–70% ethanol or methanol as the extraction solvent, whereas aqueous extracts had markedly different constituents and pharmacological effects (Vierling et al 2003).

In vivo absorption studies found that oral administration of hawthorn phenolic extract resulted in detectable plasma levels of epicatechin whereas no hyperoside and isoquercetin were detected, indicating

poor bioavailability of these compounds (Chang et al 2005). A year later the same authors, who used in vitro and in vivo experiments, showed that all three constituents have limited permeabilities and co-occurring extract components seem to have no significant effect on their intestinal absorption (Zuo et al 2006). Research with another important constituent, vitexin-2''-O-rhamnoside, showed that passive diffusion dominates its absorptive transport behaviour, and that the absorption and secretion are mediated by the efflux transport system P-glycoprotein (Xu et al 2008).

## MAIN ACTIONS

### Cardiovascular effects

The mechanisms of action for hawthorn have been extensively studied in vitro and in vivo. There is good research evidence to support cardiovascular actions that include increasing the force of myocardial contraction (positive inotropic action), increasing coronary blood flow, reducing myocardial oxygen demand, protecting against myocardial damage, improving heart rate variability and stroke volume, as well as hypotensive and antiarrhythmic effects (Garjani et al 2000, Mills & Bone 2000, Popping et al 1995).

### Positive inotrope

Studies with animal models indicate that hawthorn exerts a positive inotropic effect similar to the beta-adrenergic agonist isoprenaline and the cardiac glycoside ouabain. The pharmacological mechanism appears to be comparable to the cAMP-independent positive inotropic action of cardiac glycosides which is mediated via inhibition of the sodium pump (Na<sup>+</sup>/K<sup>+</sup>-ATPase). Preclinical research shows it does not inhibit phosphodiesterases or a beta-sympathomimetic action (Koch & Malek 2011).

### Antiarrhythmic effect and negative chronotropic effect

*Crataegus* extract blocks repolarising potassium currents in ventricular myocytes, an effect similar to the

action of class III antiarrhythmic drugs, which might be the basis for its observed antiarrhythmic effects (Muller et al 1999). Hawthorn therefore differs from other inotropic agents, which reduce the refractory period and increase the risk of arrhythmias. In contrast, it increases the refractory period, which is thought to contribute to its arrhythmic effects (Joseph et al 1995). Additionally, hawthorn extract does not cause beta-adrenergic receptor blockade at concentrations which cause negative chronotropic effects (Long et al 2006). A study elucidated that the decreased chronotropic effect in rat cardiomyocytes may be mediated via muscarinic receptors (Salehi et al 2009).

### Cardioprotective effect

In vitro and in vivo studies confirm that hawthorn extract has a significant cardioprotective effect against ischaemia and ischaemic reperfusion injury (Al Makdessi et al 1996, 1999, Jayachandran et al 2010, Jayalakshmi & Devaraj 2004, Min et al 2005, Swaminathan et al 2010, Veveeris et al 2004). For example, pretreatment with alcohol-based hawthorn extract maintained mitochondrial status, and prevented mitochondrial lipid peroxidative damage and decrease in Krebs's cycle enzymes following induced myocardial infarction in rats (Jayalakshmi et al 2006).

Interestingly, hawthorn treatment modifies left ventricular remodelling and counteracts myocardial dysfunction in animal models of cardiac hypertrophy (Hwang et al 2008). In a rat study, hawthorn demonstrated marked suppression of aortic constriction and modest beneficial effects on cardiac remodelling and function in a long-term, pressure overload-induced model of heart failure (Hwang et al 2009).

### Coronary blood flow

An increase in coronary blood flow for hawthorn extracts has repeatedly been demonstrated in multiple models.

When testing hawthorn extract WS 1442 for its effect on relaxation of rat aorta and human mammalian artery, it was shown to induce an endothelium-dependent, nitric oxide (NO)-mediated vasorelaxation (Anselm et al 2009, Brixius et al 2006, Rieckeheer et al 2011). The increase in coronary blood flow is dose-dependent (Siegel et al 1996). Moreover, long-term treatment with WS 1442 also reduced age-related endothelial dysfunction in rats by reducing the prostanoid-mediated contractile responses and decreasing cyclooxygenase-1 (COX-1) and COX-2 (Idris-Khodja et al 2012).

Much of hawthorn's cardiovascular activity is attributed to its flavonoid constituents (Nemecz 1999) and hawthorn extract is classified as a flavonoid drug in Germany. Studies using isolated guinea pig hearts suggest that the oligomeric procyanidins contribute to the vasodilating and positive inotropic effects of hawthorn (Schussler et al 1995), and ischaemia-reperfusion studies in rats suggest that

these compounds are also responsible for cardioprotective effects (Chatterjee et al 1997).

It has been reported that hawthorn extracts prepared from dried leaves and those made from dried berries have similar chronotropic activities and that the extracts may contain multiple cardioactive components, because following various chromatographic steps, several fractions retained multiple cardiac activities (Long et al 2006).

Several procyanidins found in relatively high concentrations in hawthorn have shown angiotensin-converting enzyme (ACE) inhibition in vitro, in a reversible and non-competitive manner (Murray 1995, Uchida et al 1987).

### Preventing restenosis

Hawthorn extract may prevent atherosclerosis and restenosis following angioplasty. Hawthorn extract WS 1442 (100 mcg/mL) taken from day 2 to day 13 after angioplasty reduced vascular smooth-muscle cell migration by 38% and proliferation by 44% and improved luminal volume compared to controls (Furst et al 2010).

### No antiplatelet or antithrombotic activity

A small open, crossover trial testing *Crataegus laevigata* (2.4 g/day of Crataeosor; equivalent to 50 mg of flavonoids and 134 mg of proanthocyanidins) found no inhibition of platelet aggregation or thromboxane A<sub>2</sub> synthesis compared to aspirin (100 mg/day) in 16 healthy volunteers after 15 days. Although *Crataegus laevigata* does not display antiplatelet effects as a stand-alone treatment, this has not been tested in patients with atherothrombotic vascular disease in conjunction with antiplatelet drugs (Dalli et al 2011b).

### Antioxidant

Direct and indirect antioxidant activity plays a role in the herb's ability to exert cardioprotective effects. It can protect human low-density lipoprotein (LDL) from oxidation and maintain alpha-tocopherol (Periera et al 2000, Rajalakshmi et al 2000, Zhang et al 2001). The ethanolic hawthorn extract restores glutathione and the activity of endogenous antioxidant enzymes such as superoxide dismutase, catalase and glutathione peroxidase (Akila & Devaraj 2008, Ljubuncic et al 2005, Vijayan et al 2012).

Hawthorn's free radical-scavenging capacity is mainly related to its total phenolic proanthocyanidin and flavonoid content (Bahorun et al 1996, Kiselova et al 2006, Rakotoarison et al 1997). This is supported by a study that demonstrated that the capacity of hawthorn extracts to inhibit Cu<sup>2+</sup>-induced LDL oxidation is linked to their content of total polyphenols, proanthocyanidins (global and oligomeric forms), as well as to their content of two individual phenolics: a flavonol, the dimeric procyanidin B<sub>2</sub>, and a flavonol glycoside, hyperoside (Quettier-Deleu et al 2003). The highest antioxidant activity appears to be found in the flower buds, which are high in proanthocyanidin content, and

the leaves, which are high in flavonoid content (Bahorun et al 1994), whereas the fresh and dried fruits possess less antioxidant activity.

When compared, epicatechin was found to be more efficient as an antioxidant than hyperoside or chlorogenic acid (Bernatoniene et al 2008, Sokól-Letowska et al 2007). Bernatoniene et al (2008) found that both aqueous and ethanolic hawthorn extracts have antioxidant activity, but that the effect displayed by the ethanolic extract was stronger. Moreover, the radical scavenging properties were higher for both extracts when a combination rather than individual constituents was compared (Bernatoniene et al 2008, Sokól-Letowska et al 2007).

### Lipid lowering

Hawthorn extracts lower blood cholesterol levels in vivo, an effect mediated by several different mechanisms. Most recently, the effect was demonstrated in a study with diabetic volunteers.

One study identified that hawthorn extract given to rats while on an atherogenic diet (4% cholesterol, 1% cholic acid, 0.5% thiouracil) prevented the elevation of lipids in the serum and heart, and also significantly decreased lipid accumulation in the liver and aorta, thus reversing the rats' hyperlipidaemic conditions (Akila & Devaraj 2008). Similarly, rats fed dried fruit of *Crataegus pinnatifida* in conjunction with a high-cholesterol diet over 4 weeks displayed markedly suppressed total cholesterol and LDL and an increase in high-density lipoprotein (HDL) when compared to rats fed a high-cholesterol diet alone. In addition, rats in the treatment group demonstrated less hepatocyte enlargement, fatty deposits in the liver and improved antioxidant enzyme activities in liver and kidney (Kwok et al 2010).

The monomeric catechins and oligomeric procyanidins are thought to contribute to a hypocholesterolaemic effect. This may occur through a variety of mechanisms, including an upregulation of hepatic LDL receptors, increased degradation of cholesterol to bile acids and decreased cholesterol biosynthesis (Rajendran et al 1996), as well as inhibition of cholesterol absorption mediated by downregulation of intestinal acyl coenzyme A: cholesterol acyltransferase activity (Zhang et al 2002). Moreover, in mice hawthorn flavonoids increased lipoprotein lipase expression in muscular tissue and decreased it in adipose tissue (Fan et al 2006).

### Antiviral

The O-glycosidic flavonoids and the oligomeric proanthocyanidins exhibited significant inhibitory activity against herpes simplex virus type 1 in vitro (Shahat et al 2002).

### Antimicrobial

Hawthorn extracts showed moderate bactericidal activity, especially against Gram-positive bacteria *Micrococcus flavus*, *Bacillus subtilis* and *Lysteria*

*monocytogenes*. Hawthorn was ineffective against *Candida albicans* (Tadic et al 2008).

### Anti-inflammatory

Flavonoids from hawthorn have demonstrated anti-inflammatory and hepatoprotective activity in vitro and in vivo. In a model of carrageenan-induced rat paw oedema, orally administered hawthorn extract showed dose-dependent anti-inflammatory effects. Compared to an indomethacin dose producing 50% reduction of rat paw oedema, a dose of 200 mg/kg hawthorn extract produced 72.4% of anti-inflammatory activity (Tadic et al 2008). Hawthorn fruit has been shown to be protective in experimental models of inflammatory bowel disease in mice, with restoration of body weight and colon length, increased haemoglobin count, reduced signs of inflammation, such as infiltration by polymorphonuclear leukocytes and multiple erosive lesions, along with improved survival (Fujisawa et al 2005).

It is thought that anti-inflammatory effects are achieved by reducing the release of prostaglandin E<sub>2</sub> and NO in vitro, as well as decreasing the serum levels of the hepatic enzyme markers, reducing the incidence of liver lesions, such as neutrophil infiltration and necrosis, and decreasing the hepatic expression of inducible nitric oxide synthase (iNOS) and COX-2 in vivo (Kao et al 2005). A hydroalcoholic extract from the flower heads of *C. oxyacantha* has also been found to inhibit thromboxane A<sub>2</sub> biosynthesis in vitro (Nemecz 1999). An aqueous extract of *C. pinnatifida* inhibited NO and suppressed COX-2, tumour necrosis factor (TNF)-alpha, interleukin 6 (IL-6) and IL-1β expression in murine cell culture (Li & Wang 2011).

Chemopreventive effects have been postulated after the inhibition of skin tumour formation, a decrease in the incidence of tumour, inhibition of NF-kappaB and suppressed expression of COX-2 and iNOS were detected when using the polyphenol fraction of hot-water extracts from dried fruits of *C. pinnatifida* (Kao et al 2007).

A dry extract of leaves and flowers of *C. laevigata* inhibited *N*-formyl-Met-Leu-Phe (FMLP)-induced superoxide anion generation, elastase release and chemotactic migration in human neutrophils. It also reduced FMLP-induced leukotriene B<sub>4</sub> production and lipopolysaccharide-induced generation of TNF-alpha and IL-8 (Dalli et al 2008).

In a study using 62 male rats, no effect on IL-1ss, IL-6, IL-10 and leptin could be detected. However, there was a trend suggesting suppression of IL-2 plasma concentrations (Bleske et al 2007).

### Radioprotective

A study using mouse bone marrow cells showed that a single intraperitoneal administration of hawthorn extract 1 hour prior to gamma radiation can significantly reduce the frequencies of micronucleated polychromatic erythrocytes and significantly increase the ratio of polychromatic erythrocyte/polychromatic erythrocyte + normochromatic

erythrocyte. Such a protective effect against genotoxicity appeared to be related to the antioxidant activity of the extract (Hosseinimehr et al 2007). The significant radioprotective potential of hawthorn was also detected in vitro using human peripheral blood lymphocytes. A reduced incidence of radiation-induced micronuclei, reduced levels of lipid peroxidation products and twofold enhanced apoptosis were observed. A stepwise slowdown of cell proliferation was seen as beneficial, thus enabling more time for repair (Leskovac et al 2007). Blood lymphocytes were extracted from human volunteers at different timeframes following ingestion of *C. microphylla*. Lymphocytes were exposed to gamma radiation, then assessed for binucleated cells. Hawthorn extract was most effective at reducing multinucleated cells 1 hour after ingestion (Hosseinimehr et al 2009).

### Protection against ischaemic damage

Hawthorn flavonoids have also been shown to decrease the cytotoxicity of hypoxia to human umbilical vein endothelial cells in vitro (Lan et al 2005), as well as protect against delayed cell death caused by ischaemia-reperfusion brain injury in gerbils (Zhang et al 2004). These effects have been attributed to improving energy metabolism, scavenging oxygen free radicals and inhibiting production of free radicals in ischaemic myocardium (Min et al 2005, Zhang et al 2004). Hawthorn may also display neuroprotective effects. Rats pretreated with hawthorn extract displayed reduced brain damage and improved neurological behaviour after middle cerebral artery occlusion induced ischaemia-reperfusion injury (Elango et al 2009).

### OTHER ACTIONS

The high procyanidin content in the herb provides a theoretical basis for other actions such as anti-allergic and collagen-stabilising effects. Oligomeric procyanidins isolated from the leaves of *Crataegus pinmatifida* have demonstrated collagenase and gelatinase inhibitory activity (Moon et al 2010).

Moreover, a hawthorn extract has been shown to produce dose-dependent gastroprotective activity, with the efficacy comparable to ranitidine (Tadic et al 2008).

An aqueous extract of hawthorn leaves exhibited hypoglycaemic activity in streptozotocin-diabetic rats, but not in normal rats, without affecting basal plasma insulin concentrations (Jouad et al 2003). Hawthorn has also been found to have hepatoprotective effects in rats with myocardial infarction, with protection against alterations in tissue marker enzymes of experimentally-induced liver injury and a reversal of histological changes (Thirupurasundari et al 2005).

The dried fruit of *Crataegus monogyna* was investigated for effects on anxiety levels, motor coordination, spontaneous locomotor activity and nociceptive perception in mice. Findings suggested the treatment exhibited central nervous system-depressant

activities, as well as central and peripheral analgesic effects. These were thought to be mediated by the endogenous opioid system (Can et al 2010). This correlates with the traditional use of hawthorn for nervous heart conditions and neurasthenia (Felter 1922).

## CLINICAL USE

### Congestive heart failure

There is considerable experimental and clinical evidence supporting the use of hawthorn as an effective treatment for congestive cardiac failure in patients with slight, mild limitation of activity who are comfortable at rest or with mild exertion (i.e. New York Heart Association [NYHA] class I-II). Systematic reviews and meta-analyses published since 2000 have consistently reported positive effects on a range of common symptoms and objective markers in mild congestive heart failure (CHF). Some studies have tested hawthorn extract as stand-alone therapy and others as an adjunct to standard treatment, mainly pharmaceutical diuretics. Some newer research also suggests that people with high-pressure-heart rate product increase and low maximal workload would be expected to benefit most.

The aqueous alcoholic extracts from the flowers and leaves of hawthorn that are most commonly used in trials are WS 1442 (Crataegutt forte, Schwabe Pharmaceuticals) which is standardised to 17.3–20.1% oligomeric procyanidins (4–6.6: 1 extracted in 45% ethanol) and LI 132 (70% methanol extract, MCM Klosterfrau Vertriebsgesellschaft).

A 2008 Cochrane systematic review of 14 randomised, placebo-controlled, double-blind clinical trials concluded that, in patients using hawthorn extract, symptoms such as shortness of breath and fatigue significantly improved, exercise tolerance significantly increased, the outcome measure of maximal workload significantly improved and the pressure-heart rate product (index for cardiac oxygen consumption) beneficially decreased. No data on relevant mortality and morbidity such as cardiac events were reported, except for one trial which reported deaths (three in active, one in control) without providing further details (Pittler et al 2008).

Since then, several new studies have been published which provide greater understanding of the benefits and limitations of treatment with hawthorn extracts. Eggeling et al (2011) conducted a combined analysis of 10 clinical trials ( $n = 687$ ) with hawthorn extract (900 mg/day WS 1442) or placebo using pooled data from patients with early CHF (NYHA class I–III). The groups taking hawthorn showed significantly improved maximal workload compared to placebo ( $P = 0.013$ ), with the benefits most significant in patients with the poorest baseline performance. Active treatment also significantly increased left ventricular ejection fraction (LVEF: +1.8) compared to placebo (+0.5) groups ( $P < 0.001$ ). Pressure-heart rate product increase was more effective in the hawthorn group (−9.03 mmHg/

min) compared to placebo (+3.73 mmHg/min) ( $P < 0.001$ ), with the treatment effect increasing with baseline severity. Overall, the majority of symptoms improved within the first 6 months, as measured with the von Zerssen scale, with significant improvements in physical symptoms of dyspnoea, weakness and fatigue, along with psychological symptoms such as worrying, irritability or restlessness. Researchers also confirmed the effects were similar for male and female patients (Eggeling et al 2011).

In contrast, Zick et al (2009) studied the effects of WS 1442 extract (450 mg twice daily) on 6-minute walking distance in a randomised, double-blind, placebo-controlled trial of 120 patients with NYHA class II or III CHF and an LVEF  $<40\%$ . In the HERB CHF study, patients continued standard treatment (ACE inhibitor or angiotensin receptor antagonist, a beta-blocker and a diuretic) while also taking active treatment or placebo over 6 months. At the end of the test period, hawthorn treatment did not increase 6-minute walking distance compared to placebo. There were also no significant changes to secondary outcomes such as peak exercise oxygen consumption or anaerobic threshold by maximal cardiopulmonary testing, quality of life measures (measured with the Minnesota Living with Heart Failure Questionnaire scale) and no significant linear trend in the change in NYHA (Zick et al 2009).

A closer look at these reports and previous research suggests that the typical dose range used for hawthorn extracts in patients with CHF (NYHA class I–II) is between 160 and 900 mg daily, whereas the dose range tested and shown to work for patients with CHF NYHA class III is 900–1800 mg daily (Tauchert 2002). Since the effects on exercise capacity and clinical signs and symptoms are dose-dependent and nearly half the patients in the study by Zick et al (2009) had more severe CHF (NYHA class III), it is possible that a higher dosage was required to achieve positive results; however this remains to be confirmed. It is also possible that, since the HERB CHF study participants were also using contemporary pharmaceutical treatment (ACE inhibitor or angiotensin receptor antagonist, a beta-blocker and a diuretic for NYHA class II + spironolactone for NYHA III), few further benefits were possible.

### Cardiac mortality and heart failure progression

Whether or not hawthorn, like phosphodiesterase inhibitors, has adverse effects on the prognosis of patients with chronic heart failure has been the subject of investigation recently.

Holubarsch et al (2008) conducted a large, international, multicentre, randomised, double-blind, placebo-controlled study involving 2681 patients with NYHA class II or III CHF and reduced LVEF ( $\leq 35\%$ ) despite being on standard treatment (Holubarsch et al 2008). Active treatment consisted of WS 1442 extract (900 mg daily) taken as add-on therapy, which did not alter the time to the first cardiac event but did significantly reduce cardiac mortality after 6 months ( $P = 0.009$ ) and at 18

months ( $P = 0.046$ ). For the subgroup of patients with LVEF  $\geq 25\%$ , sudden cardiac death was reduced by 39.7% ( $P = 0.025$ ) in comparison to the placebo group. Treatment was well tolerated with effects similar to placebo.

Zick et al (2008) found that patients with CHF (NYHA classes II–III) and reduced LVEF ( $<40\%$ ) taking WS 1442 (900 mg/day) over 6 months had no difference in the clinical progression of heart failure compared to placebo ( $P = 0.86$ ). Subgroup analysis of 68 participants with LVEF 35% found they were similar to the whole group, with no significant increase compared to placebo (Zick et al 2008). However, hawthorn treatment significantly increased the risk for progression of heart failure at baseline and in the more clinically compromised patients with LVEF  $\leq 35\%$  in this study. Communication with the authors identified that the test groups were not similar and further research is required to clarify these results.

### Comparative studies

One study compared hawthorn extract LI 132 (Crataegutt novo 300 mg three times daily) to the ACE inhibitor captopril (12.5 mg three times daily) in 132 patients and found that the LI 132 extract improved exercise tolerance and decreased heart failure-related symptoms (Tauchert et al 1994).

Similarly, a prospective cohort study involving 952 patients with NYHA stage II heart failure compared the use of the WS 1442 extract of hawthorn either alone or in conjunction with conventional therapy to conventional medication. After 2 years, the hawthorn cohort was found to have similar or more pronounced improvements than the conventional medication group with reduced fatigue, stress dyspnoea and palpitations, along with marked reduction in the use of drugs such as ACE inhibitors, cardiac glycosides, diuretics and beta-blockers (Habs 2004).

Commission E supports the use of hawthorn leaf and flower to treat decreased cardiac output (NYHA class II) (Blumenthal et al 2000).

### Arrhythmias, hypertension and atherosclerosis

In addition to treating congestive cardiac failure, hawthorn has traditionally been used to treat arrhythmias, hypertension and atherosclerosis (Petkov 1979). Blood pressure-lowering activity appears to take several weeks to establish and is not seen after acute dosing.

In one double-blind randomised controlled trial (RCT) of 92 subjects aged 40–60 years, a hydroalcoholic extract of Iranian hawthorn (*C. curvisepala* Lind) given three times daily was found to produce a significant decrease in both systolic and diastolic blood pressure after 3 months. Antihypertensive activity was also observed in one uncontrolled study that used hawthorn berry tincture (equivalent to 4.3 g/day of berry) (Mills & Bone 2000).

One study that focused primarily on mild hypertension compared the hypotensive effect of low-dose

hawthorn extract (500 mg) and magnesium supplements, individually and in combination, to placebo. Walker et al (2002) found hawthorn treatment significantly reduced resting diastolic blood pressure at week 10 compared with the other groups. In addition, a trend towards a reduction in anxiety was also observed with hawthorn treatment, which is an interesting observation, as sedative effects have been observed in animal models.

A 2006 randomised, placebo-controlled, clinical trial ( $n = 79$ ) focused for the first time on investigating possible hypotensive effects of hawthorn extract (1200 mg daily) in patients with type 2 diabetes while taking standard medication. Hypotensive drugs were used by 71% of the participants, with a mean intake of 4.4 hypoglycaemic and/or hypotensive drugs. The hawthorn group showed significantly greater reduction than the placebo group in mean diastolic blood pressure, but not in systolic blood pressure (Walker et al 2006).

Brachial artery flow-mediated dilation (FMD) and hypotensive activity were further investigated in an RCT crossover trial involving 21 volunteers with pre-hypertension or mildly elevated blood pressure (systolic 120–155 mmHg and diastolic 80–95 mmHg). Hawthorn extract (a 4:1 250 mg capsule standardised to 50 mg oligomeric procyanidins) was compared to placebo for effects on brachial artery FMD, an indirect measure of NO release and blood pressure. Each participant received four different dosage levels (placebo, hawthorn extract at 1000 mg, 1500 mg and 2500 mg) over 3½ days, with a 4-day washout period in between. The study found no evidence of a blood pressure-lowering effect or of a dose–response effect of hawthorn extract on FMD (Asher et al 2012). Limitations of this study include the extremely short treatment time.

Other studies have demonstrated hypotensive activity with treatment times between 10 and 16 weeks (Asgary et al 2004, Walker et al 2002, 2006) and the Commission E recommends a minimum treatment of 6 weeks.

#### IN COMBINATION FOR HYPOTENSION

Three double-blind RCTs have shown that a combination of natural D-camphor and an extract from fresh hawthorn berries was effective in treating orthostatic hypotension compared to placebo (Georg Belz & Loew 2003, Hempel et al 2005, Kroll et al 2005). Furthermore, when this combination of natural D-camphor and an extract from fresh hawthorn berries (marketed as Korodin) was given to hypotensive women in three randomised, double-blind, placebo-controlled, clinical trials, the treatment led to positive and differential effects on blood pressure and cognitive performance compared to placebo within 5 minutes (Schandry & Duschek 2008, Werner et al 2009).

#### Hyperlipidaemia

Hawthorn fruit extract has been reported to reduce serum lipid levels, as well as to reduce lipid deposits

in the liver and aortas of rats (Shanthi et al 1994) and rabbits (Zhang et al 2002) fed a hyperlipidaemic diet. In combination with other traditionally used Chinese herbs, hawthorn has been shown to also reduce serum lipid levels in both animals (He 1990, La Cour et al 1995, Xu et al 2009) and humans (Chen et al 1995, Guan & Zhao 1995).

In a 2011 double-blind RCT of type 2 diabetic outpatients with chronic coronary heart disease, treatment with *Crataegus laevigata* (flower and leaf preparation, 400 mg three times a day, standardised to 5% of procyanidins and 2% flavonoids) over 6 months produced a significant reduction in total cholesterol ( $P < 0.05$ ) and LDL ( $P = 0.03$ ) compared to baseline, but no change in HDL-cholesterol or triglyceride levels. When compared to placebo, there was a trend to lower total cholesterol ( $P = 0.11$ ) and LDL-cholesterol ( $P = 0.054$ ). In addition, a statistically significant decrease in neutrophil elastase was observed (Dalli et al 2011a). Patients were also taking conventional treatment (including aspirin, statins, ACE inhibitors, beta-blockers or nitrates). No significant changes were observed for blood cell count, glucose, urea, creatinine, electrolytes, lipid peroxidation, C-reactive protein or malondialdehyde after 6 months.

#### Adjustment disorder

The results of a double-blind trial of 182 people suggest that hawthorn in combination with other herbs such as passionflower and valerian may be beneficial for people with adjustment disorder with anxious mood (Bourin et al 1996). Another double-blind trial of 264 people found that a combination containing *Crataegus oxyacantha* and *Eschscholzia californica* along with magnesium was effective in treating mild to moderate anxiety disorder (Hanus et al 2004).

#### OTHER USES

As it has a high flavonoid content, hawthorn is also used to strengthen connective tissue, decrease capillary fragility and prevent collagen destruction of joints and therefore may be beneficial in the treatment of certain connective tissue disorders (Mills & Bone 2000).

#### DOSAGE RANGE

- Infusion of dried herb: 0.2–2 g three times daily.
- Tincture of leaf (1:5): 3.5–17.5 mL/day.
- Fluid extract (1:2): 3–6 mL/day.
- Dry extract: 900–1200 mg/day.

#### According to clinical trials

- LI 132 and WS 1442 are the most studied extracts.
- CHF (NYHA class I-II): 160–900 mg daily in divided doses.
  - CHF (NYHA class III): 900–1800 mg daily in divided doses.
  - Hyperlipidaemia: 1200 mg daily in divided doses.

## TOXICITY

No target toxicity to 100-fold the human dose of the WS 1442 extract is defined (Schlegelmilch & Heywood 1994). This is in contrast to inotropic drugs, such as digoxin, which generally have a low therapeutic index. A preclinical toxicological assessment for a combination product consisting of hawthorn, passionflower and valerian demonstrated no toxicity, genotoxicity or mutagenicity in rats, mice and dogs at high doses over 180 days (Tabach et al 2009). No clinical, chemical, haematological, morphological or histological abnormalities could be identified in either dogs or rats following 26 weeks of oral treatment at doses of 30 mg, 90 mg or 300 mg/kg/day. There was no evidence of genotoxicity of any kind, including mutagenicity or clastogenicity. Postmarketing surveillance as well as animal and clinical studies has shown no safety signals for carcinogenicity (Koch & Malek 2011).

## ADVERSE REACTIONS

A systematic review (24 clinical trials,  $n = 5577$  patients) concluded that hawthorn extracts (mostly WS 1442, LI 132) were well tolerated at doses between 160 and 1800 mg daily for a duration of 3–24 weeks. Overall, 166 adverse events were reported, most of which were mild to moderate. Eight severe adverse effects had been reported with the LI 132 extract. The most frequent adverse effects were dizziness/vertigo ( $n = 15$ ), gastrointestinal complaints ( $n = 24$ ), headache ( $n = 9$ ), migraine ( $n = 8$ ) and palpitation ( $n = 11$ ) (Daniele et al 2006). Similarly, a review of 14 clinical trials reported safe use of hawthorn with only infrequent, mild and transient adverse effects such as dizziness, cardiac and gastrointestinal complaints (Pittler et al 2008).

## INTERACTIONS

WS 1442 (900 mg daily) was safe to use in patients ( $n > 2500$ ) receiving optimal medication for heart failure (Holubarsch et al 2008). A systematic review (24 clinical trials) on the safety of hawthorn monopreparations found no reports of drug interactions (Daniele et al 2006).

### Cardiac glycosides

Hawthorn may theoretically potentiate the effects of cardiac glycosides, as both in vitro and in vivo studies indicate that it has positive inotropic activity. Furthermore, the flavonoid components of hawthorn may also affect P-glycoprotein function and cause interactions with drugs that are P-glycoprotein substrates, such as digoxin. In practice, however, a randomised crossover trial with eight healthy volunteers evaluating digoxin 0.25 mg alone for 10 days and digoxin 0.25 mg with *Crataegus* special extract WS 1442 (hawthorn leaves with flowers) 450 mg twice daily for 21 days found no significant difference to any measured pharmacokinetic parameters, suggesting that hawthorn and digoxin in these doses may be co-administered safely (Tankanow

et al 2003). Caution — use under professional supervision and monitor drug requirements.

### Antiplatelet medication

A small open, crossover design trial investigated the antithrombotic effects of *Crataegus laevigata* compared to aspirin in 16 healthy volunteers. Patients were treated with either *C. laevigata* — a daily dose of 2.4 g of Crataegor (equivalent to 50 mg of flavonoids and 134 mg of proanthocyanidins), which is comparable to the standard dose of hawthorn used in most clinical trials for CHF (900 mg WS 1442 extract, equivalent to 70 mg of flavonoids and 153 mg of proanthocyanidins) — or aspirin (100 mg/day) for 15 days, with a washout period of 14 days between treatments. In contrast to aspirin, *C. laevigata* did not inhibit the synthesis of thromboxane A<sub>2</sub> or inhibit platelet aggregation. Although *C. laevigata* does not display antiplatelet effects as a stand-alone treatment, this has not been tested in patients with atherothrombotic vascular disease in conjunction with antiplatelet drugs. Monitor (Dalli et al 2011b).

### Antihypertensive drugs

Theoretically, hawthorn may potentiate blood pressure-lowering effects, thereby requiring modified drug doses. However, hawthorn extract (1200 mg daily) was safe to use in patients with type 2 diabetes ( $n > 70$ ) while taking their prescription drugs (mean intake of 4.4 hypoglycaemic and/or hypotensive drugs) (Walker et al 2006). In general, observe patients taking this combination and monitor drug requirements — interaction would be beneficial under professional supervision.

### PREGNANCY USE

Hawthorn did not have an adverse effect on embryonic development in vitro and in vivo (Yao et al 2008). A combined extract of *Crataegus oxyacantha*, *Passiflora incarnata* and *Valeriana officinalis* in rats did not alter the oestrus cycle, did not affect fertility and did not induce teratogenesis in the offspring born from females treated during the entire pregnancy (Tabach et al 2009). Teratogenicity was not apparent in rats or rabbits following oral dosing with up to 1600 mg/kg WS 1442 (Koch & Malek 2011).

However, in vivo and in vitro evidence of uterine activity has been reported; therefore this herb should not be used in pregnancy until safety is established (Newell et al 1996).

### PATIENTS' FAQs

#### *What will this herb do for me?*

Hawthorn appears to be useful in treating a variety of heart conditions, such as high blood pressure, hyperlipidaemia and mild heart failure.

**Practice points/Patient counselling**

- Hawthorn extract is an effective treatment for mild CHF and improves signs and symptoms of disease.
- Hawthorn has positive inotropic action, increases coronary blood flow, reduces myocardial oxygen demand, protects against myocardial damage and improves heart rate variability, as well as having hypotensive and antiarrhythmic effects.
- Although considered relatively effective, heart disease can be a very serious medical condition with a rapidly changing course and should not be treated without close medical supervision. In particular, chest pain and shortness of breath are extremely serious symptoms that require immediate medical attention.
- It may take 2–6 weeks' treatment to notice a benefit of treatment with hawthorn. For modest hypotensive effects at least 10 weeks are needed. Heart rate and blood pressure should be monitored.
- Hawthorn also exhibits antioxidant, anti-inflammatory, antiviral and lipid-lowering activity.
- Great care should be exercised if hawthorn is to be combined with other drugs that affect the heart.

**When will it start to work?**

Studies suggest it will start to have effects in 2–6 weeks. For modest hypotensive effects at least 10 weeks of treatment are needed.

**Are there any safety issues?**

Heart conditions are potentially serious, therefore professional supervision is required.

## Honey

**HISTORICAL NOTE** Honey has been used since ancient times as a healing agent for wounds and a treatment for gastric complaints. In ancient Greece, Hippocrates recommended honey and vinegar for pain and honey combinations for fever. Honey was included in about 500 remedies in ancient Egypt according to papyrus scrolls, from curing wounds to embalming the dead, and in ceremonies to promote fertility. Jars of honey have been found in ancient Egyptian temples, still edible after 3000 years. Early Ayurvedic, Chinese and Roman traditions also used honey in wound care and it is recommended in the Bible and the Koran as a medicinal agent (Lee et al 2011). Over the past few decades, scientific research has confirmed its role as a successful wound treatment.

### CHEMICAL COMPONENTS

The composition of a particular honey greatly depends on the composition of the nectar it originated from, and therefore the plant species involved in its production.

Honey comprises a complex mix of glucose, fructose, sucrose, other carbohydrates, minerals, proteins, as well as other phytochemicals. It has a low pH and a significant osmolarity due to its low water content (Voidarou et al 2011).

The medicinal properties of honey have been attributed to various bioactive compounds including glucose oxidase, which generates hydrogen peroxide, flavonoid and phenolic compounds, methylglyoxal as well as methoxylated derivatives, with other active constituents still to be characterised (Fearnley et al 2011). The term ‘unique manuka factor’ (UMF) is used to describe the specific bioactive principles of manuka honey, derived from the tree genus *Leptospermum*, and is used as an indicator of relative potency of the specific honey (Fearnley et al 2011). A correlation between high concentrations of methylglyoxal and the notable antibacterial activity specific to manuka honey suggests that this may be a core active principle (Brudzynski et al 2011).

### MAIN ACTIONS

#### Antibacterial

The type of plant species involved in honey production is significant, as some confer greater antibacterial properties than others. Currently, evidence suggests that honey produced from the tea trees *Leptospermum scoparium* (New Zealand manuka) and *Leptospermum polygalifolium* (Australian jelly bush),

which are native to Australia and New Zealand, are the most clinically effective. However there is evidence to suggest that other honeys may also possess some antibacterial activity (Lusby et al 2005). Honey derived from the Malaysian tree *Koompassia excelsa* (Tualang tree), has shown particularly promising antibacterial activity (Tan et al 2009).

Research has demonstrated that honey has activity against a number of organisms, including *Escherichia coli*, *Pseudomonas aeruginosa*, *Staphylococcus aureus* (including methicillin-resistant strains), *Acinetobacter*, *Stenotrophomonas* and vancomycin-resistant *Enterococcus* (Lee et al 2011).

Several mechanisms of action account for the antibacterial effect of honey.

#### Hydrogen peroxide content

Honey contains a bee-derived enzyme, glucose oxidase, which, under certain conditions, can convert the glucose in honey to hydrogen peroxide. Researchers originally attributed much of the antibacterial activity of honey to this production of hydrogen peroxide. Factors such as dilution, the presence of a sodium from skin and body fluids and the pH of the body promote generation of hydrogen peroxide when honey is used in wound dressing. Clinically, however, it has been shown that the hydrogen peroxide is subsequently broken down by catalase, an enzyme present in wound fluids and in wound tissue cells, diminishing the amount available to support an antibacterial benefit. This suggests that although hydrogen peroxide may contribute towards the mechanism of action of honey, the main antibacterial activity may be due primarily to a non-peroxide-mediated mechanism (Brudzynski & Kim 2011, Packer et al 2012).

### High osmolarity

Honey has a high sugar and low water content, with sugar concentration reaching up to 80% in some seasons. Its high sugar concentration is considered important because the honey draws fluid from the wound by osmosis, reducing the availability of water for bacteria. This results in inhibition of bacterial growth, while simultaneously creating a moist environment that promotes wound healing (Lusby et al 2002).

### Low pH

Honey is an acidic substance (range 3.2–4.5) and therefore unfavourable to the growth of certain bacteria. *In vitro* testing shows that *Leptospermum* honey can inhibit the growth of several important bacterial pathogens, including *Escherichia coli*, *Salmonella typhimurium*, *Shigella sonnei*, *Listeria monocytogenes*, *Staphylococcus aureus*, *Bacillus cereus* and *Streptococcus mutans* (Steinberg et al 1996, Taormina et al 2001).

In a recent open-label, non-randomised prospective study, applying a manuka honey dressing to non-healing wounds was associated with a statistically significant decrease in wound pH and size. A reduction in pH of 0.1 was associated with an 8.1% reduction in wound size (Gethin et al 2008).

The antibacterial action of honey may be enhanced when combined with a synergistic compound. The antibacterial and antifungal activities of honey were increased by the addition of starch to the medium (Boukraa & Bouchegrane 2007, Boukraa & Amara 2008). When Royal Jelly was combined with four different samples of honey, the minimum inhibitory concentration (MIC) against *Staphylococcus aureus* was lowered by 50% (Boukraa et al 2008).

Honey has also been tested for efficacy against a range of drug-resistant bacteria, with positive results (Cooper et al 2002). Eighteen strains of methicillin-resistant *Staphylococcus aureus* and 27 strains of vancomycin-sensitive and -resistant enterococci, isolated from infected wounds and hospital surfaces, were sensitive to concentrations below 10% w/v of manuka honey and pasture honey. Artificial honey was also effective, but concentrations three times greater were required to produce similar results. In a study using a 10%–40% v/v medical-grade honey (Revamil®) applied to the skin of healthy volunteers colonised with antibiotic-susceptible and -resistant isolates of *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Enterococcus faecium*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Enterobacter cloacae* and *Klebsiella oxytoca*, bacterial levels were reduced 100-fold by day 2, and the number of positive skin cultures was reduced by 76% (Kwakman et al 2008).

Honey is effective (*in vitro*) against community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA), which typically infects skin and soft tissues in healthy individuals. Culture counts of  $10^6$  colony-forming units were reduced to a non-detectable amount in 24 hours in the four honey

samples tested, while levels in the control group (no honey) remained unchanged (Maeda et al 2008).

### Phenolic compounds

The antioxidant activity of honey has been associated with the levels of phenolic compounds found in a range of floral honeys, with antioxidant activity varying between 43.0% and 95.7%. The responsible compounds suggested include p-coumaric acid, kaempferol, chrysin and apigenin (Baltrusaityte et al 2007).

The variation in the concentration of the phenolic compounds among different floral honeys is further confirmed through another study, which found that the concentration of millefiori honey is the highest in polyphenols, flavonoids and has a corresponding high antioxidant activity, when compared with *Acacia* honey (Blasa et al 2006). Manuka honey has been shown to contain significant levels of phenolic compounds and methoxylated derivatives such as methoxyphenyllactic acid, 2-methoxybenzoic acid and trimethoxybenzoic acid. It has been proposed that these phenolic compounds participate in scavenging of free radicals and in promoting wound healing.

### Methylglyoxal

Recently, methylglyoxal, a bioactive compound found in high concentrations in manuka honey, has been identified as a significant contributing factor to the distinct antibacterial activity of manuka honey compared to other honeys. This compound confers a sustained non-peroxide antibacterial action to manuka honey, which is an advantage over the peroxide-derived action seen in other honeys, as it is not susceptible to catalase destruction from body fluids (Brudzynski & Kim 2011, Packer et al 2012).

### Immunomodulation

An animal study has shown that both immunocompetent and immunodeficient mice had increased humoral immunity following administration with honey (Karmakar et al 2004). Tonks et al (2007) reported that manuka honey upregulates inflammatory cytokines: tumor necrosis factor- $\alpha$ , interleukin-1 $\beta$ , interleukin-6 and prostaglandin E<sub>2</sub> production, from monocytes, according to an *in vitro* study. The authors proposed that this immunomodulatory activity was mediated by a unique 5.8-kDa component found in manuka honey, via toll-like receptor 4 (TLR4) (Tonks et al 2007). Honey has been shown to reduce both acute and chronic inflammation, although the exact mechanism is not yet fully understood (Pieper 2009).

### Antifungal

Honey has an antifungal action against three species of *Candida* in vitro (Irish et al 2006). Isolates of *C. albicans*, *C. glabrata* and *C. dubliniensis* were tested against four samples of honey: Jarrah honey with hydrogen peroxide activity, Medihoney Antibacterial Honey Barrier; a proprietary blend of

*Leptospermum* and hydrogen peroxide honeys, Comvita Wound Care; a pure *Leptospermum* honey; and an artificial honey. The natural honeys had a significantly greater antifungal effect compared to the artificial honey against *C. albicans* and *C. glabrata*, but only the Jarrah honey was effective against *C. dubliniensis*.

### Deodorises wounds

Bacteria use the glucose found in honey in preference to amino acids, thereby producing lactic acid instead of malodorous products (Molan 2001).

### Debriding

The topical application of honey to a wound may aid in wound debridement. Due to the osmolarity of honey, lymph fluid is pulled from wound tissue, debris is removed and slough and necrotic tissue is lifted off more easily. Hydrogen peroxide production may also contribute to honey's debridement properties (Pieper 2009). Honey does not adhere to the wound surface, allowing for easier and less painful wound dressing changes (Subrahmanyam 1998).

### Enhances wound healing

Clinical evidence suggests that the application of honey hastens granulation and epithelialisation of necrotic tissue by various mechanisms. It appears to stimulate the growth of new blood capillaries and cytokine production, thereby stimulating tissue regeneration. The high viscosity of honey and its hygroscopic character allow it to form a physical barrier, creating a moist environment and a reduction in local oedema (Aysan et al 2002). Clinically, it appears that epithelialisation is accelerated between days 6 and 9 (Subrahmanyam 1998), and that honey is more beneficial than Edinburgh University solution of lime (EUSOL) as a wound-dressing agent (Okeniyi et al 2005). The upregulation of matrix metalloproteinase-9 and transforming growth factor- $\beta$  in epidermal keratinocytes may also contribute to honey's wound-healing properties (Lee et al 2011).

### Antioxidant

The phenolic compounds found in honey, namely the flavonoids, render it a good source of antioxidants (Al-Mamary et al 2002, Schramm et al 2003). The antioxidants in honey neutralise free radicals that arise through inflammatory processes (Molan 2001). In vitro tests have confirmed a significant link between absorbance and antioxidant power, with darker, more opaque honeys having stronger antioxidant power than lighter, clearer honeys (Taormina et al 2001). More specifically, manuka honey has been identified to be a specific scavenger of superoxide anions (Inoue et al 2005). A study examining different samples of honey for their ability to reduce reactive oxygen species (ROS) in vitro found significant variation in activity, with buckwheat honey most effective. This is possibly

due to its high concentration of phenolic compounds, which have known antioxidant activity. Considering the fact that hydroxyl radicals and hypochlorite anions formed in the wound site impair wound healing, this honey should have superior wound-healing properties (van den Berg et al 2008). Regular daily consumption of honey (1.2 g/kg body weight) has been shown to increase serum levels of Vitamin C, beta-carotene, uric acid and glutathione reductase, according to the findings of a clinical study in 10 healthy individuals (Noori & Al-Waili 2004).

### Bone metabolism

A study performed in ovariectomised rats showed that daily oral consumption of Tualang honey for two weeks promoted an increase in bone density, which was attributed to antioxidant effects and inhibition of proinflammatory cytokines (Zaid et al 2010). A subsequent study in experimental postmenopausal rats showed that daily oral administration of Tualang honey (0.2 mg/kg body weight) for 6 weeks resulted in a greater improvement in trabecular bone structure than calcium supplementation (1% in drinking water) (Zaid 2012). Based on these findings, it has been suggested that oral consumption of honey may confer protective effects against postmenopausal bone loss in women through antioxidant and anti-inflammatory action on osteoclast activity (Mohd Effendy et al 2012). There is, however, currently insufficient clinical evidence to recommend honey for this indication.

### OTHER ACTIONS

An *in vitro* study showed that honey prevented binding of *Salmonella enteritidis* to intestinal epithelial cells (Alnaqdy et al 2005) at dilutions of up to 1:8.

Preliminary studies suggest that honey may have an impact on reducing the intoxicating effects of alcohol. Further, high quality research with more rigorous methodology is required to validate this effect (Onyesom 2004, 2005).

Honey may also have an antimutagenic activity against a common food carcinogen and mutagen, Trp-p-1 (Wang et al 2002).

### CLINICAL USE

Honey is mainly used topically for wound healing, burns or dermatological conditions; however, it is now being used in mouthwashes, oral syrups and ocular preparations.

### Wound healing

A recent Cochrane systematic review and meta-analysis of 25 trials was conducted to determine whether honey dressing increases the rate of healing in either acute wounds, such as lacerations and burns, or chronic wounds including skin ulcers and infected surgical wounds (Jull et al 2013). In summary, the review concluded that honey does not significantly increase healing in chronic leg ulcers and may delay healing of deep burns and

ulcers caused by insect bites (cutaneous Leishmaniasis). It noted that there is currently insufficient evidence in other types of wounds to make clear recommendations (Jull et al 2013).

With respect to chronic venous leg ulcers, the Cochrane review (2013) reported that honey dressing does not significantly accelerate wound healing when used as an adjuvant to compression stockings, based on the evidence from two studies (Jull et al 2008, Gethin & Cowman 2008). The reviewers called for further research, given that a benefit may be possible, especially in population subgroups such as those with infected ulcers (Jull et al 2013).

Jull et al (2008) conducted an open-labelled, randomised controlled trial involving 368 patients with venous ulcers. This study found that honey dressings did not significantly decrease the time needed to heal compared to those treated with usual care (a range of dressings). After 12 weeks, 55.6% of ulcers healed in the honey-treated group and 49.7% in the usual care group. There were no significant differences found in the other parameters, including mean time to healing (63.5 days and 65.3 days in the honey and usual care groups, respectively), reduction in ulcer size, incidence of infections or quality of life between the groups (Jull et al 2008). There were also more adverse events reported in the honey-treated group, with 25% of participants reporting one or more episodes of discomfort.

The multi-centred open label randomised controlled study conducted by Gethin and Cowman (2009) recruited 108 participants with > 50% slough coverage on leg ulcers. Treatment consisted of either honey dressing plus compression, or hydrogel dressing plus compression for a period of 4 weeks, with a follow-up assessment at 12 weeks. After 4 weeks, there was a 67% mean reduction in slough area for the honey treated group compared to 52.9% in the hydrogel group ( $P = 0.05$ ) and the median reduction in wound size was 34% compared to 13% respectively ( $P = 0.001$ ). After 12 weeks, 44% of the ulcers had healed in the honey group versus 33% in the hydrogel group ( $P = 0.04$ ). The authors concluded that manuka honey dressing resulted in a higher incidence of healing, with a lower incidence of infection (Gethin & Cowman 2009).

The Cochrane review (2013) also investigated the potential benefit of honey in abrasions, acute lacerations or minor surgical wounds. Three trials, with a combined total of 213 participants, were evaluated. The reviewers concluded that for these types of minor acute wounds, there is currently insufficient evidence to recommend honey dressing in preference to conventional therapy. It was suggested that further study was justified as a modest benefit in favour of honey dressing was considered possible (Jull et al 2013).

Data from some of the studies conducted with honey in wound management are presented below.

A case series of eight consecutive cases examined the efficacy of honey on non-healing lower limb ulcers. After 4 weeks of using a manuka honey

dressing, ulcers decreased in size by a mean of 55% and were no longer malodorous. Patients whose ulcers had an arterial component reported the least benefit and also a stinging sensation following application (Gethin & Cowman 2005). One randomised study involving 40 patients with open or infected wounds compared honey to sugar dressings (Mphande et al 2007). In the honey group, 55% of patients had positive wound cultures at the start of treatment and 23% at one week, compared with 52% and 39% respectively in the sugar group. Additionally, the median rate of healing in the first 2 weeks of treatment was 3.8 cm<sup>2</sup>/week for the honey group and 2.2 cm<sup>2</sup>/week for the sugar group and after 3 weeks of treatment 86% of patients treated with honey had no pain during dressing changes, compared with 72% treated with sugar.

Emsen (2007) used medical honey for the fixation of the split-thickness skin grafts in 11 patients. Oedema and the amount of wound exudate were reduced, and no complications such as graft loss or infection were reported, either on the fifth day of grafting or at the end of the follow-up period (average 17 months).

Several studies have compared honey dressings to currently used treatments, finding it is as effective but not necessarily more effective.

A non-randomised, prospective, open study compared the effects of honey-impregnated gauze, paraffin gauze, hydrocolloid dressings and saline-soaked gauzes in 88 patients who underwent skin grafting (Misirlioglu et al 2003). Honey gauzes produced a faster epithelialisation and reduced the sensation of pain compared with paraffin and saline-soaked gauzes. This effect was the same as that observed for hydrocolloid dressings.

A RCT of 101 haemodialysis patients compared thrice-weekly application of Medihoney with mupirocin for the healing of catheter exit sites. This study found the honey to be safe, effective and more affordable than mupirocin for this group (Johnson et al 2005).

## Burns

A recent Cochrane review (2013) concluded that honey dressing may reduce healing times in partial-thickness burns by an average of 4.68 days when compared to some conventional dressings such as polyurethane film dressing, impregnated gauze or saline soaks; however, the trials evaluated did not provide sufficient detail for findings to be considered conclusive (Jull et al 2013).

In the same review, efficacy of topical honey compared with that of silver sulfadiazine (SDD) was compared in six clinical trials. Although overall, evidence appears to be in favour of honey dressings, heterogeneity in trial design, burn assessment criteria, outcomes and follow-up periods make interpretation of the data challenging. It is still unclear whether honey either promotes healing, or is able to reduce healing times compared to SDD (Jull et al 2013).

The Cochrane review by Jull et al (2013) reports that current evidence indicates that for deeper or more extensive burns, surgical excision and skin grafting are a more suitable treatment approach than honey dressing. The recommendation is based on the findings of a small study (Subrahmanyam 1999) of 50 participants, where early excision and grafting resulted in significantly shorter hospital stays (weighted mean difference [WMD] 13.6 days, 95% CI 10.02 to 17.18 days) compared to use of honey wound dressings. In addition, 11 patients of the 25 assigned to treatment with honey dressing eventually required skin grafting. Three of the patients treated with honey dressing died of septicæmia, whereas none of the 25 patients in the excision group developed sepsis. At 3 months follow-up, 92% of the excision group had good to excellent functional and cosmetic results, compared to only 55% in the group treated with honey dressing (Subrahmanyam 1999).

Further research is required to determine the safety and efficacy of honey dressings in the management of burns, but current evidence suggests a possible role in minor burns, but that alternative treatments such as surgical excision and grafting are superior for deep or more extensive burns, unless the patient is unsuitable for surgery.

### Coughs in children

A Cochrane review (2012) concluded that honey may be better than 'no treatment' and diphenhydramine in relieving cough symptoms in children, but not better than dextromethorphan (Oduwole et al 2012).

In a randomised, partially double-blinded clinical trial involving 105 children, a single dose of buckwheat honey, given 30 minutes before bed, significantly reduced cough severity (47.3% versus 24.7%) and overall symptom score reduction (53.7% versus 33.4%) compared to no treatment (Warren & Cooper 2008). Similarly, Paul et al (2007) found that a single nighttime dose of buckwheat honey given to children with an upper respiratory tract infection resulted in greatest symptom improvement in nocturnal cough and sleeping difficulties compared to honey-flavoured dextromethorphan treatment or no treatment. A randomised controlled study involving 160 children demonstrated that a dose of 2.5 mL honey at bedtime was more effective than either dextromethorphan or diphenhydramine in alleviating night cough symptoms and sleep quality in children with upper respiratory infections (Shadkam et al 2010).

## OTHER USES

### Fournier's gangrene

The effects of topical honey has been investigated for the treatment of Fournier's gangrene (FG), a fulminating infection of the scrotum, perineum and abdominal wall in men. A study conducted in 30 male participants compared honey-soaked dressing

to antiseptic EUSOL-soaked dressing (Subrahmanyam & Ugane 2004). Mean time to healing was reduced by 8 days in the honey-treated group (95% CI) compared to the EUSOL-treated group. Nine participants from each group required skin grafting and 1 patient from the honey-dressing group died, compared to 2 patients from the EUSOL dressing group. The authors concluded that honey dressings were beneficial in the treatment of Fournier's gangrene (Subrahmanyam & Ugane 2004). Validity of these findings have been questioned, however, since the comparator treatment, EUSOL dressings, has been shown to impair wound healing (Jull et al 2013). Further research is required to confirm a benefit before clear recommendations can be made.

### Periodontal disease

In vitro tests show that honey can inhibit the growth of oral bacteria (Steinberg et al 1996). As a follow-up investigation, 10 volunteers were asked to swish 5 mL of honey around their mouths for 4 minutes and then swallow. At 10 minutes after honey use, oral bacterial counts were significantly decreased. A pilot study has also shown that manuka honey has potential in the treatment of gingivitis and periodontal disease (English et al 2004). Thirty subjects were given either a chewable 'honey leather' or a sugarless chewing gum to chew for 10 minutes after each meal for 3 weeks. The honey group had a statistically significant reduction in mean dental plaque scores and gingivitis (assessed by percentage of bleeding sites), with no significant changes in the control group (English et al 2004). Manuka honey has been shown to inhibit growth and adherence of *Streptococcus mutans*, an oral pathogen commonly associated with the formation of dental plaque (Badet et al 2011).

### Eczema

Topically-applied honey is sometimes used to enhance skin healing and prevent infection in eczema. Although controlled trials are not available, the clinical evidence generally supporting efficacy in wound healing provides a theoretical basis for its use in this condition.

### Anal fissures and haemorrhoids

A prospective pilot study examined the use of a topical preparation containing a mixture of honey, olive oil and beeswax in a ratio of 1:1:1 (v/v/v) on anal fissure or haemorrhoids. Treatment for up to 4 weeks significantly reduced the bleeding and itching in patients with haemorrhoids and pain, bleeding and itching in patients with anal fissures (Al-Waili et al 2006).

### Colon cancer

Preliminary animal studies on experimentally-induced colon cancer show the potential for reduced disease development (Duleva & Bajkova 2005), but further study is necessary to validate this for clinical use.

### Regulation of GI microflora

Honey may be of potential benefit in regulating gastrointestinal microflora. One in vitro study showed that honey promoted growth and activity of beneficial intestinal *bifidobacterium* spp (*B. longum*, *B. adolescentis*, *B. breve*, *B. bifidum* and *B. infantis*), while inhibiting the growth of the pathogenic bacteria *Clostridium perfringens* and *Eubacterium aerofaciens* (Shin & Ustunol 2005). Further in vitro, in vivo and human studies are needed to confirm this benefit.

### Pain following tonsillectomy

In a prospective, randomised, placebo-controlled preliminary study involving 60 patients, 5 mL honey combined with paracetamol and antibiotics was found to be more effective in reducing postoperative pain following tonsillectomy than treatment with paracetamol and antibiotics only. The honey combination treatment group also demonstrated increased tonsillary fossa epithelialisation (Ozlugedik et al 2006).

### Tear deficiency and meibomian gland disease

Topical application of honey (three times daily) was found to significantly reduce the total ocular bacterial colony-forming units (CFUs) of dry eye subjects caused by tear deficiency and/or meibomian gland disease. After 3 months, antibacterial effect was such that there was no significant difference in the CFUs of the patient groups and the non-dry eye (control) group (Albietz & Lenton 2006).

### Radiation-induced oral mucositis

Several studies have examined the prophylactic effect of honey against oral mucositis in patients undergoing radiation therapy for the treatment for head and neck cancer. A meta-analysis of three trials (Biswal et al 2003, Khanal et al 2010, Rashad et al 2009) comprising a total of 120 patients reported that rinsing with honey before and after radiation therapy had an 80% protective effect against radiation-induced mucositis compared to the control group. These results, while favourable, should be interpreted cautiously due to a high risk of bias (Song 2012).

In another single-blind, randomised clinical trial of 40 patients, the honey treatment group swished 20 mL of honey around in their mouth and swallowed gradually 15 minutes before radiation therapy, and again 15 minutes and 6 hours after, while the control group rinsed with 20 mL of saline before and after radiation. The level of mucositis measured by the Oral Mucositis Assessing Scale (OMAS) was significantly lower in the honey-treated group compared to the control group (Motallebnejad et al 2008). More recently, a double-blind randomised study investigating the effect of manuka honey on radiation-induced mucositis in 131 patients with head and neck cancer reported no significant difference between the severity or duration of mucositis in the patients treated with manuka honey and the

control group. The authors reported that poor compliance may have affected outcomes (Bardy et al 2012).

### Radiotherapy and chemotherapy side effects

In a prospective, controlled, randomised study, 21 adult females who had radiotherapy to the breast or thoracic wall resulting in grade 3 skin toxicities greater than 15 mm in diameter were treated daily with either a honey or a paraffin gauze dressing. The honey-treated group reported less pain, itching or irritation as measured through daily visual analogue scale (VAS) (Moolenaar et al 2006).

Honey may help to reduce the extent of neutropenia experienced as a side effect of chemotherapy and thereby reduce the amount of colony-stimulating factors (CSFs) required. Thirty cancer patients who had undergone chemotherapy and developed grade 4 neutropenia requiring treatment with CSFs repeated this schedule of chemotherapy combined with 5 days of treatment with Life-Mel honey. The addition of the honey treatment resulted in improvement in all cell lines with fewer cases of neutropenia (40% of patients did not require treatment with CSFs), 64% of patients retaining haemoglobin levels above 11 g/dL and only 10% of patients developing thrombocytopenia. No side effects were reported with honey treatment (Zidan et al 2006).

### DOSAGE RANGE

Topical use: Honey is usually applied topically (see 'Tips on how best to use honey in practice' below).

Oral use according to clinical studies:

- Coughs in children: 2.5–5 mL as a single dose up to 30 minutes before sleep.
- Mucositis: 20 mL, of honey as a rinse applied to oral mucosa then swallowed 15 minutes before radiation treatment, again 15 minutes after radiation treatment, then 6 hours later or at bedtime for up to 7 weeks.

### TOXICITY

Not generally applicable when honey is used externally.

A rare type of food poisoning has been reported with oral ingestion of honey made from nectar of plants in the *Rhodenendron* genus, due to the presence of sodium channel blockers known as grayanotoxins. Described as 'mad honey', the dose-dependent toxic effects include mild symptoms such as hypersalivation, vomiting, dizziness and weakness, while severe intoxication can lead to potentially serious cardiac complications. No fatal cases have been reported (Koca & Koca 2007). Toxic hepatic pyrrolizidine alkaloids have also been identified in honey produced from nectar of flowers in the *Rhododendron* genus. These alkaloids are considered to be a health risk to humans as they are potentially mutagenic, teratogenic and carcinogenic. Pregnant women and young infants are considered most at risk (Edgar et al 2002).

**? CONTRAINDICATIONS AND PRECAUTIONS****Diabetics**

Honey contains a large concentration of glucose. If applied to large open wounds, it may theoretically elevate blood sugar levels — monitor blood sugar levels. Caution is advised with oral ingestion of honey as it may alter plasma glucose levels. Use is potentially beneficial (Erejuwa et al 2012).

**Children**

Honey, honey flavouring and honey-containing supplements are not recommended for use in children under 12 months of age. Consumption of honey contaminated with spores from *Clostridium botulinum* may lead to infant botulism, which is potentially fatal if left untreated (Tanzi & Gabay 2002). However, older children and adults are not considered at risk.

**PREGNANCY USE**

Safety has not been scientifically established, but historical use suggests that it is generally safe. There are concerns over grayanotoxins found in some types of honey such as that produced from the flowering plants of the genus *Rhododendron* (Edgar et al 2002).

**! PATIENTS' FAQs****What will honey do for me?**

If you apply a honey preparation that has tested positive for antibacterial activity, it may enhance wound healing, reduce pain and inflammation, and reduce the risk of wound infection.

**Which honey should I use?**

Honey produced from manuka trees has tested positive for antibacterial activity and is the most effective. Medicinal honey preparations are sterilised by gamma irradiation to destroy any contaminants, without loss of the antibacterial properties of the honey. Medicinal honey preparations are available as gels, pastes and impregnated wound dressings.

**Will honey bought from the supermarket be effective if I applied it to a wound?**

Not all honeys have the properties needed to heal wounds. In addition, commercial processed honeys undergo heat treatment before being sold as food in supermarkets, which destroys much of its potential antibacterial activity.

**When will it start to work?**

Studies have found that by the seventh day of use, most wounds show considerable improvement and healing.

**Are there any safety issues?**

Use of sterile laboratory-tested honey preparations is recommended.

Honey dressings are not recommended for use on deep burns where more aggressive strategies may be required to prevent complications, or on ulcers caused by insect bites.

**Practice points/Patient counselling**

- Topical application of honey has been used to enhance wound healing treatment of burns and infection control.
- Honey has a deodorising and debriding effect on wounds, accelerates epithelialisation and reduces inflammation and pain.
- Effects are generally seen within 7 days of use.
- Not all honeys have significant antibacterial properties; however, research has identified the New Zealand *Leptospermum* (manuka honey) and Australian jelly bush honey as having potent activity.
- The honey to be used as a topical wound-healing agent or dermatological treatment should ideally be sterile and tested for clinical activity.

**Tips on how best to use honey in practice\***

- Honey may be applied using manufactured sterile gauze dressings preimpregnated with honey (20–25 g of manuka honey on a 10 × 10 cm dressing).

For minor burns, these have been left in place for up to 25 days, but the wound should be inspected every 2 days. Use of honey dressings in deep burns is not recommended as current evidence suggests that treatment by surgical excision and skin grafting results in better outcomes.

Honey-medicated dressings have been used for longer periods of time (> 25 days) in wound management and skin ulcers.

The appropriateness of routine use of honey dressing in acute or chronic wounds is unclear based on insufficient evidence of a clear clinical benefit.

Where honey is applied directly:

- Ensure that there is an even coverage of the wound surface.
- Larger cavities may be filled by pouring in slightly warmed honey.
- Spreading honey on a dressing pad or gauze rather than on the wound directly will be more comfortable for the patient.
- The amount of honey needed depends on the amount of fluid leaking from the wound — if honey becomes diluted, it will be less effective; typically, 20 mL of honey is used on a 10 × 10 cm dressing.
- Cover with absorbent secondary dressings to prevent honey oozing out from the dressing. Change the dressings more frequently if the honey is being diluted — otherwise change every day or two.

## ADVERSE REACTIONS

A mild transient stinging may occur when applied to open wounds. If this is too uncomfortable, honey can be washed away with warm water.

Allergic reactions have also been reported, but these are considered rare.

## SIGNIFICANT INTERACTIONS

None known, but theoretically honey dressings used in combination with antibiotics may have an additive effect.

Oral intake may induce CYP3A4 enzyme activity, according to a small clinical study (Tushar et al 2007).

## Hops

**HISTORICAL NOTE** The cultivation of hops started from the middle of the ninth century, between AD 859 and 875, in Germany where it extended from north to south during the early and high Medieval period, as well as to other regions of central Europe. It was originally used as a beer additive and preservative in the European area and today, the beer-brewing industry accounts for 98% of the world's use of hops. Previously, the flower heads were also used to produce a fine brown dye and as a food flavouring agent in cereals, spices and sauces, whereas the fibrous stems were used in the manufacture of crude cloth and paper (Zanoli & Zavatti 2008). Although hops are most famous for producing the bitter flavour in beer, this plant has been used since ancient times in many different cultures (China, India and North America) as a sedative for insomnia, restlessness and nervousness, and also for digestive symptoms such as dyspepsia and lack of appetite. It is related botanically, though not pharmacologically, to cannabis. The climbing nature of the herb influenced its common name, as this is derived from the Anglo-Saxon *hoppan*, which means 'to climb'.

### COMMON NAME

Hops

### OTHER NAMES

Common hops, European hops, hop strobile, hopfen, houblon, humulus, lupulus, lupulin

### BOTANICAL NAME/FAMILY

*Humulus lupulus* (family: Cannabaceae)

### PLANT PART USED

Dried strobiles

### CHEMICAL COMPONENTS

Resinous bitter principles (mostly alpha-bitter and beta-bitter acids comprising 5–20% of hop strobile weight) and their oxidative degradation products, polyphenolic condensed tannins, volatile oil, polysaccharides, mainly monoterpenes and sesquiterpenes, flavonoids (xanthohumol, isoxanthohumol, kaempferol, quercetin and rutin), phenolic acids and

amino acids (Blumenthal et al 2000) and catechins (catechin gallate, epicatechin gallate). The main alpha acids are humulone (35–70% of total alpha-acids), cohumulone (20–65%) and adhumulone (10–15%); the corresponding beta-acids are lupulone (30–55% of total beta-acids), colupulone and adlupulone (Zanoli & Zavatti 2008). The volatile oil and bitter acids are the most significant components of hops, the latter providing its valuable quality in the brewing of beer. The prenylated flavonoids, particularly xanthohumol, have oestrogenic activity.

### MAIN ACTIONS

Traditionally, hops are viewed as a bitter tonic with antispasmodic, relaxant and sedative actions.

Investigation into the mechanisms of action have focused on hops but also on several isolated constituents such as xanthohumol and 8-prenylnaringenin (Zanoli & Zavatti 2008).

### Sedative and antidepressant

A long history of use within well-established systems of traditional medicine, together with scientific testing, have suggested that hops has significant sedative activity (Blumenthal et al 2000), probably through activation of melatonin receptors. Both the extract of hops and a fraction containing alpha-bitter acids demonstrates significant sedative properties in mice and antidepressant activity (Zanoli et al 2005). The hops beta-acids also exert antidepressant effects in vivo but have less sedative activity. A reduction in GABAergic activity was reported for the beta-acids in vivo (Zanoli et al 2007).

Research with a fixed herbal combination containing hops and valerian, known as Ze91019, demonstrated binding affinities at the melatonin ML<sub>1</sub> and serotonin 5-HT<sub>6</sub> receptor subtypes (Abourashed et al 2004).

### Oestrogenic effects

In 1953, two German scientists followed up on a folk legend that women regularly began to menstruate 2 days after beginning to pick hops. Since then, there has been much research on the oestrogenic effects of hops. Hops showed significant competitive binding to alpha- and beta-oestrogen receptors and upregulation of progesterone receptors in vitro (Liu et al 2001). The oestrogenic activity is chiefly due to the constituent 8-prenylnaringenin (Milligan et al 1999, 2000), which is converted by intestinal microflora from isoxanthohumol (Possemiers et al 2005), and mimics the action of 17β-oestradiol, albeit with a 17-fold lesser potency in alpha-receptor sites (in the breast, liver, central nervous system and uterus), and a 20,000-fold lesser potency in the beta-receptor sites (mainly in the intestine, prostate, ovaries, testes and urogenital tract). The high oestrogenic activity of 8-prenylnaringenin has also been confirmed in different in vivo experiments and is considered one of the strongest phyto-oestrogens found in the plant kingdom (Zanoli & Zavatti 2008).

A small, double-blind randomised controlled trial (RCT) using standardised doses of 8-prenylnaringenin demonstrated systemic endocrine effects, including a decrease in luteinising hormone serum concentrations, in postmenopausal women. In vitro studies also show that hop extracts exert oestrogen-like activities on bone metabolism, although later in vivo studies on rats contradict this finding (Figard et al 2007).

Moderate beer consumption can provide enough 8-prenylnaringenin to ensure some biological activity in humans, with unknown consequences for health (Possemiers et al 2006).

### Possible chemopreventive and anticancer effects

Hops exhibits potential anticancer activity by inhibiting cell proliferation and angiogenesis, by inducing apoptosis and by increasing the expression of cytochrome P450 detoxification enzymes (Van et al 2009).

Antiangiogenic activity is important because angiogenesis is necessary for solid tumour growth and dissemination. In addition to angiogenesis, it has become increasingly clear that inflammation is a key component in cancer insurgence that can promote tumour angiogenesis. The hops-derived chalcone, xanthohumol, prevents angiogenesis in vivo and induces detoxification enzymes, in particular quinone reductase, which may contribute to its chemoprotective effects (Dietz et al 2005).

Xanthohumol, a prenylated chalcone derived from hops, is a very promising, potential protective agent against genotoxicity of food-borne carcinogens and has been shown to inhibit the growth of the highly angiogenic Kaposi's sarcoma tumour cells in vivo. It also demonstrates antitumour activity on B-chronic lymphocytic leukaemia cells in vitro. The prenylflavonoids are able to modulate aromatase activity, thus decreasing oestrogen synthesis, and it is hypothesised that this may have relevance for the prevention and treatment of oestrogen-dependent disorders such as breast cancer. Xanthohumol also demonstrates growth-inhibitory and apoptosis-inducing activity in hormone-sensitive and hormone-refractory human prostate cancer cells lines at a concentration range of 20–40 microM (Deeb et al 2010). Additionally, xanthohumol from hops appears to induce apoptosis by increasing release of reactive oxygen species within the mitochondria of cancer cells, leading to a rapid breakdown of the mitochondrial membrane potential and release of cytochrome c (Strathmann et al 2010). This was demonstrated in three human cancer cell lines, whereby xanthohumol induced an immediate and transient increase in superoxide anion radical formation, followed by apoptosis.

Both hops and 8-prenylnaringenin have been found to significantly inhibit oestrogen-induced malignant transformation of MCF-10A cells, suggesting cancer chemopreventive activity (Hemachandra et al 2012). In addition, 8-prenylnaringenin was a potent inhibitor of oestrogen-induced expression of CYP450 1B1 and CYP450 1A1, further adding to a chemopreventive effect.

In vitro research shows that hop bitter acids exhibit a strong growth-inhibitory effect against human leukaemia HL-60 cells, with an estimated IC<sub>50</sub> value of 8.67 mcg/mL, but were less effective against human histolytic lymphoma U937 cells (Chen & Lin 2004).

### Antimicrobial

Hops extract and hops oil have activity against mainly Gram-positive bacteria (*Bacillus subtilis* and *Staphylococcus aureus*) and the fungus *Trichophyton mentagrophytes* var. *interdigitale*, but almost no activity against the Gram-negative bacterium *Escherichia coli* and the yeast *Candida albicans* (Langezaal et al 1992). Lupulone, in particular, has been found to have some action against Gram-positive bacteria and certain Gram-negative bacteria, but not against

others, such as *E. coli*. A review of the antimicrobial properties concluded that hops was also effective against the parasite *Plasmodium falciparum* and a range of viruses, including herpes simplex virus types 1 and 2, cytomegalovirus and HIV (Gerhauser 2005). The mechanism of anti-HIV activity is not fully understood, but it is thought that the flavonoid, xanthohumol, may inhibit transcription (Wang et al 2004).

The activity of bitter acids from hops towards Gram-positive bacteria, including some species of *Micrococcus*, *Staphylococcus*, *Mycobacterium* and *Streptomyces*, may involve primary membrane leakage, due to the interaction of the hydrophobic parts of the molecules with the bacterial cell wall. Antifungal activity has also been reported for the bitter acids against *Candida albicans*, *Trichophyton*, *Fusarium* and *Mucor* species (Mizobuchi & Sato 1985). The prenylchalcones XH and 6-PN were identified as the most potent agents against *Trichophyton* spp. and *Staphylococcus aureus*, but they were practically inactive against other human pathogenic fungi (*Candida albicans* and *Fusarium* spp.) (Mizobuchi & Sato 1984).

### Cariogenic

Various components of hops have been studied for potential cariogenic activity and usefulness in dentistry. Cariogenic activity relies on a substance having an effect on dental plaque and the microorganisms involved, such as *Streptococcus mutans*. In vitro and in vivo research has shown inhibition of *S. mutans* and two clinical trials have confirmed cariogenic activity in humans (Shinada et al 2007, Yaegaki et al 2008).

## OTHER ACTIONS

### Cytochrome P450 induction and pregnane X receptor

Colupulone, a beta-bitter acid, was reported to induce the cytochrome P450 system and increase mRNA levels of cytochrome 2B and 3A in rats (Shipp et al 1994). The beta-bitter acid colupulone is also a direct activator of human pregnane X receptor (Teotico et al 2008). Another study found that the flavonoids from hops inhibit the cytochrome P450 system in vitro — in particular, cytochromes 1A1, 1B1 and 1A2, but not 2E1 or 3A4 (Henderson et al 2000). A review concluded that hops inhibits phase 1 detoxification and enhances phase 2 by inducing quinone reductase (Gerhauser et al 2002, Stevens & Page 2004). More recently, in vitro tests identified that hops extract at 5 mcg/mL with IC50 values of 0.8, 0.9, 3.3 and 9.4 mcg/mL inhibited CYP2C8 (93%), CYP2C9 (88%), CYP2C19 (70%) and CYP1A2 (27%) (Yuan et al 2013). The isoxanthohumol constituent was the most potent inhibitor of CYP2C8, whereas 8-prenylnaringenin was the most potent inhibitor of CYP1A2, CYP2C9 and CYP2C19. Clinical studies are not available to determine whether the effect on cytochromes is clinically relevant.

### Anti-inflammatory

In clinical trials, hops has demonstrable anti-inflammatory action. A double-blind, randomised ex vivo study comparing hops extracts with ibuprofen demonstrated equivalence in cyclooxygenase (COX)-2 inhibitory action but with significant COX-1-sparing activity relative to ibuprofen, therefore, without the risk of gastrointestinal side effects found with other COX enzyme inhibitors, such as ibuprofen.

The same results were found in a study utilising a modified hops extract containing a defined mixture of rho iso-alpha-acids (RIAA) which significantly inhibited prostaglandin E<sub>2</sub> formation with >200-fold selectivity of COX-2 over COX-1 (Hall et al 2008). RIAA appears to inhibit inducible, but not constitutive, COX-2 and, overall, may have lower potential for gastrointestinal and cardiovascular toxicity observed with traditional pharmaceutical COX enzyme inhibitors. Gastric safety was confirmed in a 14-day human study, whereby oral RIAA (900 mg/day) produced no change to faecal calprotectin (a biomarker of gastric irritation) compared to naproxen (1000 mg/day), which increased faecal calprotectin 200%.

The chalcones from hops, including xanthohumol, significantly reduced nitric oxide by suppressing inducible nitric oxide synthase in mouse macrophage cells (Zhao et al 2003, 2005). Xanthohumol has also been reported to inhibit the production of prostaglandin E<sub>2</sub>. Animal studies suggest that hops could be a useful agent for intervention strategies targeting inflammatory disorders and/or inflammatory pain in arthritis (Hougee et al 2006), but with low potential for gastrointestinal and cardiovascular toxicity. In fact, mouse studies indicate that hops extract may be useful for the prevention of gastric ulcer and inflammation, as it inhibits one of the important virulence factors responsible for *Helicobacter pylori*-induced gastritis and ulceration.

### CLINICAL USE

In practice, the herb is prescribed in combination with other herbal medicines, such as valerian and passionflower. As is representative of clinical practice, most studies have investigated the effects of hops in combination with other herbs.

### Restlessness and anxiety

Based on the herb's sedative activity, it is likely to have some effect in the treatment of restlessness and anxiety, but careful dosing would be required to avoid sedation. The relief of mild symptoms of mental stress is an indication that has been approved by Commission E and European Scientific Co-Operative on Phytotherapy (ESCO) (Blumenthal 1998). It has also been approved as a treatment for excitability and restlessness.

### Sleep disturbances and insomnia

Hops has been used as a bath additive for sleep disturbances. A double-blind RCT involving 40

patients found that taking three hops baths (4 g hops in a concentrated extract) on successive days significantly improved both objective and subjective sleep quality (Bone 1996).

Commission E and ESCOP support the use of hops for sleep disturbances, such as difficulty falling asleep and insomnia (Blumenthal et al 2000).

Studies on mice confirm that hops has a central sedating effect that can be attributed to the bitter acids and hop oil. Although there have been no human in vivo studies to support oral doses of hops as a stand-alone sedative agent, several studies have demonstrated that formulas combining hops with other sedative herbs are effective for insomnia.

#### IN COMBINATION

Numerous double-blind RCTs have investigated the effects of an oral preparation of hops and valerian in sleep disorders and currently, the evidence supports its use as a safe and effective treatment option for primary insomnia.

Four studies were included in a 2010 review (Salter & Brownie 2010), of which three were double-blind, placebo-controlled randomised studies and one was a single-blind randomised trial. Three of the four studies showed that the combination of valerian and hops was effective for some aspect of improving sleep. One study showed improved total sleep quantity, quality and deep sleep for valerian (480 mg) + hops (480 mg) over placebo, as calculated by electroencephalograph and subjective measures (Dimpfel & Suter 2008). Morin et al (2005) conducted a multicentre, randomised, placebo-controlled, parallel-group study in nine sleep disorder centres throughout the United States. The study, involving 184 adults with mild insomnia, used two tablets each night of standardised extracts of a valerian (187 mg native extracts; 5–8:1, methanol 45% m/m) and hops (41.9-mg native extracts; 7–10:1, methanol 45% m/m) taken for 28 days compared to placebo and two tablets of diphenhydramine (25 mg) for 14 days followed by placebo for 14 days. Modest improvements in subjective sleep parameters were obtained with the valerian-hops combination and people rated their insomnia as less severe with this treatment; quality of life (physical component) was significantly more improved in the valerian-hops group relative to the placebo group at the end of 28 days (Morin et al 2005). Koetter et al (2007) used a fixed combination of valerian (500 mg) and hops (120 mg) (Ze 91019) and found the herbal combination was significantly superior to placebo in reducing sleep latency (Koetter et al 2007). Finally, a study by Fussel et al (2000) testing the same valerian-hops preparation, Ze 91019, in 30 subjects with mild to moderate, non-organic insomnia found that treatment used at bedtime reduced sleep latency and nocturnal awakenings and improved sleep quality, as assessed by polysomnographic examination; however this study lacked a placebo group.

#### Comparisons with other treatments

One study observed equivalent efficacy and tolerability of a hops–valerian preparation comparable to benzodiazepine treatment, with withdrawal

symptoms only reported for benzodiazepine use (Schmitz & Jackel 1998). Improvement in subjective perceptions of sleep quality was confirmed in another study, which also reported that a hops–valerian combination was well tolerated compared with flunitrazepam (Gerhard et al 1996).

More recently, a parallel-group, double-blind, RCT showed that treatment with NSF-3, a polyherbal sedative hypnotic (containing standardised extracts of valerian, passionflower and hops) was as effective as zolpidem (10 mg) in primary insomnia (Maroo et al 2013). Seventy-eight volunteers took part; they had primary insomnia with a perceived total sleep time of <6 hours per night and insomnia severity index >7. Treatment consisted of either NSF-3 (one tablet) or zolpidem (one 10 mg tablet) at bedtime for 2 weeks. There was significant improvement in total sleep time, sleep latency, number of nightly awakenings and insomnia severity index scores in both groups, with no statistically significant difference observed between them.

#### Menopause

Hop extract and especially 8-PN are promising candidates for the relief of menopausal symptoms based on demonstrated mechanisms of action and the available clinical evidence; however further research is still required before a definitive conclusion can be made (Keiler et al 2013).

A randomised, double-blind, placebo-controlled trial of a standardised extract of hops (100 mcg and 250 mcg 8-prenylaringenin) demonstrated a significant reduction in menopausal discomfort, in particular hot flushes, after 12 weeks of treatment in 67 women (Heyerick et al 2005). Interestingly, no dose–response relationship could be made, as the lower standardised dose was shown to be more effective.

A 16-week double-blind placebo-controlled, crossover RCT was conducted with 36 menopausal women who were randomly allocated to either placebo or active treatment (hop extract) for a period of 8 weeks and then given the alternative treatment. After 8 weeks of active treatment following the placebo phase, a reduction in all outcome measures (Kupperman Index, the Menopause Rating Scale and a multifactorial visual analogue scale) was observed in comparison to placebo after active treatment, which resulted in an increase for all outcome measures (Erkkola et al 2010).

Single doses, from 50 to 750 mg, of 8-prenylaringenin were orally given to healthy menopausal women in a randomised, double-blind, placebo-controlled study performed by Rad et al (2006). The decrease in luteinising hormone serum levels found after the highest dose demonstrated the ability of 8-prenylaringenin to exert endocrine effects in menopausal women.

An open, non-controlled clinical trial in 100 postmenopausal women was performed over 12 weeks to investigate the effects of vaginal application of a gel (2.5 g/day for 1 week then two applications/

week for 11 weeks) containing phyto-oestrogens from hops extract, hyaluronic acid, liposomes and vitamin E, with the aim of testing its safety and efficacy in postmenopausal women with urogenital atrophy. The results showed a statistically significant reduction in vaginal dryness and other symptoms and signs associated with atrophic vaginitis (itching, burning, inflammation and rash) without any adverse effects (Morali et al 2006). The same group conducted a pilot study of 10 women with the same gel applied on the external genitals at a dose of 1–2 g/day for 30 days and confirmed acceptance of the treatment and a good safety profile, both locally and systemically (Morali et al 2006).

### Indigestion

Due to the herb's bitter nature, it is used to stimulate digestion and in the treatment of common digestive complaints such as dyspepsia and indigestion. Animal studies on rats show that hops increases gastric juice volume.

### Cariogenic — reducing dental plaque

Yaegaki et al (2008) demonstrated that hops polyphenols (HPP) significantly reduced the growth of *Streptococcus mutans* compared to controls ( $P < 0.01$ ) and of lactic acid production ( $P < 0.05$ ) and suppressed water-insoluble glucan formation in vitro (a major component of plaque) when used at all three test doses of 0.01%, 0.1%, and 0.5% ( $P < 0.01$ ,  $P < 0.001$  and  $P < 0.001$ , respectively). The same researchers conducted a single-blind RCT involving 28 healthy people and used either 20 mg or 7 mg HPP-containing tablets, representing high and low dosages, respectively, at a dose of one tablet seven times a day (before breakfast, after each meal, between meals and at bedtime) for 3 days. The study confirmed that high-strength treatment with HPP significantly reduced 3-day dental plaque regrowth ( $P < 0.05$ ).

Positive results were also obtained in a double-blind, crossover clinical study utilising an HPP mouth rinse (0.1%) which significantly suppressed dental plaque regrowth in humans ( $P < 0.001$ ) (Shinada et al 2007). Additionally, the number of mutans streptococci in the plaque samples after volunteers used the HPP mouth rinse was significantly lower than after they used the placebo ( $P < 0.05$ ).

### Allergy

A double-blind, placebo-controlled RCT showed that oral administration of a hop water extract during the allergy season significantly improved symptoms compared to placebo (Segawa et al 2007). The active treatment drink contained 100 mg of hop water extract, which was taken for 12 weeks. The effect had a slow onset, as a significant difference was observed in the symptom score and in the symptom medication score 10 weeks after the intervention in comparison with the placebo group. Improvements were observed in nasal swelling, nasal colour, amount of nasal discharge and characteristics

of nasal discharge in the intervention group 12 weeks after the treatment. Additionally, no significant eosinophil infiltration into the nasal discharge was apparent in the intervention group throughout the study period, although it was observed in the placebo group.

### Osteoarthritis

The anti-inflammatory activity of hops provides a rationale for its use in conditions characterised by inflammation such as osteoarthritis. At least two clinical studies have explored whether a preparation containing hops extracts with RIAA has any symptom-relieving benefits in osteoarthritis (Hall et al 2008, Minich et al 2007). In a 6-week open-label study of human subjects exhibiting knee osteoarthritis, a hops treatment containing RIAA (1000 mg/day) produced a 54% reduction in WOMAC global scores (Hall et al 2008). Additionally, results from a multicentre trial indicate that a herbal combination (NG440) containing RIAA from hops, rosemary and oleanolic acid reduced pain scores in patients with joint discomfort, as measured by visual analogue scale methodology (Minich et al 2007).

Double-blind studies utilising hops extract as a stand-alone treatment are warranted to explore the potential effects further.

### OTHER USES

Traditionally, hops are also used to treat neuralgia, depression and pain and to wean patients off pharmaceutical sedative medicines. Topically it is used to treat leg ulcers and oedema.

### Diabetes

Isohumulones, the bitter compounds in hops, have been shown to improve insulin resistance and hyperlipidaemia in several animal models and may prevent the progression of renal injury caused by hypertension via an antioxidative effect. Clinical studies are required to confirm significance.

### Periodontitis

In vitro studies suggest that the hop-derived polyphenols are potent inhibitors of prostaglandin  $E_2$  production by gingival epithelial cells stimulated with periodontal pathogen and may be useful for the prevention and treatment of periodontitis. The clinical significance of this finding is unknown and remains to be tested.

### Deodorant

In vitro antibacterial activity of a hop extract against *Corynebacterium xerosis* and *Staphylococcus epidermidis* and the evaluation of the odour-reducing capacity of a hops/zinc ricinoleate-containing product by a sensory evaluation panel were employed to verify deodorant performance (Dumas et al 2009). The hops extract had good antibacterial activity against *C. xerosis* and *S. aureus*. In the clinical underarm

odour reduction evaluation, the mean malodour score dropped from 6.28 ( $\pm 0.70$ ) to 1.80 ( $\pm 0.71$ ) 8 hours after application, with a noticeable effect lasting at both 12 and 24 hours after the application, with a score of 1.82 ( $\pm 0.74$ ) and 2.24 ( $\pm 0.77$ ), respectively.

### Use in flavouring, preserving and colouring beer

The bitter acids of hops (*Humulus lupulus* L.) mainly consist of alpha-acids, beta-acids and their oxidation products that contribute the unique aroma of the beer beverage. The alpha-acids in particular are the crucial compounds for the quality of hops used in the brewing industry, contributing to foam stability as well as exerting antibacterial activity (Verzele & De Keukeleire 1991).

### DOSAGE RANGE

- Infusion or decoction: 0.5 g in 150 mL water.
- Fluid extract (1:1) (g/mL): 0.5 mL/day; 0.5–1 mL three times daily.
- Tincture (1:5) (g/mL): 1–2.5 mL/day.
- Also used as a bath additive (4 g hops in a concentrated extract) and in pillows.

### TOXICITY

Toxicological studies in animals stated that LD<sub>50</sub> for orally administered hop extract in mice ranges from 500 to 3500 mg/kg (Hänsel et al 1993).

### ADVERSE REACTIONS

Drowsiness is theoretically possible at excessive doses. Contact with the herb or oil has resulted in reports of systemic urticaria, allergic dermatitis, respiratory allergy and anaphylaxis (Pradalier et al 2002).

### SIGNIFICANT INTERACTIONS

Interactions reported here are theoretical and yet to be tested clinically for significance.

#### Pharmaceutical sedatives

Additive effects are theoretically possible — observe the patient (this interaction may be beneficial).

#### Drugs metabolised chiefly with CYP2C8, CYP2C9 or CYP2C19

Altered drug effect — cytochrome (CYP) inhibition has been demonstrated in vitro. However, it is unknown whether these effects are clinically significant — observe the patient for signs of altered drug effectiveness.

#### Antioestrogenic drugs

Hops may alter the efficacy of these medicines; use with caution in patients taking antioestrogenic drugs. However the effect is theoretical and not anticipated to be significant — observe.

### Practice points/Patient counselling

- Hops are often used as a mild sedative in combination with other herbs, such as valerian and passionflower.
- Several randomised trials have found that the combination of hops and valerian improves sleep quality, without next-day drowsiness; however, further investigation is required to determine the role of hops in achieving this effect.
- Although generally taken orally, it has also been successfully used as a bath additive and in aromatherapy pillows to induce sleep.
- It is traditionally used to treat anxiety, restlessness, pain, neuralgia and indigestion.
- It should not be used in patients with oestrogen-dependent tumours, and should be used with caution in pregnancy.

### CONTRAINDICATIONS AND PRECAUTIONS

According to one source, hops should be used with caution in depression (Ernst 2001). Due to the herb's oestrogenic activity, disruption to the menstrual cycle is considered possible. While caution is advised in patients with oestrogen-dependent tumours, new research indicates chemopreventive activity against breast cancer cell lines.

### PREGNANCY USE

Caution in pregnancy because of the possible hormonal effects.

### PATIENTS' FAQs

#### What will this herb do for me?

Hops may be a useful treatment for anxiety and restlessness, and when combined with other sedative herbs, such as valerian or passionflower, improves sleep quality without inducing next-day hangover effects.

#### When will it start to work?

Several doses may be required; however, effects are generally seen within 2 weeks.

#### Are there any safety issues?

Constituents in the herb appear to have some oestrogenic activity; therefore, people with oestrogen-dependent tumours should avoid its use.

# Horse chestnut

**HISTORICAL NOTE** The horse chestnut tree is native to the countries of the Balkan Peninsula and is commonly found in ornamental gardens throughout Europe, growing up to 36 metres tall (Anonymous 2009). The seeds are not edible due to the presence of alkaloid saponins, but both the dried seeds and bark of the horse chestnut tree have been used medicinally since the 16th century. The seeds are also used for the children's game 'conkers' and were used to produce acetone during World War I and II. In modern times, a dry extract, referred to as horse chestnut seed extract (HCSE), is standardised to contain 16–21% triterpene glycosides (anhydrous aescin). HCSE has been extensively researched for its beneficial effects and is commonly used by general practitioners in Germany for the treatment of chronic venous insufficiency. Homeopathic preparations of both the leaf and the seed are also used for treating haemorrhoids, lower back pain and varicose veins, and the buds and flower are used to make the Bach flower remedies chestnut bud and white chestnut. The active component aescin is also used intravenously and topically in cosmetics (Bombardelli et al 1996, Herbalgram 2000, PDR Health 2006).

## OTHER NAMES

Aescule, buckeye, chestnut, Castaño de Indias, graine de marronnier d'inde, escine, eschilo, hes-tekastanje, hippocastani semen, marroneuropeen, marronnier, roßkastaniensamen, Spanish chestnut

## BOTANICAL NAME/FAMILY

*Aesculus hippocastanum* (family [Sapindaceae] Hippocastanaceae).

It should be differentiated from *A. chinensis*, *A. turbinata*, *A. indica*, *A. californica* and *A. glabra*.

## PLANT PARTS USED

Seed. Less commonly bark, flower and leaf.

## CHEMICAL COMPONENTS

Horse chestnut seed contains 3–6% aescin (escin), a complex mixture of triterpene saponins (including the triterpeneoligoglycosides escins Ia, Ib, IIa, IIb and IIIa) (Yoshikawa et al 1996), the acylated polyhydroxyoleanenetrimerpeneoligoglycosides aescins IIIb, IV, V and VI and isoescins Ia, Ib and V (Yoshikawa et al 1998). Beta-aescin appears to be the active component of the triterpene saponins mixture and is the molecular form present in major available pharmaceutical products (Sirtori 2001). Horse chestnut also contains sapogenol shippocaesculin, barringtonenol-C (Konoshima & Lee 1986), flavonoids (flavonol oligosides of quercetin and kaempferol) (Dudek-Makuch & Matawska 2011, Hubner et al 1999), including 3-O-alpha-arabinofuranoside, 3-O-beta-glucopyranoside, 3-O-alpha-rhamnopyranoside, 3-O-alpha-rhamnopyranosyl (1 → 6)-O-beta-glucopyranoside (Dudek-Makuch & Matawska 2011). Condensed tannins, quinines, sterols (including stigmasterol, alpha-spinasterol and beta-sitosterol) (Senatore et al 1989), sugars (including glucose, xylose and rhamnose) (Hubner et al 1999) and fatty acids (including linolenic, palmitic and stearic acids) (Herbalgram 2000). Horse chestnut bark and flowers also contain the sterols stigmasterol, alpha-spinasterol and beta-sitosterol (NMCD 2006).

Although the majority of trials in the scientific literature have focused on the benefits of the HCSE extract, some authors suggest that the flavonoids contained in horse chestnut may provide additional benefits (Mills & Bone 2000).

## MAIN ACTIONS

HCSE and various key components such as aescin have been investigated for pharmacological activities.

### Vasoprotective/normalises vascular permeability

Horse chestnut appears to prevent the activation of leucocytes and therefore inhibit the activity of lysosomal enzymes (hyaluronidase and elastase) involved in the degradation of proteoglycan (the main component of the extracellular matrix), thus reducing the breakdown of mucopolysaccharides in vascular walls (Pittler & Ernst 2004). Aescin is the major constituent thought to be responsible for the inhibitory effects on hyaluronidase. Interestingly, rusco-genins found in *Ruscus aculeatus* L. (butcher's broom), while ineffective on hyaluronidase activity, exhibit significant anti-elastase activity (Facino et al 1995), which may explain the practice by many herbalists of combining the two herbs. By reducing degradation, the synthesis of proteoglycans is able to occur, which reduces capillary hyperpermeability, preventing the leakage of fluid into intercellular spaces that results in oedema. The anti-exudative activity appears to be mediated by PGF<sub>2α</sub> (Berti et al 1977). In animal studies the aescins Ia, Ib, IIa and IIb have been shown to reduce capillary hyperpermeability induced by histamine, acetic acid, carageenan and serotonin (Guillaume & Padioleau 1994, Matsuda et al 1997). In experimental rat aortic-ring models, aescin has been shown to increase endothelial cell permeability to calcium, which enhances the production of nitric oxide (NO) (due to the effect of endothelial NO synthase, a calcium-dependent enzyme), and results in enhanced endothelium-dependent relaxation. This is thought

to contribute to aescin's beneficial effect in the treatment of venous insufficiency (Carrasco & Vidrio 2007). The mechanism of selective vascular permeabilisation can allow for a higher sensitivity to molecular ions, for example, calcium channels, resulting in increased venous and arterial tone in addition to enhanced venous contractile activity (Sirtori 2001).

Horse chestnut promotes the proliferation behaviour of human endothelial cells in vitro in a dose-dependent manner (Fallier-Becker et al 2002) and may therefore also play a role in maintaining as well as protecting vascular walls.

By improving vascular tone, HCSE may improve the flow of blood back to the heart, as demonstrated in animal studies in which it significantly increased, within normal arterial parameters, femoral venous pressure and flow, as well as thoracic lymphatic flow (Guillaume & Padioleau 1994).

### Anti-oedema

Horse chestnut prevents the excessive exudation of fluid through the walls of the capillaries that result in oedema by inhibiting the degradation of vascular walls. In animal experiments, HCSE reduced oedema of both inflammatory and lymphatic origin (Guillaume & Padioleau 1994).

### Anti-inflammatory

Under experimental conditions, aescin pretreatment reduced IL-6 release from vascular endothelium (Montopoli et al 2007). In animal studies the aescins Ia, Ib, IIa and IIb have been shown to reduce capillary hyperpermeability induced by histamine, ascorbic acid, carrageenan and serotonin (Guillaume & Padioleau 1994, Matsuda et al 1997). A sterol extract of horse chestnut bark was shown to have anti-inflammatory effects comparable to phenylbutazone in an inflammatory animal study utilising carrageenan-induced paw oedema (Senatore et al 1989). Studies suggest that aescin can effectively alter the cellular phase of the inflammatory process, such as leucocyte activation (Sirtori 2001).

### Antioxidant

Oxidative stress is increasingly recognised as a fundamental factor in inflammatory responses (Braga et al 2012). HCSE dose-dependently inhibits both enzymatic and non-enzymatic lipid peroxidation in vitro (Guillaume & Padioleau 1994).

Horse chestnut bark extract altered reactive oxygen/nitrogen species (ROS/RNS) production in a concentration-dependent manner with significant effects being observed for even very low concentrations, for example, 10 mcg/mL (Braga et al 2012).

The component aescin enhanced endogenous antioxidative capacity in mice with acute liver injury induced by endotoxin (established by injecting lipopolysaccharide (LPS)). Aescin also down-regulated levels of inflammation mediators (TNF- $\alpha$ , IL-1 $\beta$  and NO) and 11 $\beta$ -HSD2 expression in liver, up-regulated glucocorticoid receptor expression and

it is suggested that aescin can alleviate the degree of necrosis and decrease serum ALT and AST activities (Jiang et al. 2011).

### Chemopreventive, anti-angiogenic and anti-proliferative

Beta-aescin demonstrated in vitro potent inhibition of cell proliferation and induction of apoptosis in HL-60 acute myeloid leukaemia cells (Niu et al 2008b) and human chronic myeloid leukaemia K562 cells (Niu et al 2008a), in addition to inhibiting the growth of colon cancer cells in rats (Patlolla et al 2006). Beta-aescin sodium (40 micrograms/mL) also induced endothelial cell apoptosis and inhibited endothelial cell proliferation in a dose-dependent manner (10, 20, 40 micrograms/mL) (Wang et al 2008).

### Anti-ageing

A number of studies by Fujimura and others (2006a, 2006b, 2007) have suggested that horse chestnut extract can generate contraction forces in fibroblasts through stress fibre formation followed by activation of Rho protein and Rho kinase (Fujimura et al 2006b), and thus act as a potent anti-ageing factor. In a controlled trial of 40 women using an eye gel (3% horse chestnut extract) applied around the eyes three times a day for 9 weeks a significant reduction in wrinkle scores around the corners of the eye and lower eyelids was observed after 6 weeks (Fujimura et al 2006a, 2007).

### OTHER ACTIONS

Animal studies have demonstrated that isolated aescins Ia, Ib, IIa and IIb inhibit gastric emptying time and ethanol absorption, and exert a hypoglycaemic activity in the oral glucose tolerance test in rats (Matsuda et al 1999, Yoshikawa et al 1996). Aescin also appears to possess a weak diuretic activity (Mills & Bone 2000).

Blood-retinal barrier (BRB) breakdown is a hallmark of diabetic retinopathy. The aim of the study by Zhang et al. (2013) was to investigate whether aescin exhibited synergistic protective effects on BRB breakdown, when combined with glucocorticoids in a rat model of retinal ischaemia. Low concentrations of aescin and triamcinolone acetonide (TA) alone did not affect BRB permeability. However, when administered together, low-dose aescin and TA significantly reduced BRB permeability following ischaemia. Furthermore, low-dose aescin and TA alone did not affect the expression of occludin in the ischaemic retina; however, when administered together, they significantly increased occludin expression in the ganglion cell layer of the ischaemic retina.

### CLINICAL USE

The most commonly used preparation is a dry extract, referred to as horse chestnut seed extract (HCSE), which is standardised to contain 16–21% triterpene glycosides (anhydrous aescin). It is used

internally and also in topical preparations. HCSE has been extensively researched, mainly in Europe, for its beneficial effects in conditions where improving circulation and blood vessel integrity would be beneficial. In particular, HCSE is chiefly used in chronic pathological conditions of the veins where there is increased activity of lysosomal enzymes resulting in damage to and hyperpermeability of vascular walls (Herbalgram 2000).

### Chronic venous insufficiency

HCSE taken orally is an effective treatment for chronic venous insufficiency (CVI), reducing leg pain, fatigue and heaviness, volume and oedema and pruritic symptoms according to placebo controlled studies. Approximately 10–15% of men and 20–25% of women present signs and symptoms consistent with the diagnosis of CVI (Pittler & Ernst 2012). This supports its traditional use as a treatment of CVI and its associated symptoms, such as lower leg swelling. The ability of HCSE to inhibit the catalytic breakdown of capillary wall proteoglycans and reduce inflammation is thought in part to mediate this effect.

A Cochrane systematic review that assessed 17 RCTs utilising HCSE capsules (standardised to aescin) concluded that signs and symptoms of CVI improve with HCSE treatment as compared with placebo (Pittler & Ernst 2012). Of these trials, 10 were placebo-controlled. Leg pain was assessed in seven placebo-controlled trials with six of these trials ( $n = 543$ ) reporting a significant reduction in leg pain for HCSE, another study reported a significant improvement compared with baseline and one study reported that HCSE may be as effective as treatment with compression stockings.

Meta-analysis of six trials ( $n = 502$ ) suggested a reduction in leg volume compared with placebo, as did the studies in which the circumference at calf and ankle ( $n = 172$ ) was assessed overall. Adverse events were usually mild and infrequent. From this analysis, patients given 100–150 mg aescin daily for 2–8 weeks led to a significant reduction in leg volume and the symptoms of pain, fatigue, sensation of tension and itching compared to placebo. Three of the studies using 100 mg aescin daily reported a statistically significant reduction of mean leg volume after 2 weeks of treatment compared with placebo ( $P < 0.01$ ). In the eight placebo-controlled trials where pruritus was assessed, four trials ( $n = 407$ ) showed a significant reduction compared with placebo ( $P < 0.05$ ) and two trials showed a significant difference in favour of HCSE compared with baseline ( $P < 0.05$ ), whereas one trial found no significant differences for a score including the symptom pruritus compared with compression. The results of this systematic review suggest that when compared with placebo and reference treatment, HCSE is an effective treatment option for CVI (Pittler & Ernst 2012).

An earlier meta-analysis of 13 RCTs ( $n = 1051$ ) and three observational studies ( $n = 10,725$ ) found

that HCSE reduced leg volume by 46.4 mL (95% CI, 11.3–81.4 mL) and increased the likelihood of improvement in leg pain 4.1-fold (95% CI, 0.98–16.8), oedema 1.5-fold (95% CI, 1.2–1.9) and pruritus 1.7-fold (95% CI, 0.01–3.0). Observational studies reported significant improvements in pain, oedema and leg fatigue/heaviness (Siebert *et al* 2002).

A case observational study involving more than 800 general practitioners and more than 5000 patients with CVI taking HCSE reported that symptoms of pain, tiredness, tension and swelling in the leg, as well as pruritus and tendency to oedema, all improved markedly or disappeared completely, with the additional advantage of better compliance than compression therapy (Greeske & Pohlmann 1996). In an open study carried out to assess the safety and tolerability of horse chestnut, 91 subjects received a tablet (equivalent to 50 mg aescin) twice daily for 8 consecutive weeks. At the end of the study the majority of patients rated horse chestnut to be good or very good for Widmer stage I and II CVI (Dickson *et al* 2004).

A study was carried out to compare the efficacy (oedema reduction) and safety of compression stockings class II and HCSE (50 mg aescin, twice daily) in 240 patients with chronic venous insufficiency (Diehm *et al* 1996). The patients were treated over a period of 12 weeks in a randomised, partially blinded, placebo-controlled, parallel study design. Lower leg volume of the more severely affected limb decreased on average by 43.8 mL ( $n = 95$ ) with HCSE and 46.7 mL ( $n = 99$ ) with compression therapy, while it increased by 9.8 mL with placebo ( $n = 46$ ) after 12 weeks therapy.

In patients suffering from CVI, oedema can give rise to trophic skin changes, inflammatory lesions and an increase in blood coagulability with the associated risk of thrombosis development. Therapy should therefore be aimed at providing protection against oedema at the earliest possible stage of venous disease (Widmer CVI stages I or II) to prevent complications (Pohlmann *et al* 2000). As HCSE therapy appears to provide more significant benefits in the earlier stages (less so with the advancement of the condition) (Ottlinger & Greeske 2001), it would appear prudent to initiate HCSE therapy early in order to prevent or delay the need for compression therapy, which is associated with discomfort and poor patient compliance. In the later stages, combined treatment with compression stockings and HCSE may provide added benefit (Blaschek 2004, Pittler & Ernst 2004).

Although the standard dose used in clinical trials appears to be equivalent to 50 mg aescin twice daily, one study observed that reducing the dose to 50 mg aescin once daily at 8 weeks appeared to maintain similar benefits to the twice-daily routine at the end of the 16-week observation period (Pohlmann *et al* 2000).

### Venous leg ulceration

Chronic venous leg ulceration (VLU) is a common recurrent problem in the elderly population and may result in immobility, with 45% of patients being housebound (Baker & Stacey 1994). As a result, individuals with VLU frequently experience depression, anxiety, social isolation, sleeplessness and reduced working capacity (Leach 2004). CVI, which is characterised by an increase in capillary permeability, inflammatory reactions, decreased lymphatic reabsorption, oedema and malnutrition of tissues, is a precursor to VLU. As HCSE increases venous tone while reducing venous fragility and capillary permeability, and possesses anti-oedematous and anti-inflammatory properties, it has been speculated that by improving microcirculation, ulceration may be delayed or prevented (Blaschek 2004).

In a prospective triple-blind randomised placebo-controlled trial, 54 patients with venous leg ulcers received HCSE ( $n = 27$ ) or placebo ( $n = 27$ ) for 12 weeks. At weeks 4, 8 and 12 the difference between groups in the number of healed leg ulcers and change in wound surface area, depth, volume, pain and exudate was not statistically significant. There was, however, a significant effect on the percentage of wound slough over time ( $P = 0.045$ ) and on the number of dressing changes at week 12 ( $P = 0.009$ ) (Leach et al 2006a). As a result, after taking into account the cost of HCSE, dressing materials, travel, staff salaries and infrastructure for each patient, this study determined a cost benefit for the addition of HCSE to conventional therapy of AU\$95 in organisational costs, and AU\$10 in dressing materials per patient (Leach et al 2006b). Further large-scale trials are required to fully elucidate the potential use in practice.

### Haemorrhoids

Horse chestnut is also used both internally and topically for the treatment of haemorrhoids. Although there are not many studies on the effectiveness of horse chestnut in the treatment of haemorrhoids, oral treatment with aescin has been shown to significantly improve signs and symptoms according to a placebo-controlled double-blind study of 72 volunteers with haemorrhoids. Symptom relief was experienced by 82% of subjects compared with 32% for placebo, and swelling improved in 87% compared with 38% for placebo (Sirtori 2001). Symptom improvement required at least 6 days of treatment to become established and the dose used was 40 mg aescin three times daily.

### Bruising

In a double-blind, placebo-controlled, randomised crossover study, the influence of aescin on the capillary resistance was investigated in 12 males (aged 24–31) with healthy vessels. The dosage of HCSE was 500 mg three times per day (1500 mg daily). Using capillary-resistometry (petechiae test), under standardised conditions, the number and area of petechiae were significantly lower after 7 days. The

study noted a carryover effect where it was found that HCSE may have had a more permanent impact on the reduction of petechiae. The authors of the study concluded that capillary resistance was significantly improved after horse chestnut administration.

### Cosmetics

Horse chestnut extracts have anti-inflammatory and antioxidant activities, together with the ability to improve capillary fragility and reduce oedema, making it a good candidate for inclusion into topical cosmetic preparations. It also contains saponins (aescin) which have a gentle soapy feel (Wilkinson & Brown 1999).

A study involving 40 healthy women tested the use of an eye gel containing 3% horse chestnut extract, which was applied around the eyes three times a day for 9 weeks (Fujimura et al 2006). After 6 weeks, significant decreases in the wrinkle scores at the corners of the eye or in the lower eyelid skin were observed compared with controls, a result evaluated using visual scoring based on photo scales. After 9 weeks, similar results were obtained suggesting no further changes occurred.

### OTHER USES

Traditionally the seeds are used to treat conditions affecting the veins, including haemorrhoids, phlebitis and varicose veins; bruising, diarrhoea, fever, enlarged prostate, eczema, menstrual pain, painful injuries, sprains, swelling and spinal problems. The leaf is used for soft tissue swelling from bone fracture and sprains, complaints after concussion, cough, arthritis and rheumatism, and the bark for malaria and dysentery, and topically for SLE and skin ulcers (NMCD 2006, PDR Health 2006).

There is some evidence to support its use for preventing postoperative oedema (Sirtori 2001) and the antioxidant, vascular toning and anti-inflammatory effects of *A. hippocastanum*, as well as the presence of flavonoids and other active constituents, may support some of the other traditional uses (Wilkinson & Brown 1999).

### DOSAGE RANGE

- Chronic venous insufficiency: HCSE standardised to 50–100 mg aescin twice daily. The dose may be reduced to a maintenance dose of 50 mg aescin once daily after 8 weeks (Pohlmann et al 2000).
- Australian manufacturers recommend 2–5 mL/day of 1:2 liquid extract.
- 1–2 g dried seed daily (Mills & Bone 2005).

### ADVERSE REACTIONS

According to clinical trials horse chestnut and oral HCSE appears to be well tolerated with only mild, infrequent reports of adverse reactions, including gastric irritation, skin irritation, dizziness, nausea, headache and pruritus. Postmarketing surveillance reports adverse effects of 0.7% (Micromedex 2003, NMCD 2006, PDR Health 2006, Pittler & Ernst 2004, Siebert et al 2002).

**Practice points/Patient counselling**

- Horse chestnut extract has been extensively researched for its beneficial effects and is commonly used by GPs in Germany for the treatment of chronic venous insufficiency. There is strong evidence to support its use for this indication.
- In practice, a dry extract is used (HCSE standardised to contain 16–21% triterpene glycosides (anhydrous aescin)).
- HCSE is also used for venous leg ulceration because it increases venous tone while reducing venous fragility and capillary permeability, and possesses anti-oedematous, antioxidant and anti-inflammatory properties.
- HCSE is also used in the treatment of haemorrhoids. Although it has not been investigated for this indication, aescin has been shown to significantly improve signs and symptoms under double-blind study conditions.
- HCSE is well tolerated with only mild, infrequent reports of adverse reactions, including gastric irritation, skin irritation, dizziness, nausea, headache and pruritus. Do not use on broken skin due to the irritant effect of the saponins.
- Horse chestnut can cause hypersensitivity reactions, which occur more commonly in people who are allergic to latex.

Horse chestnut contains a toxic glycoside aesculin (esculin), a hydroxycoumarin that may increase bleeding time because of its antithrombin activity and may be lethal when the raw seeds, bark, flower or leaves are used orally. Poisoning has been reported from children drinking tea made with twigs and leaves (NMCD 2006).

Symptoms of overdose include diarrhoea, vomiting, reddening of the face, severe thirst, muscle twitching, weakness, loss of coordination, visual disturbances, enlarged pupils, depression, paralysis, stupor and loss of consciousness (NMCD 2006, PDR Health 2006). Reports of poisoning with horse chestnut seeds are consequent to the presence of the toxic principle aesculoside, not to aescin (Sirtori 2001).

Horse chestnut can also cause hypersensitivity reactions, which occur more commonly in people who are allergic to latex (Diaz-Perales et al 1999).

Isolated cases of kidney and liver toxicity have occurred after intravenous and intramuscular administration (Micromedex 2003, Mills & Bone 2005, NMCD 2006).

Aescin has undergone toxicological studies in rodents. Toxic manifestations following IV administration of high doses were due to haemolysis. The LD<sub>50</sub> following IV administration in rodents was equivalent to 28 times the maximum dose recommended for therapeutic use; the LD<sub>50</sub> following oral dosing was over 100 mg/kg, equivalent to

59 times the recommended therapeutic range (Sirtori 2001).

**SIGNIFICANT INTERACTIONS**

In vitro studies have revealed that horse chestnut may inhibit CYP3A4-mediated metabolism and P-glycoprotein efflux transport activity (Hellum & Nilsen 2008). The clinical significance of these findings remains to be tested.

**Antiplatelet/ anticoagulant medications**

Properly prepared HCSE should not contain aesculin and should not carry the risk of antithrombin activity — observe. The clinical significance is unclear.

**Hypoglycaemic agents**

Due to possible hypoglycaemic activity, blood glucose levels should be monitored when horse chestnut or HCSE and hypoglycaemic agents are used concurrently (Yoshikawa et al 1996) — observe. The clinical significance is unclear.

**H****? CONTRAINDICATIONS AND PRECAUTIONS**

As saponins may cause irritation to the gastric mucosa and skin, horse chestnut should be taken with food. It is suggested that it should be avoided by people with infectious or inflammatory conditions of the gastrointestinal tract, including coeliac disease and malabsorption disorders and should not be applied topically to broken or ulcerated skin.

Horse chestnut flower, raw seed, branch bark or leaf may be toxic and are not recommended (Tiffany et al 2002).

Avoid use in the presence of hepatic or renal impairment (Micromedex 2003, NMCD 2006, PDR Health 2006).

In toxicity studies in rats, aescin decreased white blood cells, increased the number of red blood cells and platelets and haemoglobin content and reduced prothrombin time and thrombin time (5, 10, 15 mg/kg) (Li et al 2006).

**! PREGNANCY USE**

Safety in pregnancy and lactation has not been well established.

**! PATIENTS' FAQs****What will this herb do for me?**

Horse chestnut standardised extract (HCSE) will relieve signs and symptoms of chronic venous insufficiency such as pain, pruritus and oedema. It may also be of benefit in alleviating signs and symptoms in people with haemorrhoids and has been used in venous leg ulceration.

**When will it start to work?**

Beneficial effects in chronic venous insufficiency have been reported within 3–6 weeks; however,

12 weeks may be required in some cases. Aescin provided symptom relief in haemorrhoids after 6 days of treatment.

### Are there any safety issues?

HCSE is well tolerated with only mild, infrequent reports of adverse reactions including gastric irritation, skin irritation, dizziness, nausea, headache and pruritus. It can cause hypersensitivity reactions, which occur more commonly in people who are allergic to latex.

# Horseradish

**HISTORICAL NOTE** Horseradish is a commonly used spice with a long history of use in traditional medicine. The leaves are used in cooking and as a salad green. Horseradish is one of the 'five bitter herbs' of the biblical Passover.

## COMMON NAME

Horseradish

## OTHER NAMES

*Amoracia rusticanae* radix, great mountain root, great raifort, mountain radish, pepperrot, red cole

## BOTANICAL NAME/FAMILY

*Armoracia rusticana*, synonym *Armoracia lopathifolia*; *Cochlearia armoracia*, *Nasturtium armoracia*, *Roripa armoracia* (family Brassicaceae [Cruciferae])

## PLANT PARTS USED

Fresh or dried roots and leaves

## CHEMICAL COMPONENTS

Horseradish root contains volatile oils: glucosinolates (mustard oil glycosides); gluconasturtiin and sinigrin (S-glucosides); coumarins (aesculetin, scopoletin); phenolic acids, including caffeic acid derivatives and hydroxycinnamic acid derivatives, ascorbic acid; asparagin; resin; and peroxidase enzymes. Allyl isothiocyanate is the chief glucosinolate present in horseradish and responsible for most of its clinical activity. The concentration of allyl isothiocyanate in horseradish is dependent on the concentration of sulfate in the soil it is cultivated in (Alnsour et al 2013). Horseradish is one of the richest plant sources of peroxidase enzymes, in particular horseradish peroxidase, which are commonly used as oxidising agents in commercial chemical tests.

## MAIN ACTIONS

### Irritant

Horseradish is widely known for its pungent burning flavour. The pungency of horseradish is due to the release of allyl isothiocyanate and butyl thiocyanate upon crushing (Yu et al 2001). These mustard oil glycosides may irritate the mucous membranes upon contact or inhalation and may act as circulatory and digestive stimulants; however, the mechanism of action has not been fully elucidated (Blumenthal et al 2000, Jordt et al 2004). It has been found that topical application of allyl isothiocyanate to the skin activates sensory nerve endings producing pain, inflammation and hypersensitivity to thermal and mechanical stimuli due to depolarising the same sensory neurons that are activated by capsaicin and tetrahydrocannabinol (Jordt et al 2004).

### Circulatory stimulant

The mustard oils released when horseradish is crushed may be responsible for this activity.

### Digestive stimulant

Again, it is suspected that the mustard oils may be responsible as these act as irritants. Large doses may cause emesis (Pengelly 1996).

### Antimicrobial activity

Allyl isothiocyanate has been well known to possess antimicrobial effects against *Escherichia coli* O157:H7, *Listeria monocytogenes*, *Salmonella typhimurium* and *Staphylococcus aureus* (Shin et al 2010).

### Fungistatic and insecticidal activity

Horseradish extract, prepared from fresh plants in a solution of ethanol 80%, was found to have significant insecticidal activity against larvae of *Aedes albopictus* (Skuse) and when applied in a 10% ethanolic extract, a fungistatic activity against *Sclerotium rolfsii* Sacc., *Fusarium oxysporum* Schlecht. and *F. culmorum* (Wm. G. Sm) Sacc. (Tedeschi et al 2011).

Horseradish oil-derived compounds and several isothiocyanates are potential acaricides for the control of house dust mite populations as fumigants with contact action (Yun et al 2012).

## OTHER ACTIONS

Isothiocyanates may inhibit thyroxine formation and be goitrogenic (Langer & Stole 1965), although this has not been demonstrated clinically.

The peroxidase enzymes assist in wound healing, whereas the sulfur-containing compounds may decrease the thickness of mucus by altering the structure of its mucopolysaccharide constituents (Mills & Bone 2000). Antispasmodic and antimicrobial effects have also been reported (Blumenthal et al 2000, Newell et al 1996). Horseradish has been found to lower plasma cholesterol and faecal bile acid excretion in mice fed with a cholesterol-enriched diet, possibly due to interference with exogenous cholesterol absorption (Balasinska et al 2005).

Horseradish has also been found to contain compounds that inhibit tumour cell growth and cyclooxygenase-1 enzymes (Weil et al 2005). In vivo trials testing a combination of herbs, including horseradish, has been found to protect against viral transmission of avian influenza (Oxford et al 2007).

**Clinical note — Horseradish peroxidase: an important plant enzyme**

Few plant enzymes are represented so widely in the scientific and patent literature as horseradish peroxidase. It is one of the most important enzymes obtained from a plant source and the subject of thousands of papers in the scientific literature. It is commercially produced from horseradish roots on a relatively large scale. This is due to its broad use, for example, as a component of clinical diagnostic kits and for immunoassays (Veitch 2004). Research is also being undertaken to understand how it may be used clinically.

**CLINICAL USE**

The therapeutic effectiveness of horseradish has not been significantly investigated.

**Nasal congestion and sinusitis**

Horseradish is widely used in combination with other ingredients such as garlic in herbal decongestant formulations. Anecdotal evidence suggests that a mild, transient decongestant effect occurs. It is reputed to eliminate excessive catarrh from the respiratory tract (Drew 2002, Tancred 2006), although clinical research is not available to confirm its efficacy.

**OTHER USES**

It has been used traditionally to treat both bronchial and urinary infections, joint and tissue inflammations, as well as treating gallbladder disorders, reducing oedema and as an abortifacient (Skidmore-Roth 2001).

An in vivo study in mice demonstrated that allyl isothiocyanate markedly inhibited the formation of gastric lesions (Matsuda et al 2007).

**DOSAGE RANGE**

- The typical dose of horseradish is 2–20 g/day of the root or equivalent preparations.
- Topical preparations with a maximum of 2% mustard oil content are commonly used (Blumenthal et al 2000).

**ADVERSE REACTIONS**

Despite the potential for severe irritation, horseradish is generally recognised as safe for human consumption in quantities used as food. Consuming large amounts of horseradish can cause gastrointestinal upset, vomiting and diarrhoea, and irritation of mucous membranes. Skin contact with fresh horseradish can cause irritation and blistering or allergic reactions. If used topically it should be diluted 50% with water and not applied for prolonged periods. Application to a small test area before wider application is recommended for people with sensitive skin.

**Practice points/Patient counselling**

- Horseradish has been used as a vegetable, condiment, diuretic and treatment for bronchial and urinary infections, joint and tissue inflammation and swelling.
- It is widely used together with other herbal ingredients, such as garlic, as a decongestant in the treatment of colds and sinusitis.
- No scientific investigation has been undertaken to support its use, although anecdotal evidence suggests that it may be useful.
- Horseradish is generally safe when the root is ingested in usual dietary amounts, although excessive intake may cause irritation to the stomach, respiratory tract and kidneys.

**SIGNIFICANT INTERACTIONS**

None known.

**CONTRAINDICATIONS AND PRECAUTIONS**

Internal use should be avoided in people with stomach and intestinal ulcers and kidney disorders, as well as in children under the age of 4 years (Blumenthal et al 2000).

Traditionally, horseradish is considered a warming herb that will exacerbate any 'hot' condition and is specifically indicated for 'cold' conditions.

**PREGNANCY USE**

The mustard oils released upon crushing are potentially toxic, therefore doses exceeding dietary intakes are contraindicated (Newell et al 1996).

**PATIENTS' FAQs****What will this herb do for me?**

Anecdotal evidence suggests that it may have decongestant effects and is a very popular treatment when combined with other herbs, such as garlic, to relieve the symptoms of colds and sinusitis.

**When will it start to work?**

It may relieve symptoms within the first few doses, but scientific tests are not available to confirm this.

**Are there any safety issues?**

Horseradish can be quite irritating for some people due to its bitter and pungent characteristics.

## Iodine

### BACKGROUND AND RELEVANT PHARMACOKINETICS

Iodine is an essential trace element required for proper functioning of the thyroid gland. It is mainly consumed as iodide salts obtained from sea salt, shellfish and seawater fish and vegetables, which are more bioavailable than the organic forms. The iodine content of soil is considered to be one of the most variable of all minerals, influenced by local geography and the type and quantity of fertiliser used in agriculture (Groff et al 2009). There is evidence of iodine-deficient soils in many regions of Australia. Dietary iodine content is also significantly influenced by agricultural iodine-containing compounds, used in irrigation products, fertiliser and livestock feeds (Zimmermann et al 2008).

Iodide is rapidly absorbed from the stomach to the small intestine and distributed via the blood to a range of tissues, most notably the thyroid, which traps iodide through an ATP-dependent iodide pump called the sodium iodide symporter. The thyroid contains 80% of the body's iodine pool, which is approximately 15 mg in adults. Also found in high concentrations in the salivary, gastric and mammary glands (exclusively during pregnancy and lactation in the latter), iodine's uptake is regulated by thyroid-stimulating hormone (TSH) (Groff et al 2009, Kohlmeier 2003).

Excess iodine is excreted via the kidneys when the needs of the thyroid have been met (Kohlmeier 2003), therefore urine concentrations are used as a means of assessing iodine status. Interestingly, there is no renal conservation mechanism for this mineral and the only evidence of iodine preservation comes from the scavenging and recycling of thyroid hormones by the selenium-dependent deiodinase DII (Kohlmeier 2003). Of the total amount excreted, 20% occurs via faeces and additional losses can occur through sweat, which, although a minor eliminatory

pathway under normal circumstances, can be a significant contributor for people living in hot climates with low dietary consumption (Groff et al 2009).

### FOOD SOURCES

Iodine can occur in foods as either an inorganic or organic salt, or as thyroxine in animal sources. Unlike many other essential nutrients, the organic form of iodine found in animal products has poor bioavailability, whereas the iodide salts found in the sea are almost completely absorbed (Jones 2002).

However, irrespective of whether it is animal or plant derived, food from the land has enormous variability in terms of iodine content, from 1 to 10 microgram/kg (Geissler & Powers 2005), due to iodine's high solubility and therefore susceptibility to leaching (Wahlqvist 2002).

Additionally, chemicals known as goitrogens are naturally found in some foods (e.g. brassica [cabbage] family), and these interfere with iodine utilisation and thyroid hormone production.

### Best sources

Due to the high saltwater levels of bioavailable iodide, all sea-dwelling creatures, animal or plant, are considered as superior dietary sources.

- Seawater fish
- Shellfish
- Sea vegetables such as seaweeds
- Iodised salt (fortified form of table salt) — providing 20–40 microgram/g
- Recommended for use in Australia by the Foods Standard Australia New Zealand
- Commercially manufactured breads due to the iodate dough oxidisers
- Dairy milk (variable)

In Australia, milk no longer supplies a significant amount of iodine, whereas in the United Kingdom

it is still an important dietary source because of the use of both supplemented feeds and iodine-based antiseptics in the dairy industry (Geissler & Powers 2005).

## DEFICIENCY SIGNS AND SYMPTOMS

### Primary deficiency

Iodine status is considered optimal in a population if the median urinary iodine concentration (MUIC) lies between 100 and 200 micrograms/L. An MUIC of between 50 and 100 micrograms/L is defined as a mild iodine deficiency; 29–49 micrograms/L as moderate deficiency and <20 micrograms/L as severe iodine deficiency. Intervention, such as fortification of salt, is recommended where a population MUIC is <100 micrograms/L. Urinary iodine concentration alone is not however considered an accurate measure of individual iodine status due to high intra-individual variability (Australian Population Health Development Principal Committee [APHDPC] 2007).

Inadequate intake of iodine leads to a decreased thyroid function which results in a collection of physical and mental disorders referred to as 'iodine deficiency disorders' (IDD). These disorders range from being mild to life-threatening (Groff et al 2009, Eastman 2012). A normal adult thyroid contains up to 20 mg of iodine, but this may drop as low as 20 micrograms in cases of chronic iodine deficiency (Zimmerman 2011).

In situations of moderate iodine deficiency, TSH induces thyroid hypertrophy in order to concentrate iodide, resulting in goitre. Most of these cases remain euthyroid, but in cases of severe iodine deficiency, myxoedema may result in adults and cretinism in infants, both of which are serious conditions.

Myxoedema is characterised by swelling of the hands, face, feet and peri-orbital tissues and can lead to coma and death if sufficiently severe and left untreated. Endemic cretinism is divided into two forms, neurological or myxoedematous, depending on the interplay of genetics and iodine deficiency. Usually, children with neurological cretinism are mentally deficient and often deaf-mute, but of normal height and strength and may have goitre. Myxoedematous cretinism is characterised by dwarfism, mental deficiency, dry skin, large tongue, umbilical hernia, muscular incoordination and puffy facial features. Concomitant selenium deficiency may be a contributing factor in myxoedematous cretinism. Early treatment with thyroid hormone supplementation can promote normal physical growth; however, intellectual disability may not be prevented and in very severe cases death may ensue.

Although severe iodine deficiency is rare in Australia and New Zealand, the Australian Population Health Development Principal Committee reports a high incidence of mild to moderate iodine deficiency in primary-school-aged children in Australia

and New Zealand (APHDPC 2007). Many parts of the world have notoriously low iodine levels, which is attributed to factors such as depletion in soils, low intake of iodised salt and fish farming practices (Kotsirilos et al 2011). Countries where iodine deficiency is a primary concern include China, Latin America, Southeast Asia and the eastern Mediterranean (Wahlqvist 2002). A report conducted by the World Health Organization in 2007 found that while many countries had succeeded in reaching optimal iodine nutrition through enhanced monitoring and fortification programs over the past decade, worldwide, an estimated almost 2 billion people still have insufficient iodine intakes, including one-third of all school-going children (Zimmerman 2011). Iodine deficiency is considered the single most important cause of preventable mental retardation and brain damage worldwide (APHDPC 2007).

### Fetal deficiency

The fetus depends solely on maternal thyroid hormones during the first trimester of pregnancy (Soldin et al 2002) and iodine deficiency uncorrected prior to mid-gestation results in irreversible brain damage (de Escobar et al 2007). To accommodate for this, increasing plasma volume, renal clearance and the increased thyroid hormone degradation secondary to hyperactivity of the uterine-placental deiodinases, healthy pregnant women exhibit a surge in T<sub>4</sub> production, partly under the stimulation of human chorionic gonadotrophin (HCG). From week 11 of gestation, fetal thyroid hormone synthesis usually begins, still dependent on maternal provision of iodine and at term a residual 20–40% of T<sub>4</sub> found in cord blood is of maternal origin (de Escobar et al 2008, Delange 2007, Glinoe 2007, Zimmermann 2008). These demands necessitate an approximately 100% increase (e.g. 250–300 microgram/day) (de Escobar et al 2008, Delange 2007) in maternal iodine intake from conception and throughout the pregnancy. Should such needs go unmet, the mother will adapt by preferentially producing T<sub>3</sub> to stave off both clinical and biochemical hypothyroidism. The fetus, however, yet to develop rapid adaptations to circulating iodine levels, will exhibit reductions of all thyroid hormones and develop hypothyroidism in spite of the mother's euthyroid state (de Escobar et al 2008).

Adequate iodine and healthy functioning of both the maternal and the fetal thyroid glands play a critical role in fetal neuropsychological development, due to its role in neuronal migration and myelination, with brain damage risk secondary to a deficiency, peaking in the second trimester and the early neonatal period. Studies have also confirmed that 'mild but measurable' psychomotor deficits in early childhood can result from subclinical hypothyroidism and hypothyroxaemia caused by mild-to-moderate iodine deficiency in pregnancy (Glinoe 2007, Soldin et al 2002). Finally, severe iodine deficiency during pregnancy also increases risk of

stillbirths, miscarriage, perinatal mortality and congenital abnormalities (Zimmermann 2008).

Because of the severe neurological consequences of untreated congenital hypothyroidism, neonatal screening programs have been established in some developed countries; however, early or pre-pregnancy detection of subclinical iodine deficiency would be most effective (Ares et al 2008).

#### Premature infant deficiency

Premature infants face a significantly elevated risk of iodine deficiency secondary to a collusion of factors: interruption of maternal supply (small amounts of breast milk provide substantially smaller quantities of iodine than placental transfer), immaturity of the hypothalamic pituitary thyroid axis and the deiodinase systems, maternal antibodies and postnatal exposure to drugs (e.g. dopamine, heparin, corticosteroids) (Ares et al 2008). Research suggests that 75% of premature neonates demonstrate a negative iodine balance at 5 days post-partum prior to intentional repletion.

#### Secondary deficiency

High consumption of goitrogens can induce a secondary deficiency state. Goitrogens are substances that inhibit iodine metabolism and include thiocyanates found in the cabbage family (e.g. cabbage, kale, cauliflower, broccoli, turnips and Brussels sprouts) and in linseed, cassava, millet, soybean and competing entities, such as other members of the halogen family (e.g. bromine, fluorine and lithium, as well as arsenic) (Groff et al 2009). Most researchers agree, however, that moderate intake of goitrogens in the diet is not an issue, except when accompanied by low iodine consumption (Groff et al 2009, Kohlmeier 2003). A very rare cause of secondary iodine deficiency and hypothyroidism is TSH deficiency.

#### Low selenium intake

Low dietary intake of selenium is a factor that exacerbates the effects of iodine deficiency. Selenium is found in the thyroid gland in high concentrations, and while iodine is required for thyroid hormone synthesis, selenium-dependent enzymes are required for the peripheral conversion of thyroxine ( $T_4$ ) to its biologically active form triiodothyronine ( $T_3$ ) (Higdon 2003), as well as the general recycling of iodine. Selenium deficiency results in decreased  $T_4$  catabolism, which leads to increased production of peroxide and thyroid cell destruction, fibrosis and functional failure.

### SIGNS AND SYMPTOMS

Overall, in addition to highly visible goitre, moderate-to-severe iodine deficiency produces subtle but widespread effects secondary to hypothyroidism, including reduced educability, apathy and impaired productivity, culminating ultimately in poor social and economic development (Zimmermann 2008).

#### Mild hypothyroidism

This refers to biochemical evidence of thyroid hormone deficiency in patients who have few or no apparent clinical features of hypothyroidism. Current literature does not adequately describe the health consequences of a mild iodine deficiency, although there is reasonable evidence of an association between a mild iodine deficiency and suboptimal neurological development in children such as a reduced IQ.

#### Congenital hypothyroidism

The majority of infants appear normal at birth and <10% are diagnosed with hypothyroidism based on the following clinical features:

- prolonged jaundice
- feeding problems
- hypotonia
- enlarged tongue
- delayed bone maturation
- umbilical hernia.

Importantly, permanent neurological damage results if treatment is delayed.

#### Adult hypothyroidism

According to Beers (2005), the clinical signs of hypothyroidism in adults are as follows:

- weakness, tiredness and sleepiness
- dry skin
- cold intolerance
- hair loss and diffuse alopecia
- poor memory and difficulty concentrating
- constipation
- reduced appetite and weight gain
- dyspnoea
- hoarse voice
- increased susceptibility to infectious diseases
- increased susceptibility to cardiovascular diseases
- paraesthesia
- puffy hands, feet and face and peripheral oedema
- impaired hearing
- menorrhagia (later amenorrhoea)
- carpal tunnel and other entrapment syndromes are common, as is impairment of muscle function with stiffness, cramps and pain
- reduced myocardial contractility and pulse rate, leading to a reduced stroke volume and bradycardia.

In adults, mild–moderate iodine deficiency also results in higher rates of more aggressive subtypes of thyroid cancer and an increased risk of (non) toxic goitre (Zimmermann 2008).

### MAIN ACTIONS

#### Thyroid hormone production

Iodine is essential for the manufacture of  $T_4$  and  $T_3$ , which are hormones that influence growth, maturation, thermogenesis, oxidation, myelination of the CNS and the metabolism of all tissues (Jones 2002). The thyroid hormones, especially  $T_3$ , exert their effects by binding to nuclear receptors on cell

surfaces, which in turn trigger binding of the zinc fingers of the receptor protein to the DNA (Groff et al 2009).

### OTHER ACTIONS

Due to the concentration of appreciable iodine levels in a range of other tissues, including salivary, gastric and lactating mammary glands, and the ovaries, questions remain about potential additional actions of iodine. One hypothesis postulates iodine as an indirect antioxidant, via its capacity to reduce elevated TSH, a trigger of increased peroxide levels in the body (Smyth 2003).

### CLINICAL USE

Increased iodine intake can be achieved through dietary modification and supplementation with tablets. Dietary modification usually refers to increased intake of iodised salt, but may also refer to use of iodised water, iodised vegetable oil or seafood or the use of iodised salt in bread manufacture.

### Treatment and prevention of deficiency

Iodine deficiency is accepted as the most common cause of brain damage worldwide, with IDD affecting 740 million people (Higdon 2003). Although it is well accepted that severe deficiency is responsible, evidence is now emerging that mild deficiency during pregnancy is also important and can have subtle effects on brain development, lowering intellectual functioning and inducing psychomotor deficits in early childhood (Glinoe 2007). Preliminary data are also emerging to suggest an association between iodine deficiency hypothyroidism of pregnancy and the incidence of attention-deficit/hyperactivity disorder (ADHD) in the offspring; however, this still requires confirmation in larger studies (Soldin et al 2002, Vermiglio et al 2004).

### Pregnancy

Severe iodine deficiency is uncommon in Western countries, such as Australia and New Zealand, but several local surveys have identified that mild-to-moderate deficiency is more prevalent than once thought. The published studies on iodine status in pregnant Australians are limited to New South Wales, Victoria and Tasmania; however, the results are of concern as they consistently suggest that iodine intake is inadequate, with median urinary iodine concentrations (MUIC) ranging from 47–104 micrograms/L, well below the adequate range of 150–249 micrograms/L as defined by WHO for pregnant women (APHPDC 2007).

A research group at Monash Medical Centre in Melbourne screened 802 pregnant women and found that 48.4% of Caucasian women had urinary iodine concentration (UIC) below 50 microgram/L compared to 38.4% of Vietnamese women and 40.8% of Indian/Sri Lankan women (Hamrosi et al 2005). A study conducted at a Sydney hospital involving 81 women attending a 'high' risk clinic found moderate-to-severe iodine deficiency in

18.8% of subjects and mild iodine deficiency in another 29.6% (Gunton et al 1999), the former clearly too close to the WHO maximum acceptable level of 20%. This study also revealed that almost 5% of the sample had MUIC < 25 microgram/L.

Aside from fortification programs in populations affected by severe iodine deficiency, there have been several RCTs of iodine supplementation in mild-to-moderately deficient pregnant women (Zimmermann 2008). While treatment effects include reductions in maternal and newborn thyroid size and, in some, reduced maternal TSH, none of the studies have demonstrated a positive effect on T<sub>4</sub> and T<sub>3</sub> of mother or child, or measured longer term clinical outcomes. Future research needs to address these issues.

### Infants

An investigation of infant TSH levels within 72 hours of birth at the Royal North Shore Hospital in Sydney suggests that endemic IDD may be emerging (McElduff et al 2002). Currently, the WHO recommends that less than 3% of newborns should have TSH levels greater than 5 mIU/L and of the 1773 infants enrolled in the study, 5–10% had a TSH reading > 5 mIU/L.

### Children and adolescents

Evidence of iodine deficiency has also been demonstrated in Australian schoolchildren (Li et al 2006). Iodine status in schoolchildren is based on median UIC values and is categorised as normal (UIE ≥ 100 microgram/L), or as mild (UIE 50–99 microgram/L), moderate (UIE 20–49 microgram/L) or severe deficiency (UIE < 20 microgram/L). The UIC is considered in combination with the child's sex, year of school and presence of goitre.

A study of Melbourne schoolchildren aged 11–18 years found that 76% (439/577) had abnormal UIC values, with 27% (156/577) possessing values consistent with moderate-to-severe iodine deficiency (McDonnell et al 2003). The median UIC value in girls was lower than that in boys (64 microgram/L vs 82 microgram/L), and girls had significantly lower UIC values overall ( $P < 0.002$ ). A study of 324 schoolchildren aged 5–13 years from the Central Coast of New South Wales produced similar results; there was a median UIC concentration of 82 microgram/L, with 14% of children having levels below 50 microgram/L (Guttikonda et al 2003).

These findings were confirmed in the Australian National Iodine Nutrition Study, which identified inadequate iodine intake in the Australian population and called for the urgent implementation of mandatory iodisation of all edible salt in Australia (Li et al 2006). The study consisted of a survey of 1709 schoolchildren aged 8–10 years in the five mainland Australian States and was conducted between July 2003 and December 2004. It found that, overall, children in mainland Australia are borderline iodine deficient, with a national median UIC of 104 microgram/L. On a state basis, children

in Victoria and New South Wales are mildly iodine deficient, with median UIC levels of 89 microgram/L and 73.5 microgram/L, respectively; South Australian children are borderline iodine deficient, with a median UIC of 101 microgram/L, whereas both Queensland and Western Australian children are iodine sufficient, with median UIC levels of 136.5 microgram/L and 142.5 microgram/L, respectively. Researchers attributed the decline in iodine intake to changes within the dairy industry, with chlorine-containing sanitisers now replacing iodine-containing sanitisers and a decreased intake of iodised salt.

In 2001, an iodine supplementation program was initiated in Tasmania because it was identified as an area of endemic goitre by the Department of Health Services. The program involves the use of iodised salt in 80% of Tasmania's bread production and aims to reduce the incidence of iodine deficiency. Despite encouraging preliminary data (Doyle & Seal 2003),

iodine levels are still inadequate according to the WHO standards. There have been conflicting opinions about the success of this program, with the largest study demonstrating evidence of ongoing iodine deficiency (Guttikonda et al 2002, Seal et al 2003).

Iodine deficiency in children and adolescents is associated with poorer school performance, reduced achievement motivation and a higher incidence of learning disabilities (Tiwari et al 1996, Zimmermann 2008). A meta-analysis of 18 studies from eight countries of people aged between 2 and 30 years showed that iodine deficiency alone reduced mean IQ scores by 13.5 points in children (Bleichrodt et al 1996). Iodine repletion studies in children have yielded improved somatic growth, partial reversal of cognitive impairment and normalisation of age of onset of puberty; however, the strength of the evidence is hampered by methodological issues (Markou et al 2008, Zimmermann et al 2006, Zimmermann 2008).

#### **Clinical note — Why is iodine deficiency on the rise?**

In spite of increased rates of household iodised salt use globally since 1990, iodine intakes in Australia are falling (Zimmermann 2008). The emergence or re-emergence of iodine deficiency, however, is not limited to Australia; median urinary iodine concentration had declined by more than 50% between 1971 and 1994 in the United States (Gunton et al 1999, Zimmermann 2008).

Several reasons have been proposed to explain the emergence of iodine deficiency in developed countries. Firstly, from the 1960s, milk had become an unplanned major dietary source of iodine due to residues left from sanitising agents used in the dairy industry. However, from the 1990s, the use of iodine-containing sanitisers were gradually replaced with chlorine-containing substitutes and better practice standards, resulting in significantly reduced iodine concentrations in milk. The significance of this change within the dairy industry was recently shown by Li et al (2006), who compared the iodine content of Australian milk products from 1975 and 2004. The researchers identified mean iodine concentrations of 593.5 microgram/L and 583 microgram/L from samples taken from Victoria and New South Wales (NSW), respectively in 1975 compared to a median concentration of 195 microgram/L in 2004 (250 mL providing 50–60 microgram iodine). Interestingly, the same researchers demonstrated that dairy products and water in northern and central Queensland contained higher iodine levels, which may explain the lower incidence of iodine deficiency in these areas (Li et al 2006). In spite of this, a survey of dietary habits of Tasmanian schoolchildren has revealed that consumption of dairy products is associated with improved iodine status (Hynes et al 2004), a case of some being better than none.

A second reason may relate to public health campaigns that have resulted in increased awareness of the potential adverse effects of salt and reduced its consumption, but failed to highlight the potential benefits of a moderate intake of iodised salt. The last decade has also seen the use of non-iodised rock salt in salt-grinders becoming more fashionable than the use of traditional iodised salt, although in recent years, iodised rock salt has become available. In addition, few food manufacturers use iodised salt in their products, further reducing exposure to iodine (Gunton et al 1999). The trend towards an increased consumption of processed foods has also impacted on iodine status, as only 0.5% of salt used in commercial manufacture is iodised.

Lastly, the mineral depletion of soils is another possible contributing factor, in particular, the depletion of selenium. Due to its role in iodine utilisation, a selenium deficiency would potentiate the effects of an iodine deficiency. Flooding, erosion and glaciation have also contributed to leaching of iodine from soil.

Other theoretical considerations include increased environmental exposure to halogens, such as fluorine and chlorine, and increased consumption of goitrogens, such as soy, in the diet.

Although identifying the key factors responsible for the increased incidence of iodine deficiency is important (Thomson 2004), many authors argue that implementation of national iodine monitoring and surveillance of the iodine content in foods are the most immediate concern (Li et al 2006, McDonnell et al 2003). Lessons learnt from Tasmania's iodine supplementation program, where statewide bread fortification failed to reduce the prevalence of iodine deficiency in children, indicate that greater efforts are required to create significant improvements in iodine status.

## Adults

A study of non-pregnant adults in 1999 demonstrated iodine deficiency in 26.3% of 'healthy' subjects and 34.1% of diabetic subjects (Gunton et al 1999).

## Non-toxic goitre thyroidectomy

One 12-month study involving 139 patients who had undergone thyroidectomy for non-toxic goitre identified that supplementing L-thyroxine therapy with iodised salt produced significant improvements in thyroid function compared with stand-alone L-thyroxine therapy (Carella et al 2002).

## Antiseptic

Iodine solution has been used as a topical antiseptic in the treatment of superficial wounds for more than a century and is still widely used for this indication. It is a highly effective method of decontaminating intact skin and minor wounds and has a low toxicity profile. Povidone-iodine preparations have replaced older iodine solutions and are now the most commonly used form. Results from a systematic review of 27 randomised clinical trials on chronic and acute wound care demonstrated that iodine shows either equivalent or superior benefits to both non-antiseptic wound dressings (paraffin dressings, dextranomer or zinc paste) and other antiseptic agents (silver sulfadiazine cream or chlorhexidine dressings). The review also noted that use of topical iodine did not adversely affect thyroid function, cause significant allergic responses or reduce the speed of wound healing (Vermeulen et al 2010). Povidone-iodine has also been shown to be an effective disinfectant in ocular surgery as well as being an oral antibacterial agent.

Although the treatment is considered safe, a number of reports of iodine toxicity in newborns receiving ongoing treatment with topical iodine-based solutions suggest that it should be used with caution as an ongoing treatment in this group and TSH monitoring considered where appropriate.

## Water purification

Iodine-releasing tablets and iodine tincture have been used for many years to decontaminate water and have been used by the United States Army since World War II. A weak aqueous solution of 3–5 ppm of elemental iodine can destroy a wide range of enteroviruses, amoebae and their cysts, bacteria and algae. Under temperate conditions of 25°C, the disinfection process takes 15 minutes, and longer in colder conditions. Adding to the versatility of iodine as a water decontamination agent is its ability to act over a wide range of pH and still be effective in the presence of ammonia and amino ions from nitrogenous wastes that may be also present in the water (Kahn & Visscher 1975). Heiner et al (2010) reported that a 10% povidone-iodine (PVI) solution at a concentration of at least 1:1000 in water is an effective bactericidal agent against *Escherichia coli* (*E. coli*), which is the most common cause of

traveller's diarrhoea. Disinfection of the water occurred after 15 minutes of contact time with the iodine.

## OTHER USES

### Fibrocystic breast disease and cyclic mastalgia

A 1993 review that focused on three clinical studies suggested that iodine supplementation may improve objective and subjective outcomes, including pain and fibrosis, for women with fibrocystic breast disease and cyclic mastalgia (Ghent et al 1993). Together the trials involved 1000 women and used a variety of different forms, the most successful being molecular iodine at a dose of 0.08 mg/kg (approximately equivalent to 500 microgram/day in a 60 kg woman) (Ghent et al 1993).

Recently, a placebo-controlled trial conducted with 11 euthyroid women with cyclic mastalgia tested different doses of molecular iodine ranging from 1.5 to 6 mg/day and showed that after 3 months of treatment, 50% of patients consuming 3 or 6 mg/day experienced a significant decrease in pain (Kessler 2004). Although no dose-related adverse events were detected, further investigation is required to confirm both efficacy and safety.

### Breast cancer

There is suggestive evidence of a preventive role for iodine in breast cancer. As far back as 1896, research suggested a link between iodine deficiency, thyroid disease and breast cancer (Gago-Dominguez & Castelao 2008, Smyth 2003, Stoddard et al 2008). Epidemiological data have demonstrated a correlation between increased incidence of breast cancer and a range of thyroid conditions, most notably hypothyroidism, with both conditions demonstrating peak incidence in postmenopausal women (Gago-Dominguez & Castelao 2008, Smyth 2003). A prospective study of peri- and postmenopausal women revealed that low free T<sub>4</sub> was an independent risk for the development of breast cancer (OR 2.3). Another study found that the premenopausal women treated for differentiated thyroid cancer with radioactive iodine were at an increased risk of developing breast cancer over the following 5–20 years (Gago-Dominguez & Castelao 2008). In addition, the observed low rates of breast cancer in Japanese women consuming a traditional diet are speculated to be partly due to a high dietary iodine intake, further suggesting a protective effect (Patrick 2008). Notably, this protection disappears when Japanese women consume a 'Western diet'.

It is noteworthy that both the thyroid and the breast share the capacity to concentrate iodide, which exerts both an oxidant effect, triggering and facilitating apoptosis, and antioxidant effect, protecting cells from peroxidative damage (Gago-Dominguez & Castelao 2008, Venturi 2001) and converting it to iodine. The thyroid retains this capacity throughout life, whereas the healthy breast can only concentrate iodide during pregnancy and

lactation; states associated with a reduced risk of breast cancer. Curiously, approximately 80% of breast cancers also demonstrate iodide uptake (Stoddard et al 2008). It has been theorised that with iodine insufficiency during pregnancy and lactation, the protective effect of iodide may be compromised, concomitant with diminished oxidant and antioxidant activities. Researchers speculate that this scenario may be compounded by co-existing selenium deficiency (Turken et al 2003).

Besides the diminished antioxidant effect, studies with animal models show that iodine deficiency results in changes in the mammary gland that make it more sensitive to the effects of oestradiol (Stoddard et al 2008, Strum 1979). Iodine has been implicated in the synthesis of alpha-oestrogen receptors, down-regulation of several oestrogen-responsive genes and increased expression of the cytochrome P450 genes responsible for its phase I detoxification (Stoddard et al 2008). Together with other sources of evidence, it is clear that the potential protective effect of iodine against breast cancer is independent of its thyroid role (Stoddard et al 2008).

At present, the only interventional evidence comes from rat studies, demonstrating that administration of Lugol's iodine or iodine-rich Wakame seaweed suppressed the development of induced mammary tumours (Funahashi et al 2001) and in vitro evidence confirming that molecular iodine induces apoptosis in breast cancer cell lines (Shrivastava et al 2006). In light of ongoing evidence of a superior effect of molecular iodine rather than iodide in relation to breast pathology in both animals and humans, rigorous human studies using this form are required (Patrick 2008, Stoddard et al 2008).

### Prevention of attention-deficit hyperactivity disorder

Emerging data from research conducted over the past 15 years suggest a possible link between low maternal iodine status and increased risk of ADHD in the offspring. According to a report published in 2004, 11 of 16 children born to women living in a moderately iodine-deficient region in Italy developed ADHD compared to no offspring from the 11 control mothers living in a marginally iodine-deficient region (Vermiglio et al 2004).

On the other hand, another group of researchers investigated whether  $T_4$  levels at birth could represent a biomarker for later development of ADHD and found that all newborns in the sample had  $T_4$  within the normal range and no correlation between values and risk could be demonstrated (Soldin et al 2002, Soldin et al 2003). This evidence invalidated TSH levels as a biomarker of risk, but does not disprove a link between iodine and ADHD, as earlier studies found that those newborns who later developed ADHD were all euthyroid at birth (Vermiglio et al 2004).

Although further investigation is required to clarify these observations, they have provided a new avenue for ADHD research.

## DOSAGE RANGE

### Australia and New Zealand recommended daily intake (RDI)

- Infants
  - 0–6 months: 90 microgram/day.
  - 7–12 months: 110 microgram/day.
- Children
  - 1–3 years: 90 microgram/day.
  - 4–8 years: 90 microgram/day.
  - 9–14 years: 120 microgram/day.
  - >14 years: 150 microgram/day.
- Adults: 150 microgram/day.
- Pregnancy: 220 microgram/day.
- Lactation: 270 microgram/day.
- Upper level of intake
  - 1–3 years: 200 microgram/day.
  - 4–8 years: 300 microgram/day.
  - 9–13 years: 600 microgram/day.
  - 14–18 years (including pregnancy, lactation): 900 microgram/day.
  - Adults >18 years (including pregnancy, lactation): 1100 microgram/day.

These are the revised Australian RDIs (2006), which are more closely aligned with the WHO recommendations than previously.

### According to clinical studies

- ADHD prevention: adequate intake to prevent maternal deficiency (approximately 250 microgram/day)
- Topical antimicrobial: Various concentrations have been used depending on site, type and severity of the wound, with a range of 2–10% povidone-iodine being the most commonly used.
- Fibrocystic breast disease and cyclic mastalgia: 1.5–6 mg iodine/day for 6–18 months.
- Breast cancer prevention: dose is unknown; however, it is suggested that women meet RDI to prevent deficiency.
- Water disinfectant: Widely used practice suggests 3–10 drops iodine tincture per litre of water provides an antibacterial effect after 15 minutes.

## TOXICITY

Chronic iodine toxicity results when iodide intake is approximately 2 mg daily or greater (Beers 2005). Overconsumption of iodine can cause gastrointestinal irritation, abdominal pain, nausea, vomiting and diarrhoea, cardiovascular symptoms and can induce both hypo- and hyperthyroidism, depending on the patient's preexisting susceptibility (Wahlqvist 2002, Zimmermann 2008). Excess iodine during pregnancy has also been associated with increased risk of postpartum thyroiditis (Guan et al 2005). Alternatively, there are many cases in which excesses have been tolerated without any overt consequences, particularly in individuals with healthy thyroid function (Geissler & Powers 2005, Groff et al 2009, Zimmermann 2008). Chronic ingestion of  $\geq 500$

microgram/day by children has resulted in increased thyroid size (Zimmermann 2008). Intake of very high doses can lead to a brassy taste in the mouth, increased salivation, gastric irritation and acneiform skin lesions.

## SIGNIFICANT INTERACTIONS

### Goitrogens

These are substances that interfere with iodine utilisation, uptake into the thyroid or thyroid hormone production. These include thiocyanates found in the cabbage family (e.g. cabbage, kale, cauliflower, broccoli, turnips and Brussels sprouts) and in linseed, cassava, millet and soybean — separate intake of iodine and goitrogens where possible. Smoking has also been shown to increase thiocyanate levels and reduce iodine content in the breast-milk of smoking mothers (Zimmermann et al 2008). Other chemical goitrogens include perchlorate and disulphides, the latter from coal processes and there is accumulating evidence of thyroid endocrine disruptors in the form of ingredients used in cosmetics, as pesticides or plasticisers. Major targets are the sodium-iodide symporter (NIS), the haemoprotein thyroperoxidase (TPO), the T<sub>4</sub> distributor protein transthyretin (TTR) and the deiodinases (Köhrle 2008).

### Soy

The actions of this particular goitrogen are twofold: ingestion of soy appears to inhibit iodine absorption to some extent (particularly when presented in its thyroxine form in the gut) and also high levels of the isoflavones, genistein and daidzein, can inhibit T<sub>3</sub> and T<sub>4</sub> production — separate intake of iodine and goitrogens where possible. Particular attention should be paid to minimising soy consumption in individuals taking thyroid hormone supplementation, as it has been shown that soy consumption can increase dosage requirements.

### Selenium

Selenium is intrinsic to the metabolism and activity of the thyroid hormones, facilitating the conversion of T<sub>4</sub> to T<sub>3</sub> and is also responsible for the only iodine recycling pathway of the body through the action of the deiodinases on excess or unnecessary thyroid hormones to release the iodine — beneficial interaction.

## CONTRAINDICATIONS AND PRECAUTIONS

### Thyroid conditions

Due to the complex and diverse causes of thyroid conditions, it is advised that iodine supplementation should be avoided unless under the supervision of a medical practitioner.

## Practice points/Patient counselling

- Iodine is an essential trace element required for healthy functioning of the thyroid gland and for normal growth and development.
- It is mainly consumed as iodide salts from sea salt, shellfish, seawater fish and vegetables.
- Iodine is essential for the manufacture of thyroxine (T<sub>4</sub>) and liothyronine (T<sub>3</sub>), which are hormones that influence growth, maturation, thermogenesis, oxidation, myelination of the CNS and the metabolism of all tissues (Jones 2002).
- Iodine supplementation is commonly used to prevent and treat deficiency. There is also some evidence that it may reduce pain in fibrocystic breast disease and cyclic mastalgia and suggestive evidence of a protective role against breast cancer; however, rigorous research is required to confirm these observations.
- Current evidence points to widespread mild-to-moderate iodine deficiency in Australia, suggesting that dietary intake is inadequate and supplementation or fortification of foods with additional iodine may be required. Use of iodised salt is recommended.

## PREGNANCY USE

Up until 2006, the Australian recommended daily intake of iodine was 150 micrograms for pregnant women and 170 micrograms for lactating women; however, reflecting new research, the Australian RDI levels for pregnancy and lactation have been revised and increased to 220 micrograms and 270 micrograms respectively. Care should be taken to avoid ingestion of excessive amounts during pregnancy due to suspected links with increased rates of postpartum thyroiditis and other disorders of thyroid function (Guan et al 2005).

## PATIENTS' FAQs

### What will this supplement do for me?

Adequate intake of iodine is critical for healthy thyroid function and normal growth and development. Ensuring adequate intake becomes critical during pregnancy and breastfeeding when the infant is solely dependent on the mother's intake for normal growth and brain development. Currently, there is some suggestive evidence that adequate iodine particularly during the female reproductive years may be protective against breast cancer and supplementation may relieve symptoms of breast pain in fibrocystic breast disease and cyclic mastalgia.

### When will it start to work?

The time frames depend on the indication it is being used to treat and the level of deficiency. In

the case of breast pain, studies suggest that 3 months of treatment are required to attain significant symptom relief.

### Are there any safety issues?

People with preexisting thyroid conditions should only increase iodine intake under professional supervision. Doses in excess of the RDI should be avoided unless under the supervision of a medical practitioner.

# Iron

## BACKGROUND AND RELEVANT PHARMACOKINETICS

Iron is an essential mineral, vital to human health. The average human body contains 2–4 g of iron. Iron is found in the body in: haemoglobin (65%); myoglobin (10%); enzymes (1–5%); with the remaining approximately 20% of body iron being found in storage or in the blood (Gropper & Smith 2013).

Although the metal exists in several oxidation states in nature, only the ferrous ( $\text{Fe}^{2+}$ ) and ferric ( $\text{Fe}^{3+}$ ) forms are stable in the aqueous environment of the body (Gropper & Smith 2013).

Iron is found in the haem form, which comes from animal sources, and the non-haem form, derived from plants and dairy products.

The haem form of iron is more soluble than the non-haem form and is absorbed 2–3 times more readily. Absorption of haem iron occurs across the brush border of the small intestine, especially in the proximal region, and is facilitated by haem carrier protein 1 (hcp1). Non-haem iron is bound to other substances in food when ingested, and must first be enzymatically released by gastric secretions such as hydrochloric acid and pepsin before absorption can occur. Non-haem iron in the ferrous form ( $\text{Fe}^{2+}$ ) is absorbed more readily than iron in the ferric ( $\text{Fe}^{3+}$ ) form, and occurs primarily in the duodenum with the aid of divalent mineral transporter 1. Iron in the ferric form ( $\text{Fe}^{3+}$ ) is susceptible to aggregation and precipitation in the alkaline environment of the small intestine which impairs absorption (Gropper & Smith 2013). Intestinal absorption of non-haem iron is influenced by a number of factors, as summarised below.

### Solubility enhancers of non-haem iron

- Acids (including ascorbic acid) aid solubility of non-haem iron, thus improving absorption; the addition of 20 mg ascorbic acid has been shown to increase non-haem iron absorption by 39% (Hallberg et al 2003)
- Sugars (e.g. fructose and sorbitol) aid absorption
- Mucin
- Meat stimulates digestive secretions, and breakdown products such as cysteine-containing peptides aid absorption (Hurrell et al 1988). The addition of red meat increases non-haem iron absorption by 85% (Hallberg et al 2003). This appears to be dose-dependent, as a study found that the addition of 60 g Danish pork meat three times daily improved the absorption of non-haem iron from 5.3% to 7.9% (Bach-Kristensen et al 2005), although the addition of smaller amounts was not as effective (Baech et al 2003)
- The addition of fish to a high-phytate bean meal has also been shown to increase iron absorption (Navas-Carretero et al 2008)
- Alcohol improves iron uptake. The consumption of up to two alcoholic drinks per day is associated with reduced risk of iron deficiency and more than two can increase the risk of iron overload (Ioannou et al 2004).

### Solubility inhibitors of non-haem iron

- Polyphenols, including tannin derivatives of gallic acid. A number of studies have shown that tea catechins can inhibit intestinal non-haem iron absorption (Ullmann et al 2005); however, polyphenols do not have chelating effects on cooked haem iron (Breet et al 2005). Overall, tea consumption has been reported to reduce non-haem iron absorption by 60% (Kaltwasser et al 1998) and coffee consumption by 40% when taken with or shortly after a meal (Gropper & Smith 2013). Recent studies suggest that impaired absorption is unlikely to be significant in people with normal iron stores (Breet et al 2005, Ullmann et al 2005). The addition of milk to tea may reduce the chelating effects.
- Phytic acid or phytates (whole grains, legumes, maize) (Gropper & Smith 2013)
- Oxalic acid (spinach, chard, chocolate, berries, tea) (Gropper & Smith 2013)
- Phosvitin, a protein found in egg yolks (Gropper & Smith 2013)
- Calcium — a transient inhibitory effect has been observed which does not occur with long-term high-dose calcium intake (Lonnerdal 2010). This includes calcium found in dairy foods, and other forms such as calcium phosphate, calcium citrate, calcium carbonate and calcium chloride; when consumed in amounts of 300–600 mg, it significantly impairs iron absorption (ferrous sulfate and dietary iron) (Gropper & Smith 2013)
- Zinc competes with iron for absorption (Gropper & Smith 2013) — inorganic zinc supplements may reduce iron absorption by 66–80% (Crofton et al 1989), and supplements containing both iron and zinc may not be as efficacious as the same doses given in isolation (Fischer Walker et al 2005, Lind et al 2003). Nutrients consumed in a meal may not be as affected (Whittaker 1998)
- Manganese may reduce absorption by 22–40% (Rossander-Hulten et al 1991)
- Rapid intestinal transit time (Gropper & Smith 2013)
- Malabsorption syndromes (Gropper & Smith 2013)
- *Helicobacter pylori* infection (Ciacci et al 2004, Duque et al 2010)

- Gastrointestinal blood loss (Higgins & Rockey 2003)
- Insufficient digestive secretions (including achlorhydria), or raised gastric pH due to age-related decrease in gastric acid production
- Antacids, H<sub>2</sub> antagonists and proton pump inhibitor drugs due to raising pH within the gastrointestinal tract.

Systemic and local mechanisms have also been identified which regulate iron absorption and play a role in iron homeostasis. Hcpicidin, a 25-amino-acid peptide, is the regulatory protein for systemic iron absorption from intestinal enterocytes as well as for the efflux of iron from macrophages. Factors that alter hepcidin levels, such as inflammation, infection and hypoxia, will in turn have an effect on iron levels, although exact mechanisms are yet to be fully elucidated. Local regulatory mechanisms involve an iron-responsive element/iron-regulatory protein system, which affects the regulation of proteins involved in iron metabolism. Disturbances in these local or systemic iron absorption regulatory mechanisms are implicated in both iron-loading and iron-deficiency disorders (Fuqua et al 2012).

#### **Clinical note — Factors affecting the absorption of iron**

If the dietary intake of iron is adequate, it is often assumed that a patient's iron levels will be within the normal range. In practice, this is not always the case as absorption is significantly affected by a number of factors, thereby increasing or decreasing the amount of ingested dietary iron that reaches the systemic circulation.

## **CHEMICAL COMPONENTS**

Ferrous sulfate is the most widely studied form and is generally considered the treatment of choice based on proven efficacy, cost and tolerability, especially when administered as oral sustained-release preparations (Santiago 2012). Other ferrous forms include ascorbate, carbonate, citrate, fumarate, gluconate, lactate, succinate and tartrate (non-haem iron). Iron from ferrous sulfate has a significantly greater bioavailability than ferrous glycine chelate or ferric ethylenediamine tetraacetic acid (EDTA) (Ferreira da Silva et al 2004). Other ferric forms include ammonium citrate, chloride, citrate, pyrophosphate and sulfate. Amino acid chelates, such as iron glycine, are also available. Dietary ferritin is as equally well absorbed as ferrous sulfate and therefore food sources are likely to be effective (Davila-Hicks et al 2004). Cooking in iron pots may also improve iron status (Geerligs et al 2003).

## **FOOD SOURCES**

The average Western diet is estimated to contain 5–7 mg iron/1000 kcal.

### **Haem iron**

About 50–60% of the iron in animal sources is in the haem form. Sources include liver, lean red meat,

poultry, fish, oysters, clams, shellfish, kidney and heart.

### **Non-haem iron**

This is found in plant and dairy products in the form of iron salts and makes up about 85% of the average intake. Sources include egg yolks, nuts, legumes, fruit, dried fruit, raisins, dark molasses, vegetables, including beetroot, grains and tofu. Dairy is a relatively poor source of iron.

A number of iron-fortified foods are also available and include wholegrain and enriched bread, pasta, cereal, soy sauce, Thai fish sauce, milk, orange juice and wines.

Considering that minerals such as calcium may reduce iron absorption, fortification of some foods may be relatively ineffectual unless absorption enhancers such as vitamin C are also included (Davidsson et al 1998).

## **DEFICIENCY SIGNS AND SYMPTOMS**

Iron deficiency is the most common and widespread nutritional disorder in the world, affecting approximately 1.6 billion people according to World Health Organization reports (de Benoist et al 2008). Iron deficiency may occur with or without anaemia (Gillespie et al 1991); however an estimated 50% of all anaemias worldwide are attributed to a deficiency in iron (Stoltzfus 2003).

The term iron deficiency is used when there are no iron stores that can be mobilised and there are signs of a compromised supply of iron to tissues; however this has not yet led to a low haemoglobin level and thus a classification of 'anaemia' (Ratthalli et al 2013). A mild deficiency, without anaemia, will still result in symptoms such as mood changes, poor concentration, fatigue and reduced physical performance and may still warrant iron replenishment, especially in vulnerable patient groups (Ratthalli et al 2013).

Iron-deficiency anaemia results when an ongoing iron deficiency results in reduced erythropoiesis and a drop in haemoglobin levels, which leads to a decrease in red blood cell count and mean corpuscle volume. The World Health Organization defines anaemia in terms of a haemoglobin concentration <13 g/dL for men and <12 g/dL for non-pregnant women. Iron-deficiency anaemia is associated with an increased risk of maternal and child mortality, especially in developing countries, and results in reduced work capacity and physical performance in adults, and in children leads to a reduced ability to learn and develop physically.

Signs and symptoms include:

- Fatigue and lethargy
- Decreased resistance to infection
- Cardiovascular and respiratory changes, which can progress to cardiac failure if left untreated
- Increased lead absorption, which in turn inhibits haem synthesis
- Decreased selenium and glutathione peroxidase levels

- Pale inside lower eyelid or mouth
- Pale-coloured nail bed
- Pale lines on stretched palm (palmar creases)
- Ridged, spoon-shaped, thin flat nails
- Brittle hair
- Impaired cognitive and motor function
- Adverse pregnancy outcomes and increased perinatal maternal mortality (NMCD 2005)
- Reduced thyroid function and ability to make thyroid hormones (Beard et al 1990)
- Difficulty maintaining body temperature in a cold environment.

### Risk groups for iron deficiency

The four main population groups that are most at risk of developing iron deficiency are:

1. Young children (6 months–4 years), due to factors such as inadequate dietary intake, inadequate reserves to meet physiological requirements, rapid growth phases, low iron content in milk
2. Adolescents, due to pubertal growth spurts and increased need to match expansion in mass of red blood cells
3. Women during child-bearing years, due to menstrual blood loss
4. Pregnant women, due to increased fetal demands, expanding blood volume and blood loss associated with childbirth (Groppe & Smith 2013).

### Primary deficiency

Primary deficiency is most common in vegetarians, the elderly, those with protein-calorie malnutrition, and during periods of increased iron requirement due to expanded blood volume in infancy, adolescence and pregnancy.

### Secondary deficiency

Underlying causes of iron-deficiency anaemia include blood loss, inefficient absorption due to gastrointestinal disturbances and increased destruction of red blood cells.

- Blood loss (menstruation, menorrhagia, bleeding haemorrhoids, parasites, bleeding peptic ulcer, malignancy, *Helicobacter pylori* infection, gastrointestinal bleeding due to medication such as non-steroidal anti-inflammatory drugs)
- Inefficient absorption (chronic gastrointestinal disturbances, malabsorption syndromes, coeliac disease) (Annibale et al 2001)
- Increased destruction of red blood cells (malaria, high-intensity exercise).

Note: The majority of iron utilised in erythropoiesis is provided by recovered iron from old erythrocytes (Handelman & Levin 2008), thus a failure in this system will also impact on iron status.

### MAIN ACTIONS

Iron plays a central role in many biochemical processes in the body.

### Clinical note — Testing for iron deficiency

In iron-deficiency anaemia, storage iron declines until the delivery of iron to bone marrow is insufficient for erythropoiesis to occur. In the early stages, blood tests will reveal low plasma ferritin, followed by decreased plasma iron and transferrin saturation, and ultimately low haemoglobin in red blood cells (Handelman & Levin 2008). As isolated haemoglobin has both low specificity and low sensitivity for determining iron status, the optimal diagnostic approach is to measure the serum ferritin as an index of iron stores and the serum transferrin receptor as an index of tissue iron deficiency (Cook 2005, Flesland et al 2004, Mei et al 2005). Iron deficiency is associated with a plasma ferritin concentration of <12 ng/mL. In the presence of infection or inflammation, however, plasma ferritin levels are a less reliable indicator of iron status. Inflammation or infection lead to a rise in plasma ferritin concentration and it may therefore still appear within normal range or high, even though iron levels are depleted (Groppe & Smith 2013).

### Oxygen transport and storage

The key function of iron is to facilitate oxygen transport by haemoglobin, the oxygen-carrying pigment of erythrocytes. It is also involved in oxygen storage by myoglobin, an iron-containing protein that transports and stores oxygen within muscle and releases it to meet increased metabolic demands during muscle contraction.

### Immunity

Iron is vital for the proliferation of all cells, including those of the immune system. In vitro and in vivo studies have indicated a link between iron deficiency and impaired T-lymphocyte proliferation. In anaemic children in Bolivia who received iron treatment for 3 months, the proportion of circulating immature T lymphocytes decreased from 18.3% to 9.2% (Sejas et al 2008).

Iron deficiency causes several defects in both humoral and cellular immunity (Bowlus 2003), including a reduction in peripheral T cells secondary to atrophy of the thymus and inhibition of thymocyte proliferation (Bowlus 2003) and a reduction in interleukin-2 (IL-2) production (Bergman et al 2004). Reduced IL-2 production may partly explain the increased susceptibility to infections and cancer in patients with iron-deficiency anaemia (Bergman et al 2004). Supplementation of ferrous sulfate (60 mg Fe) once daily for 8 weeks has been shown to reduce the incidence and duration of upper respiratory tract infections in children (De-Silva et al 2003).

However, there is also preliminary evidence that iron may be implicated in the pathogenesis of autoimmune disorders, including systemic lupus

erythematosus, scleroderma, type 1 diabetes, Goodpasture's syndrome, multiple sclerosis and rheumatoid arthritis (Bowlus 2003). A review conducted by Recalcati et al (2012) highlights the importance of macrophages in autoimmune diseases, and the potential role that iron retention may play in promoting the proinflammatory, pathogenic activity of M1 macrophages, rather than allowing for modulation by the anti-inflammatory action of M2 macrophages. In this way, iron accumulation in macrophages may potentially exacerbate autoimmune disease (Recalcati et al 2012).

### Protein and enzyme systems

Iron forms a part of several proteins and is a cofactor for many different enzymes. Processes in which iron plays a role include:

- Production of adenosine triphosphate and cellular respiration
- Amino acid metabolism (e.g. arginine, phenylalanine, tryptophan, tyrosine)
- Carbohydrate metabolism
- As a component of enzymes, including catalase, myeloperoxidase, thyroperoxidase and oxidoreductase, providing protection against free radical damage
- Synthesis of carnitine and niacin
- Synthesis of nitric oxide, which plays a role in blood pressure regulation, intestinal motility, macrophage function and inhibition of platelet aggregation
- Synthesis and function of hormones (e.g. thyroid hormone) and neurotransmitters (serotonin, dopamine and noradrenaline)
- Synthesis of procollagen and elastin.

### CLINICAL USE

Iron supplementation is used to prevent deficiency in at-risk populations and also to rectify deficiency states. The best form of iron to use, administration form and dosage regimen are yet to be determined and likely to vary depending on the individual presentation. This review will mainly focus on oral supplementation as this is the most commonly used form. Oral ferrous iron supplements are a popular commercial form which is available in complexes as ferrous sulfate or ferrous fumarate, but may also be found in complexes with succinate, citrate, tartrate, lactate and gluconate. Amino acid-iron chelates such as iron glycine are also available. Administration in the chelate form has not been shown to provide better absorption than administration of iron as ferrous sulfate (Gropper & Smith 2013).

### Iron deficiency and iron-deficiency anaemia

Ferrous sulfate is the most commonly used oral treatment for iron deficiency and iron-deficiency anaemia. Daily iron therapy has been shown to be the most effective treatment, but is associated with a higher incidence of adverse effects, such as nausea, constipation and dental discolouration, as well as poor compliance, and may not be feasible in all

population groups (Fernandez-Gaxiola & De-Regil 2011). In practice, it is often prescribed in divided doses rather than a single, larger daily dose in an attempt to reduce the incidence and severity of these side effects.

Intermittent iron therapy is less effective than daily iron therapy in the prevention and treatment of iron-deficiency anaemia, but still a successful alternative strategy where daily supplementation is not possible, according to a recent Cochrane review of 21 trials involving 10,258 women in their menstrual years (Fernandez-Gaxiola & De-Regil 2011).

Previous evidence also suggested that weekly administration of iron was an effective strategy for the treatment and prevention of iron deficiency and iron-deficiency anaemia in most population groups, including pregnant women and children (Agarwal et al 2003, Mukhopadhyay et al 2004, Siddiqui et al 2004, Sungthong et al 2004, Yang et al 2004). Although this is associated with lower cost, fewer side effects and improved compliance (Haidar et al 2003), this notion has been challenged when twice-weekly doses of iron (ferrous dextran containing 60 mg elemental iron) for 12 months failed to improve haemoglobin or serum ferritin (iron stores) in children or adults (Olsen et al 2006). The results from some studies suggest that weekly doses may assist in maintenance but may not improve iron status (Wijaya-Erhardt et al 2007). To achieve a better result, it may be necessary to use higher weekly doses and also address concomitant nutritional deficiencies and other factors affecting iron absorption.

### Children

According to a 2013 meta-analysis by Thompson et al, iron supplementation in children aged 2–5 years increases both haemoglobin and ferritin levels and may also lead to a small improvement in cognitive, but not physical, development in this age group (Thompson et al 2013). Benefits for growth appear most likely if iron is given together with a combination of micronutrients according to systematic reviews and meta-analyses (Allen et al 2009, Ramakrishnan et al 2004, 2009, Sachdev et al 2005).

Daily iron supplementation is more effective than intermittent supplementation in children under 12 years, according to a 2011 Cochrane systematic review (De-Regil et al 2011). Despite this, intermittent supplementation is still better than placebo and presents an effective solution should daily supplementation not be possible. It may also be associated with fewer side effects, according to a 2004 study of 60 children (age 5–10 years) with iron-deficiency anaemia given ferrous sulfate (200 mg) weekly for 2 months and compared to daily treatment with the same dose (Siddiqui et al 2004). Another study found that children receiving weekly doses of ferrous sulfate (300 mg) had similar improvements in haemoglobin, but a significantly higher increase in IQ, compared to those taking the

same dose of iron 5 days per week (Sungthong et al 2004).

Preliminary data suggests that low iron status and low serum ferritin concentration should be investigated in children presenting with febrile seizures as these may be risk factors for the development of this condition (Zareifar et al 2012).

### Elderly

The prevalence of iron-deficiency anaemia increases with age. This is mainly due to a combination of factors, including poor dietary intake together with decreased digestive function, use of medications affecting uptake and disease states associated with chronic inflammation, gastrointestinal bleeding and malabsorption, renal failure, portal hypertension, colorectal cancer and angiodysplasia (Andres et al 2008).

Elderly patients are particularly vulnerable to the dose-dependent adverse effects of iron supplementation, and should be given the lowest effective dose. A randomised controlled trial (RCT) of 90 hospitalised elderly patients demonstrated that 15 mg of liquid ferrous gluconate produced similar improvements in haemoglobin and ferritin over 60 days to 150 mg of ferrous calcium citrate tablets without the negative side effects (Rimon et al 2005). Iron supplementation appears to be effective and safe for the treatment of comorbid anaemia in elderly patients undergoing knee or hip surgery, according to recent meta-analysis (Yang et al 2011).

In all cases the lowest safe and effective dose at the lowest frequency of dosing should be used to correct iron deficiency with or without anaemia.

It is becoming clearer that long-term iron deficiency is also associated with an increased risk for cardiovascular disease and all-cause mortality in the elderly (Hsu et al 2013) and has implications in congestive heart failure (CHF). Anaemia is reported in over 50% of patients with CHF, and is associated with an increased risk of death compared to non-anaemic CHF patients (Avni et al 2012). Iron deficiency has also been highlighted as a potential problem in CHF patients, decreasing aerobic performance and exercise tolerance, and may be a predictor of disease severity and mortality (Klip et al 2012). A recent review reported that intravenous iron supplementation (1000–2000 mg total dose) may improve exercise capacity and quality of life and reduce the need for hospitalisation in CHF patients. Benefits were also reported in non-anaemic patients, suggesting that anaemia is not the only reason for improvement in symptoms of CHF with use of iron supplementation (Avni et al 2012).

### Pregnancy

Women taking iron supplementation during pregnancy are at less risk of giving birth to babies of low birth weight (<2500 g) and more likely to have a baby with a higher mean birth weight than women not taking iron supplements, according to a recent Cochrane review of 43 trials ( $n = 27,400$ )

(Pena-Rosas et al 2012). Prophylactic use of iron supplementation reduced the risk of iron deficiency at term by 57% and/or iron-deficiency anaemia by 70%. In the review, iron supplementation was also associated with a marginally higher risk of maternal adverse effects and raised haemoglobin levels, suggesting a need for updating recommendations on dosing and iron supplementation regimens. Improved birth weight with iron supplementation was also reported in a 2013 review of 48 RCTs ( $n = 17,793$  women) and 44 cohort studies, involving almost 2 million women (Haider et al 2013). It was found to significantly decrease the risk of iron-deficiency anaemia in pregnancy and substantially improved birth weight in a linear dose–response manner.

Due to the possibility of uncontrolled lipid peroxidation, predictive of adverse effects for mother and fetus, iron supplementation should be prescribed on the basis of biological criteria, not on the assumption of anaemia alone (Lachili et al 2001) and the minimum dose possible should be used. Low-dose iron supplements (20 mg elemental iron) have demonstrated efficacy in treating anaemia in pregnancy with fewer gastrointestinal side effects (Zhou et al 2009).

According to trials, a supplement of 40 mg ferrous iron/day from 18 weeks' gestation appears adequate to prevent iron deficiency in 90% of women and iron-deficiency anaemia in at least 95% of women during pregnancy and postpartum (Milman et al 2004). A single weekly dose of 200 mg elemental iron, however, may be sufficient, as this has been shown to be comparable with 100 mg elemental iron daily on erythrocyte indices (Mukhopadhyay et al 2004). Other trials have found that low doses of sodium feredetate (33 mg and 66 mg of elemental iron given twice daily) produced comparable results to ferrous fumarate (100 mg elemental iron given twice daily), with no reports of adverse effects (Sarkate et al 2007).

Although iron supplementation is often used as stand-alone treatment in pregnant iron-deficient women, one RCT indicated that a combination of iron and folate therapy (80 mg iron protein succinylate, with 0.370 mg folic acid daily) for 60 days produces a better therapeutic response than iron-only supplementation (Juarez-Vazquez et al 2002).

### Postpartum anaemia

Postpartum anaemia is associated with breathlessness, tiredness, palpitations, maternal infections and impaired mood and cognition. A 2004 Cochrane review suggested that further high-quality trials were required before the benefits of iron supplementation or iron-rich diets in the treatment of postpartum anaemia could be established (Dodd et al 2004). Since then a randomised placebo-controlled study of iron sulfate (80 mg daily) for 12 weeks starting 24–48 hours after delivery demonstrated an improvement in haemoglobin levels and iron stores (Krafft et al 2005) and supplementation of ferrous sulfate (125 mg) with folate (10 mcg) and

vitamin C (25 mg) demonstrated improvements in cognitive function, as well as depression and stress compared with folate and vitamin C alone (Beard et al 2005). However, further studies are still warranted.

### Restless-leg syndrome

Low serum iron levels are frequently seen in patients with restless-leg syndrome. Whether this is a cause or consequence of the syndrome remains unclear. A Cochrane review of six RCTs ( $n = 192$ ) concluded that currently there is insufficient evidence to determine whether iron supplementation would be of benefit in the treatment of restless-leg syndrome (Trotti et al 2012). The trials included patients with and without iron deficiency.

### Unexplained fatigue without anaemia

Iron supplementation may be considered as a treatment in non-anaemic menstruating women with haemoglobin levels within normal range ( $>120$  g/L) who complain of unexplained fatigue without identifiable secondary causes.

A recent multicentre RCT involving 198 women aged 18–53 years assessed the effect of oral iron therapy for 12 weeks in women with considerable fatigue without obvious clinical cause. Eligibility criteria included ferritin levels of  $<50$  mcg/L and haemoglobin levels  $>12$  g/dL (120 g/L). Iron supplementation (80 mg elemental iron/day as ferrous sulfate for 12 weeks) was shown to decrease fatigue by 47.7% in the treatment group compared to 28.8% in the placebo group ( $P = 0.02$ ). No significant effects on anxiety or quality of life unrelated to fatigue were observed (Vaucher et al 2012). These findings support earlier research by Verdon and colleagues (2003), who conducted a double-blind, randomised placebo-controlled trial designed to determine the subjective response to iron therapy in non-anaemic women (haemoglobin  $> 117$  g/L) with unexplained fatigue. This study found that supplementation with oral ferrous sulfate (80 mg/day elemental iron) for 4 weeks reduced the level of fatigue in the iron group by 29% compared with 13% in the placebo group. Subgroup analysis showed that only women with ferritin concentrations  $<50$  mcg/L improved with oral supplementation. This was common in 85% of subjects and 51% of subjects had ferritin concentrations  $<20$  mcg/L (Verdon et al 2003). It has been suggested that the current reference levels for women may need to be revised.

### Improving athletic performance

Sports anaemia is a common finding among professional and non-professional athletes engaging in strenuous physical activity. Optimal iron balance is important to maintain athletic performance, yet elite athletes appear to be at greater risk of developing iron deficiency (Reinke et al 2012).

Possible mechanisms include: increased iron loss due to factors such as sweating, gastrointestinal bleeding and inflammation (McClung 2012).

Proinflammatory cytokines such as IL-6 stimulate expression of hepcidin, a hormone that reduces absorption of iron in the enterocyte, while promoting the sequestering of iron in macrophages (McClung & Karl 2009). Some athletes may also consume carefully controlled diets which are low in meat and other sources of haem iron, yet high in grains and vegetable products that inhibit iron absorption (McClung 2012). Another possibility is dilutional pseudoanaemia, which is caused by plasma volume expansion greater than that of the red blood cell mass, but does not reflect actual blood loss and will generally normalise within 3–5 days of ceasing training; intravascular haemolysis due to mechanical trauma such as ‘foot strike haemolysis’, which can result in urinary loss of iron; or transient ischaemia resulting from vasoconstriction of the splanchnic and renal vessels, which can also result in blood loss from the gastrointestinal and urinary tracts (Merkel et al 2005).

In a placebo-controlled trial, iron supplementation (50 mg ferrous sulfate twice daily) for 6 weeks significantly improved iron status and maximal oxygen uptake ( $VO_{2max}$ ) after 4 weeks’ concurrent aerobic training in previously marginally deficient and untrained women (Brownlie et al 2002). In a later randomised double-blind placebo-controlled study of 41 untrained iron-deficient women without anaemia, ferrous sulfate (100 mg) for 6 weeks improved endurance capacity after aerobic training (Brownlie et al 2004). However, a review concluded that the current evidence does not justify the use of supplementation solely for the purpose of performance enhancement (Rodenberg & Gustafson 2007).

Due to the potential side effects of inappropriate iron supplementation and the possibility of masking more serious underlying complaints, athletes should only be supplemented if iron deficiency is established on the basis of biological criteria (Zoller & Vogel 2004). Short recuperation periods between intense athletic training may also allow for some recovery of iron storage; however, it may not be sufficient to fully normalise decreased iron levels and iron deficiency in athletes. Monitoring of iron status in elite athletes is recommended (Reinke et al 2012).

### Anaemia of inflammation/chronic disease

In this form of anaemia storage iron is often abundant but not available for erythropoiesis. Thus, elevated markers of inflammation should be used for diagnosis. Treatment is difficult but often involves intravenous iron and erythropoietin (EPO) supplements (Handelman & Levin 2008). Emerging future therapies for anaemia associated with chronic inflammation and autoimmune disease may include iron chelation anticytokine administration, modulation of EPO receptors, use of erythropoietin-stimulating agents and agonists/antagonists to modulate the levels of the proteins hepcidin and ferroportin, which are involved with iron homeostasis (Recalcati et al 2012).

### Cognitive function

Iron deficiency and iron-deficiency anaemia are associated with impaired cognitive function, which suggests that iron supplementation may have a potential role in improving cognitive function. Iron deficiency has been associated with delayed achievement of developmental motor milestones in a study of infants aged 9–10 months (Shafir et al 2008) and poor cognitive and motor development with behavioural problems (Otero et al 2004).

A systematic review and meta-analysis of 14 RCTs reported that iron supplementation results in a slight improvement (2.5 points) in IQ in anaemic participants ( $P = 0.0002$ ), but not in non-anaemic ones (Falkingham et al 2010). Most of the studies included in the review were conducted on children or adolescents, but some studies in women were also included. Interestingly, iron supplementation may also improve attention and concentration in adolescents and women, irrespective of baseline iron status, although it was not found to have a significant effect on memory, psychomotor function or scholastic achievement (Falkingham et al 2010).

Modest improvements in mental development scores were found for iron supplementation according to a systematic review; however benefits were more prevalent in those who were initially anaemic or iron deficient (Sachdev et al 2005). Two-month supplementation of 15 mg iron (and multivitamin) was better than a multivitamin alone in preschoolers with iron-deficiency anaemia as it resulted in improvements to discrimination (specifically selective attention), accuracy and efficiency (Metallinos-Katsaras et al 2004). Another study found that iron deficiency was associated with compromised working memory in children between the ages of 8 and 10, with iron supplementation being able to restore attention and cognitive capabilities in this group (Otero et al 2008).

An increased incidence of iron deficiency and iron-deficiency anaemia has been reported in children with autistic spectrum disorders; this appears to be mainly due to low iron intake relating to feeding difficulties and food selectivity. These low iron levels may exacerbate the severity of psychomotor and behavioural problems in these children (Bilgic et al 2010).

In adults, iron deficiency in the absence of anaemia has been reported to impair cognitive function in a small study conducted on premenopausal women (Blanton et al 2011). Another study found that iron supplementation improved cognitive function and depression in postpartum anaemic women (Beard et al 2005).

### Attention-deficit hyperactivity disorder (ADHD) in children

Whether iron supplementation has benefits in ADHD is difficult to determine at this stage due to a lack of RCTs; however, preliminary research

suggests it may be of use in improving some aspects of ADHD. In particular, it appears that iron deficiency may contribute to behavioural problems, including ADHD (as well as restless-leg syndrome and Tourette's) due to an influence on the metabolism of dopamine and other catecholamines (Cortese et al 2008). As a result, children with ADHD and a positive family history of restless-leg syndrome appear to be at increased risk for severe ADHD symptoms (Konofal et al 2007). Iron supplementation (80 mg/day) for 12 weeks significantly improved ADHD symptoms in children with low serum ferritin levels but without anaemia. The mean Clinical Global Impression-Severity ( $P < 0.01$ ) and ADHD Rating Scale ( $P < 0.008$ ) were improved in a manner comparable to pharmaceutical stimulants (Konofal et al 2008).

### Perioperative care

Iron is sometimes given before surgery to reduce postoperative decreases in haemoglobin (Andrews et al 1997). However, this use is contentious and numerous studies have failed to report benefits for preoperative autologous blood collection (Cid et al 2005) or for correcting anaemia associated with cardiac surgery (Madi-Jebara et al 2004) or orthopaedic surgery, such as hip or knee arthroplasty (Mundy et al 2005, Weatherall & Maling 2004). In a more recent randomised placebo-controlled trial in patients undergoing colorectal surgery, oral ferrous sulfate (200 mg TDS) for 2 weeks preoperatively resulted in increased mean haemoglobin and ferritin concentrations, and reduced the need for operative blood transfusion (mean 0 units transfused [range, 0–4 units] versus 2 units transfused [range, 0–11 units];  $P = 0.031$ ; 95% confidence interval 0.13–2.59) (Lidder et al 2007).

### Gastric bypass patients

Iron deficiency may develop after gastric bypass due to red meat intolerance, diminished gastric acid secretion and exclusion of the duodenum from the gastrointestinal tract. Patients require lifelong follow-up of haematological and iron parameters since iron deficiency and anaemia may develop years after surgery and, once developed, may prove refractory to oral treatment, resulting in the need for parenteral iron, blood transfusions or surgical interventions (Love & Billett 2008).

### Blood donors

Iron supplementation (150 mg ferrous sulfate three times daily) for 1 week following blood donation reduced the decline in haemoglobin concentration and maintained haematocrit, serum iron, serum ferritin and percentage saturation (Maghsudlu et al 2008). Normalisation of low haemoglobin, and thus blood donor retention, may be further enhanced by a standardised protocol offering iron supplementation and simple oral and written advice based on plasma ferritin measurements (Magnussen et al 2008).

## OTHER USES

### Breath-holding spells

According to one RCT in iron-deficient children, iron supplementation significantly reduced the incidence of breath-holding spells (Daoud et al 1997). No further research on this indication for iron supplements appears to have been conducted, according to a Cochrane review (Zehetner et al 2010).

### Haemodialysis

Intravenous iron is frequently, but contentiously, prescribed for the aggressive management of anaemia associated with dialysis (Agarwal et al 2004, Gillespie & Wolf 2004, Ruiz-Jaramillo et al 2004). CYP3A4 activity is reduced in haemodialysis patients, which may be related to functional iron deficiency. However, with the exception of a subset of haemodialysis patients with low baseline CYP3A4 activity, intravenous iron does not appear to have a significant effect on hepatic CYP3A4 (Pai et al 2007). It has been suggested that strategies to improve vitamin C status and to decrease inflammation would lead to better utilisation of iron in these patients (Handelman 2007).

### Hypothyroidism

#### Adjunct therapy in thyroid disorders

Iron supplementation as adjunct therapy to iodine supplementation results in greater improved thyroid function than giving iodine alone in populations that are deficient in both nutrients (Hess 2010). For patients with comorbid iron-deficiency anaemia and subclinical hypothyroidism, but raised thyroid-stimulating hormone levels, the addition of levothyroxine (50 mcg/day) to iron supplementation (ferrous sulfate 65 mg/day) resulted in better outcomes of both conditions than monotherapy with either iron or levothyroxine, according to one small study of 60 patients (Ravanbod et al 2013). The authors suggest that all patients with iron-deficiency anaemia of unknown aetiology should also be investigated for subclinical hypothyroidism.

### DOSAGE RANGE

- Therapeutic dose: Generally 2–5 mg/kg/day; depending on the condition being treated. In many cases the equivalent of this dose may be given as a weekly dose rather than a daily dose. The duration of therapy may need to be individualised until iron stores are replenished.
- In cases of deficiency, initial effects on haemoglobin and erythrocyte concentrations take about 2 weeks but it may take 6–12 months to build iron stores (Gropper & Smith 2013).
- The Australian Iron Status Advisory Panel advocates dietary intervention as the first treatment option for mild iron deficiency (serum ferritin 10–15 mcg/L) (Patterson et al 2001). Trials have shown a significant increase in serum ferritin levels (26%) using dietary intervention alone (Heath et al 2001).

TABLE 1 AUSTRALIAN RECOMMENDED DAILY INTAKE (RDI) BY AGE AND SEX

Age	Australian RDI (mg/day)
Infants (0–6 months; breastfed)	0.2
Infants (7–12 months)	11
Children (1–8 years)	9–10
Girls (9–13 years)	8
Girls (14–18 years)	15
Boys (9–13 years)	8
Boys (14–18 years)	11
Men (>18 years)	8
Women (18 to menopause)	18
After menopause	8
Pregnancy	27
Lactation	9

In Table 1, the RDI of iron is expressed as a range to allow for differences in bioavailability of iron from different Australian foods.

Studies have shown that there can be a significant sex difference in haemoglobin and other indicators of iron status during infancy. Some of these may be genetically determined, whereas others seem to reflect an increased incidence of true iron deficiency in boys (Domellof et al 2002).

### TOXICITY

Iron toxicity causes severe organ damage and eventually death. The most pronounced effects are haemorrhagic necrosis of the gastrointestinal tract, which manifests as vomiting, bloody diarrhoea and hepatotoxicity. Acute overdose or iron accumulation may progress to shock and/or impaired consciousness (Singhi & Baranwal 2003). Iron overdose in pregnant women has been associated with spontaneous abortion, preterm delivery and maternal death (Tran et al 2000). Excess iron accumulation is being investigated as a potential contributing factor for the development of diseases such as Parkinson's and Alzheimer's disease (Dwyer et al 2009, Rhodes & Ritz 2008, Sian-Hulsmann et al 2011). Some studies suggest that chronic iron overload may contribute to the development of type 2 diabetes and coronary heart disease; however, further research is required to confirm these associations (Mojiminiyi et al 2008).

Conditions that increase risk of toxicity include:

- Haemochromatosis (iron overload) — excess absorption and accumulation of iron in the body, which can cause organ and tissue damage (especially liver, heart and pancreas) and an increased risk for hepatic carcinoma. The most important

causes are a genetic disorder (hereditary haemochromatosis), which leads to abnormal iron absorption, or as a secondary consequence of a transfusion, or repeated transfusions.

- Haemosiderosis — iron overload without tissue damage.
- Iron-loading anaemias — thalassaemia and sideroblastic anaemia.

### ADVERSE REACTIONS

Oral supplements may cause gastrointestinal disturbances such as nausea, diarrhoea, constipation, heartburn and upper gastric discomfort, and may cause stools to blacken.

Taking supplements with food appears to reduce the possibility of gastrointestinal side effects. Liquid iron preparations can discolour teeth — brush teeth after use.

Intermittent dosing on a weekly basis rather than a daily basis may also reduce side effects.

In the absence of appropriate storage or chelation, excess free iron can readily participate in the formation of toxic free radicals, inducing oxidative stress and apoptosis (Whitnall & Richardson 2006). Iron depletion leads to decreased availability of redox-active iron *in vivo* and appears to reduce atherosclerotic lesion size and increase plaque stability (Sullivan & Mascitelli 2007). Iron toxicity and subsequent organ damage can develop from long-term excessive intake.

There is preliminary evidence that iron may be implicated in the pathogenesis of autoimmune disorders (Bowls 2003) and neurodegenerative diseases (Whitnall & Richardson 2006) and that moderately elevated iron stores may be associated with an overall increased risk for cancer, especially colorectal cancer (McCarty 2003). In younger people iron depletion is associated with a reduced risk of all-cause mortality (Sullivan & Mascitelli 2007), although numerous confounding factors cannot be ignored. While haem iron intake from red meat may present a risk for increased blood pressure, non-haem dietary intake may slightly reduce systolic blood pressure (Tzoulaki *et al* 2008). For the time being, supplementation without demonstrated biological need cannot be justified as the potential risks may outweigh any short-term benefits.

### SIGNIFICANT INTERACTIONS

Iron interacts with a variety of foods, herbs and drugs through several different mechanisms. Most commonly, the formation of insoluble complexes occurs whereby both iron and drug absorption is hindered. Separation of doses by several hours will often reduce the severity of this type of interaction. Additionally, substances that alter gastric pH have the theoretical ability to reduce iron absorption. A summary of interactions is presented in Table 2 for easy reference.

TABLE 2 SUMMARY OF IRON INTERACTIONS

Drug/therapeutic substance	Mechanism	Possible outcome	Action required
Angiotensin-converting enzyme (ACE) inhibitors	Oral iron supplementation with ferrous sulfate 200 mg may suppress cough induced by ACE inhibitors through an effect on nitric oxide generation (Bhalla <i>et al</i> 2011, Lee <i>et al</i> 2001)	Reduced drug adverse effect	Beneficial interaction possible
Antacids and products containing aluminium, calcium or magnesium	Reduces iron absorption (O'Neil-Cutting & Crosby 1986)	Reduced effect of iron	Separate doses by at least 2 h
Ascorbic acid	Increases iron absorption	Increased effects of iron	Beneficial interaction is possible — caution in haemochromatosis
Cholestyramine and colestipol	<i>In vitro</i> investigations have shown that cholestyramine and colestipol both bind iron citrate (Leonard <i>et al</i> 1979)	Reduced drug and iron effect	Monitor for iron efficacy if cholestyramine is being used concurrently. Separate doses by 4 h. Increased iron intake may be required with long-term therapy
Cimetidine	Iron can bind cimetidine in the gastrointestinal tract and reduce its absorption (Campbell <i>et al</i> 1993)	Reduced drug and iron effect	Separate doses by at least 2 h
Dairy products and eggs	May reduce iron absorption	Reduced effect of iron	Monitor for iron efficacy

TABLE 2 SUMMARY OF IRON INTERACTIONS (continued)

Drug/therapeutic substance	Mechanism	Possible outcome	Action required
Erythropoietin	Pharmacodynamic interaction (Carnielli et al 1998). In patients with chemotherapy-related anaemia without iron deficiency, the addition of intravenous iron supplementation may improve the success of darbepoetin (92.5% versus 70% for darbepoetin alone; $P = 0.0033$ ) without increasing toxicity (Pedrazzoli et al 2008)	Additive pharmacological effect possible	Beneficial interaction is possible
H <sub>2</sub> -receptor antagonists (antiulcer drugs)	Iron absorption is dependent upon gastric pH; therefore, medications that affect gastric pH may interfere with absorption of iron (Aymard et al 1988)	Reduced effect of iron	Monitor for iron efficacy if these drugs are being used concurrently
Haloperidol	May cause decreased blood levels of iron (Leenders et al 1994, Threlkeld 1999)	Reduced effect of iron	Monitor for iron efficacy if these drugs are being used concurrently. Increased iron intake may be required with long-term therapy
L-Dopa and carbidopa	May reduce bioavailability of carbidopa and L-dopa (van Woert et al 1977)	Reduced drug effect	Separate doses by 2 h
Omeprazole and other proton pump inhibitors	Reduced iron absorption due to changes in gastric pH	Reduced effect of iron	Monitor for iron efficacy if omeprazole is being used concurrently
Penicillamine	Reduced drug and iron absorption	Reduced drug and iron effect	Separate doses by at least 2 h. Sudden withdrawal of iron during penicillamine use has been associated with penicillamine toxicity and kidney damage (Harkness & Blake 1982) — caution
Quinolone antibiotics (e.g. norfloxacin)	Reduced drug absorption (Brouwers 1992)	Reduced drug effect	Take drug 2 h before or 4–6 h after iron dosing. Monitor patient for continued antibiotic efficacy
Sulfasalazine	May bind together, decreasing the absorption of both (Dukes & Duncan 1995)	Reduced drug and iron effect	Separate doses by at least 2 h
Tannins — herbs with significant tannin content (e.g. green tea, bilberry, raspberry leaf)	Tannin can bind to iron and reduce its absorption	Reduced effect of iron	Monitor for iron efficacy if these herbs are being used concurrently. Separate doses by 2 h
Tetracycline antibiotics (e.g. minocycline, doxycycline)	While early studies suggested reduced drug and iron absorption (Neuvonen 1976), more recent human data found no effect on erythrocyte iron uptake when in patients taking 100 mg iron orally and oral tetracycline (Potgieter et al 2007)	Reduced drug effect	Monitor for iron efficacy if tetracyclines are being used long-term. Separate doses by 4 h
L-Thyroxine	Decreased drug absorption possible. Iron supplements may decrease absorption of thyroid medication; however, iron deficiency may impair the body's ability to make thyroid hormones	Reduced drug effect	Thyroid function should be monitored and L-thyroxine dose may need alteration during treatment with iron. Separate doses by at least 2–4 h (Shakir et al 1997)
Vitamin A	Iron supplementation may cause a redistribution of retinol, inducing vitamin A deficiency in infants with marginal vitamin A status (Wieringa et al 2003)	Redistribution of retinol	Iron supplementation in infants should be accompanied by measures to improve vitamin A status

**Practice points/Patient counselling**

- Iron is an essential mineral that facilitates oxygen transport and storage in the body and is part of many enzyme systems.
- Haem iron, found in animal products, is absorbed two- to threefold better than non-haem forms found in vegetable sources. However, iron absorption is influenced by many factors, such as other foods ingested, medicines and gastric activity.
- Iron deficiency is the most common nutritional deficiency in the world and may occur with or without anaemia. Excessive blood loss during menstruation is the most common cause.
- Supplements are generally used to treat or prevent deficiency. Excess iron can be dangerous and can lead to organ damage and death.
- As inappropriate iron supplementation can inhibit growth in non-deficient children and adversely affect pregnancy outcomes, iron status should be tested before administration.
- Correction of iron deficiency with or without anaemia may be achieved with lower doses than those recommended in some trials. In many cases, once-weekly dosing of iron is as effective as daily dosing and improves compliance, while reducing side effects and cost.
- Oral liquid iron supplements should be diluted with water and drunk through a straw to prevent discolouration of teeth, especially if used long-term.

**? CONTRAINDICATIONS AND PRECAUTIONS**

Iron poisoning can occur due to accidental ingestion of excess iron supplements. As such, iron supplements should be kept in childproof bottles and out of the reach of children.

Caution should be exercised when supplementing iron to infants or children with apparently normal growth when the iron status of the child is unknown. A double-blind placebo-controlled trial showed that, while iron therapy produced a significant improvement of mean monthly weight gain and linear growth in iron-deficient children, it significantly decreased the weight gain and linear growth of iron-replete children (Majumdar et al 2003). This study confirms the results of earlier studies (Dewey et al 2002).

Iron supplements should not be used in haemochromatosis, haemosiderosis or iron-loading anaemias (thalassaemia, sideroblastic anaemia).

Daily oral iron supplementation providing 50 mg elemental iron for 8 weeks did not result in increased oxidative damage in the plasma of college-aged women (Groppe et al 2003). However,

more recently 100 mg doses of iron daily for 8 weeks were shown to increase lipid peroxidation. As iron status and duration of supplementation increased, so too did indicators of lipid peroxidation (King et al 2008). As the use of iron supplements may potentially result in oxidative damage, risk should always be assessed against benefit before prescribing iron supplements.

Elevated levels of serum ferritin have been implicated in the pathogenesis of vascular (and other) diseases, although this remains controversial (McCarty 2003, Zacharski et al 2004).

Haem-rich flesh foods may need to be limited in people with insulin resistance due to a possible link with increased cancer risk mediated by iron excess in such populations (McCarty 2003).

Iron supplementation should be prescribed on the basis of biological criteria, not on the assumption of anaemia alone, as unnecessary iron supplementation can result in adverse effects. The lowest safe and effective dose and frequency of dose should be recommended.

**! PREGNANCY USE**

Oral iron preparations are considered safe in pregnancy; while adequate iron in pregnancy is important, unnecessary iron supplementation can result in uncontrolled lipid peroxidation (Lachili et al 2001), lowered serum levels of copper and zinc (Ziaei et al 2008), low birth weight and maternal hypertension disorder (Ziaei et al 2007). As a result, iron supplementation should be prescribed on the basis of biological criteria, and the woman's iron status should be assessed first, rather than basing it on the assumption of anaemia alone.

**! PATIENTS' FAQs****What will this supplement do for me?**

Iron is necessary for health and wellbeing. It facilitates oxygen transport and storage in the body and is part of many enzyme systems. Iron deficiency is the most common nutrient deficiency in the world.

**When will it start to work?**

Iron deficiency responds to supplementation within 2 weeks; however, 6–12 months may be required to build up the body's iron stores.

**Are there any safety issues?**

Excess iron can be dangerous and ultimately can lead to severe organ damage and death.

## Kava

**HISTORICAL NOTE** For many centuries, Pacific Islanders have used the kava root to prepare a beverage used in welcoming ceremonies for important visitors. Drinking kava is not only done to induce pleasant mental states but also to reduce anxiety and promote socialising. It is believed that the first report about kava came to the West from Captain James Cook during his voyages through the Pacific region.

### COMMON NAME

Kava, kava kava

### OTHER NAMES

Kawa, awa, intoxicating pepper, rauschpfeffer, sakau, tonga, yagona

### BOTANICAL NAME/FAMILY

*Piper methysticum* (family Piperaceae)

### PLANT PARTS USED

Root and rhizome

### CHEMICAL COMPONENTS

The most important constituents responsible for the pharmacological activity of kava rhizome are the fat-soluble kava lactones (kavapyrones), mainly methysticin, dihydromethysticin, kavain (kawain), dihydrokavain yangonin and desmethoxyangonin and flavonoids (flavokavains).

### MAIN ACTIONS

#### Central nervous system (CNS) effects

The kava lactones reach a large number of targets that influence CNS activity and act centrally and peripherally. They interact with dopaminergic, serotonergic, GABAergic and glutamatergic neurotransmission, seem to inhibit monoamine oxidase B and exert multiple effects on ion channels, according to in vitro and in vivo research (Grunze et al 2001). Additionally, animal studies show that kava lactones are chiefly responsible for these effects that give rise to many of the herb's clinical actions (Cairney et al 2002).

#### Hypnotic

Although the exact mechanism of action is not yet understood, it has been observed that sleep promotion may be due to the preferential activity of D,L-kavain and kava extract on the limbic structures and,

in particular, the amygdalar complex (Holm et al 1991) in the brain.

In an electroencephalogram brain-mapping study it was demonstrated that D,L-kavain could induce a dose-dependent increase in delta-, theta- and alpha-1 power, as well as a decrease in alpha-2 and beta power. These results indicate a sedative effect at the higher dose range (Frey 1991).

#### Anxiolytic effects

In vivo research showed that kava extract produces a statistically significant dose-dependent anxiolytic-like behavioural change in a rat model of anxiety (Garrett et al 2003). The effect is not mediated through the benzodiazepine-binding site on the GABA-A receptor complex, as flumazenil, a competitive benzodiazepine receptor antagonist, did not block this effect.

More recently, kava was shown to inhibit both noradrenaline uptake and sodium and potassium channels (Weeks 2009). Furthermore, kava appears to have a similar mechanism of action to the anxiolytic chlordiazepoxide, although it is less potent (Bruner & Anderson 2009). The yonganin constituent (a kavalactone) exhibits an affinity and selectivity for the human recombinant CB<sub>1</sub> receptor, indicating that the endocannabinoid system might contribute to kava's anxiolytic effects (Ligresti et al 2012).

#### Analgesic and local anaesthetic

Both the aqueous and lipid-soluble extracts of kava exhibit antinociceptive properties in experimental animal models (Jamieson & Duffield 1990). The effect is not mediated by an opiate pathway, as naloxone does not reduce the effects when administered in doses that reverse the effects of morphine. The lack of opioid activity was confirmed again in a rat model by Sullivan et al (2009), which also showed that the analgesic properties of kava were similar to morphine.

In vitro research has identified several compounds in kava that have the ability to inhibit cyclooxygenase-1 (COX-1) and, to a lesser extent, COX-2 enzyme activities (Wu et al 2002). A more recent study of various kava products (GNC, Sundown, Solaray) confirmed selective inhibition of COX-2 (Raman et al 2008).

The local anaesthetic effect of kava is well known for topical use and has been described as similar to procaine and cocaine (Mills & Bone 2000).

#### Antispasmodic activity

Antispasmodic activity for skeletal muscle has been observed in vitro and in vivo for both kava extract and kava lactones (Mills & Bone 2000). In vivo research suggests that kavain impairs vascular smooth-muscle contraction; this is likely to be through inhibition of calcium channels (Martin et al 2002).

## OTHER ACTIONS

### Anicancer/chemopreventive effects

Consumption of kava in the South Pacific Islands is inversely correlated with cancer incidence, even among smokers (Warmka et al 2012). Recently, it was found that men living in Fiji and drinking kava have low incidence of prostate cancer; however the incidence increased 5.1-fold when Fijian men migrated to Australia (Li et al 2012).

An early in vivo study (mice) showed that kava inhibited proliferation and enhanced apoptosis in lung tumours, as shown by a reduction in proliferating cell nuclear antigen, an increase in caspase-3 and cleavage of poly(ADP-ribose) polymerase. Kava treatment also inhibited the activation of nuclear factor kappaB (NF-κB), a potential upstream mechanism of kava chemoprevention (Johnson et al 2008). The same authors later confirmed, by analysing lung adenoma tissues derived from kava-treated mice, that kava significantly inhibited adenoma cell proliferation while it had no detectable effect on cell death, indicating that kava primarily suppressed lung tumorigenesis in A/J mice via inhibition of cell proliferation.

Investigation has begun in earnest to identify the key components in kava responsible for the anticancer/chemoprevention activities. A major class of compounds found in the beverage kava are the chalcones which have demonstrated anticancer properties in a variety of animal and cell culture models (Eskander et al 2012, Sakai et al 2012, Tang et al 2008, Warmka et al 2012, Zhao et al 2011). Chemoprevention activity has been identified for flavokawains A, B and C (Johnson et al 2011). Methysticin has also been identified as a potent and non-toxic NF-κB inhibitor, potentially responsible for kava's chemopreventive activity. Other kava constituents, including four kavalactones of similar structures to methysticin, demonstrate minimum activities in inhibiting NF-κB (Shaik et al 2009). A study in mice identified kava-derived compounds which mediate tumour necrosis factor-alpha suppression. For example, kavain was found to render mice immune to lethal doses of lipopolysaccharide (Pollastri et al 2009).

An in vivo study found that the consumption of kava or kava fractions reduces colon cancer risk in rats which were carcinogen-treated (Triolet et al 2012).

Due to the observation that kava-drinking Fijian men have a substantially increased rate of prostate cancer when migrating to Australia, Li et al (2012) investigated the effects of kava root extracts and its active components (kavalactones and flavokawains) on prostate cancer cell growth in an in vitro study. They found that the kava root extract and flavokawain B reduced tumour growth, AR expression in tumour tissues and levels of serum prostate-specific antigen in the patient-derived prostate cancer xenograft models (Li et al 2012). The same authors had demonstrated in an earlier study that flavokawain B

induces apoptosis via upregulation of death receptor 5 and Bim expression in androgen receptor-negative, hormonal-refractory prostate cancer cell lines and reduced tumour growth (Tang et al 2010).

### Antiparasite activity

Two phenolic compounds and three kava lactones possess an  $\alpha$ -pyrone which inhibited *Trypanosoma brucei brucei* in vitro. In particular,  $\beta$ -phenethyl caffeate, farnesyl caffeate and dihydrokawain exhibited high or moderate selective and potent antitrypanosomal activity (Otoguro et al 2012).

### Cytochromes and P-glycoprotein (P-gp)

There is no clinical evidence that kava affects substrates of CYP2C19, CYP3A4, CYP2D6 and P-gp, but further research is necessary to strengthen the evidence (Gurley et al 2005, 2008a, 2008b, Shi & Klotz 2012). It appears to mildly inhibit CYP2E1; however, whether this is sufficient to cause a major drug interaction has been questioned (Zadoyan & Fuhr 2012).

No significant effects were observed on digoxin pharmacokinetics when taken by healthy volunteers concomitantly with a standardised kava supplement (1227 mg daily) for 14 days (Gurley et al 2007).

## CLINICAL USE

Kava extracts are popular in Europe and have been investigated in numerous clinical trials, primarily in European countries. As a result, many research papers have been published in languages other than English. In order to provide a more complete description of the evidence available, secondary sources have been used where necessary. The extract which has been most studied is kava extract WS 1490.

### Anxiety

Several meta-analyses and systematic reviews have been published over the last two decades, evaluating the results of randomised trials investigating kava extract in anxiety. All have concluded that kava extract is an effective treatment for anxiety. The effect is not apparent after a single dose but requires treatment for at least 1 week to establish benefits. Importantly, no clinically significant changes to liver enzyme levels or hepatotoxic effects have been reported in clinical trials. As such, the expected benefits of treatment outweigh possible risks when aqueous extracts of the dried root and rhizome are used in recommended doses. Teschke et al (2011) recommend that safety may be further improved with the use of a noble kava cultivar such as Borogu, at least 5 years old at the time of harvest, and avoiding the use of poor-quality kava starting materials.

The first Cochrane systematic review published in 2000 assessed the results from seven double-blind, randomised, placebo-controlled trials and concluded that kava kava extract has significant anxiolytic activity and is superior to placebo for the

symptomatic treatment of anxiety (Pittler & Ernst 2000). An update of this review was published in 2003 and analysed results from 12 clinical studies involving 700 subjects and once again concluded that kava treatment produces a significant reduction in anxiety when compared to placebo. The extract most commonly tested was WS 1490 at a dose of up to 300 mg daily.

According to the authors of the review, none of the trials reported any hepatotoxic events and seven trials measured liver enzyme levels as safety parameters and reported no clinically significant changes.

In 2005 a meta-analysis included data from six placebo-controlled, randomised trials with the kava extract WS 1490. The endpoints were the change in Hamilton Anxiety Scale (HAM-A) during treatment (continuous and binary). Kava significantly improved anxiety, with a mean improvement of 5.94 points on the HAM-A scale better than placebo. Interestingly, kava seemed to be more effective in females and in younger patients. The rigorous meta-analysis found no evidence of publication bias and no remarkable heterogeneity amongst the studies and concluded that trials had high methodological standards. Based on this impressive result, the authors concluded that kava remains as an effective alternative to benzodiazepines, selective serotonin reuptake inhibitors and other antidepressants in the treatment of non-psychotic anxiety disorders (Witte et al 2005).

In 2010, two more systematic reviews were published, both concluding that clinical evidence supports the use of kava extract for anxiety symptoms and disorders (Lakhan & Vieira 2010).

The Cochrane review analysed results of 12 double-blind, randomised trials using kava as a stand-alone treatment ( $n = 700$ ). It concluded that, based on the current evidence, the effect size seems small; however treatment is relatively safe with short-term use (up to 24 weeks' use has been tested). Further research with larger participant numbers was called for to clarify the remaining uncertainties. A more recent comprehensive review of the literature which included research published in 2010 also concluded in favour of kava treatment for anxiety, with a significant result occurring for four out of six studies reviewed (Sarris et al 2011a).

Since then, another double-blind, placebo-controlled study has been published which involved 75 participants with generalised anxiety disorder (GAD), but no comorbid mood disorders, and utilised an aqueous extract of kava (120/240 mg of kavalactones per day depending on response) (Sarris et al 2013c). The 6-week study found a significant reduction in anxiety with active treatment compared to placebo with a moderate effect size ( $P = 0.046$ ; Cohen  $d = 0.62$ ). The effect was larger amongst people with moderate to severe GAD ( $P = 0.02$ ;  $d = 0.82$ ). The main side effects reported with kava treatment was headaches ( $P = 0.05$ ), but no other significant differences were found between

the groups for other adverse effects or liver function tests. Interestingly, they also found that specific GABA transporter polymorphisms appear to potentially modify the anxiolytic response to kava.

### Anxiety with depression

In a placebo-controlled, double-blind crossover trial, 60 adult participants with 1 month or more of elevated GAD took five kava tablets per day (250 mg of kavalactones/day) for 3 weeks. This aqueous kava preparation produced significant anxiolytic and antidepressant activity compared to placebo and raised no safety concerns at the dose and duration studied. Importantly, a substantial effect size ( $d = 2.24$ ) was identified with active treatment. As such, kava appeared equally effective in cases where anxiety was accompanied by depression (Sarris et al 2009b).

### Increased female libido in GAD

Oral kava tablets made with an aqueous extract (delivering 120–240 mg kavalactones daily) significantly increased female libido compared to placebo ( $P = 0.040$ ) on a subdomain of the Arizona Sexual Experience Scale (ASEX) in this randomised, placebo-controlled study ( $n = 75$ ) in GAD. There was a highly significant correlation between ASEX reduction (improved sexual function and performance) and anxiety reduction in the whole sample, with no negative effects seen in males (Sarris et al 2013a).

### Comparative studies

Comparative studies suggest the absence of significant differences between benzodiazepines and kavain or kava extract as treatments for anxiety when used in multiple doses. A 1993 double-blind, comparative study involving 174 subjects over 6 weeks demonstrated that 300 mg/day of a 70% kava lactone extract produced a similar improvement in anxiety level, as measured by HAM-A scores, to 15 mg oxazepam or 9 mg bromazepam taken daily (Woelk et al 1993). D,L-kavain produced equivalent anxiolytic effects to oxazepam in 38 outpatients with neurotic or psychosomatic disturbances, under double-blind study conditions (Lindenberg & Pitule-Schodel 1990).

It appears that a single dose of kava (180 mg kavalactones) is not as effective as oxazepam (30 mg) in moderately anxious volunteers (Sarris et al 2012). In this study, oxazepam significantly reduced anxiety whereas kava was ineffective.

An 8-week randomised, double-blind, multicentre clinical trial involving 129 outpatients with GAD showed that kava LI 150 (400 mg/day) was as effective as buspirone in the acute treatment of GAD, with about 75% of patients responding to treatment (Boerner et al 2003).

### Benzodiazepine withdrawal

Kava may have a role in reducing anxiety and improving subjective wellbeing during benzodiazepine

withdrawal, according to a 2001 randomised, double-blind, placebo-controlled study (Malsch & Kieser 2001). During the first 2 weeks of that study, kava dose was increased from 50 mg/day to 300 mg/day while benzodiazepine use was tapered off during the same period. Kava extract was superior to placebo in reducing anxiety as measured by the HAM-A scale and improved subjects' feelings of wellbeing according to a subjective wellbeing scale (Bf-S total scores).

### Combination therapy

A combination of St John's wort (SJW) and kava was ineffective as a treatment for major depressive disorder with comorbid anxiety according to a randomised controlled trial ( $n = 28$ ) conducted in 2009. After a placebo run-in of 2 weeks, the trial had a crossover design testing SJW and kava against placebo over two controlled phases, each of 4 weeks. SJW and kava gave a significantly greater reduction in self-reported depression on the Beck Depression Inventory over placebo in the first controlled phase. However, in the crossover phase, a replication of those effects in the delayed medication group did not occur. Nor were there significant effects on anxiety or quality of life. The authors postulated that a potential interaction with SJW, the presence of depression or an inadequate dose of kava could be explanations for the negative result (Sarris et al 2009a).

### Menopausal and perimenopausal anxiety

A randomised, placebo-controlled study conducted with 40 menopausal women found that, using kava extract, together with hormone replacement therapy (HRT), led to significant reductions in anxiety, as measured by the HAM-A scale at both 3- and 6-month follow-up (De et al 2000). A 3-month, randomised, open study of 68 perimenopausal women showed that treatment with kava (100 mg/day) significantly reduced anxiety ( $P < 0.001$ ) at 1 month and 3 months. This was significantly greater than that spontaneously occurring in controls ( $P < 0.009$ ) (Cagnacci et al 2003).

### Insomnia

The hypnotic activity of kava extract was confirmed in a randomised controlled trial in which a single dose of 300 mg kava extract was found to improve the quality of sleep significantly (Emser & Bartylla 1991, as reported by Ernst et al 2001). In vivo experiments with D,L-kavain have shown that it reduces active wakefulness and significantly prolongs sleep compared with placebo (Holm et al 1991).

### OTHER USES

Traditionally, the herb has been used to treat urinary tract infections, asthma, conditions associated with pain, gonorrhoea and syphilis, and to assist with weight reduction, muscle relaxation and sleep. Topically, it has been used as a local anaesthetic and to treat pruritus.

## DOSAGE RANGE

- Cut rhizome: 1.7–3.4 g/day.
- Dried rhizome: 1.5–3 g/day in divided doses or equivalent to 60–120 mg kavapyrones daily.
- Fluid extract (1:2): 3–8.5 mL/day in divided doses.

Ideally, ethanolic extracts should contain > 20 mg/mL kava lactones.

According to clinical studies:

- Anxiety: generally doses up to 300 mg daily of kava kava extract WS 1490 providing 105–210 mg kavalactones. A kava kava extract LI 150 (400 mg/day) and an aqueous kava extract (in solid-dose form) delivering 120/240 mg of kavalactones per day have successfully treated GAD.
- Anxiety with depression: an aqueous kava extract (in solid-dose form) delivering 250 mg of kavalactones per day.
- Insomnia — a single dose of 300 mg kava kava extract.
- Benzodiazepine withdrawal — 300 mg/day of kava kava extract.

## ADVERSE REACTIONS

Two postmarketing surveillance studies involving more than 6000 patients found adverse effects in 2.3% and 1.5% of patients taking 120–240 mg standardised extract (Ernst 2002). The most common side effects appear to be gastrointestinal upset and headaches when used in recommended doses. Headaches were confirmed as a side effect with aqueous extract of kava (120/240 mg of kavalactones per day) taken over 6 weeks in a randomised controlled trial (Sarris et al 2013c). Clinical trials using therapeutic doses of kava extract have found no clinically significant changes to liver enzyme levels or hepatotoxic effects.

In contrast, the long-term use of high doses of water-based infusions of kava, such as sometimes seen amongst Pacific Islanders and those involved with kava abuse, are known to induce reversible, adverse outcomes such as kava dermatopathy, raised gamma-glutamyltranspeptidase liver enzyme levels, nausea, loss of appetite or indigestion (Rychetnik & Madronio 2011). The reversible ichthyosiform eruption caused by heavy long-term use is known as kanikani in Fijian. This condition is characterised by yellow discolouration of the skin, hair and nails and reverses once kava intake ceases. A 2003 report found no evidence of brain dysfunction in heavy and long-term kava users (Cairney et al 2003).

Research with animal models has further explored the effects of long-term use. A 2011 study with a mouse model found that kava at all dosages and treatment regimens did not induce detectable adverse effects, particularly with respect to liver reactions. Specifically, kava treatment showed no effect on liver integrity indicator enzymes or liver weight, indicating that kava may be potentially safe for long-term use (Johnson et al 2011).

One case was reported which claimed that a patient presented with rhabdomyolysis related to the ingestion of a large amount of kava. The patient developed peak creatine phosphokinase levels in excess of 30,000 U/L, but had no significant renal damage. The amount of kava taken was not specified (Bodkin et al 2012).

## Hepatotoxicity risk minimised

People in the Pacific Islands have used a kava rhizome preparation mixed with water as a ceremonial and social beverage for generations without reported hepatotoxicity. As a result, it was considered without serious side effects until 1998, when the first case reports of kava hepatotoxicity appeared. Causality of hepatotoxicity for kava, sometimes with concomitant use of other medicines, was evident after the use of predominantly ethanolic and acetonetic kava extracts in Germany ( $n = 7$ ), Switzerland ( $n = 2$ ), United States ( $n = 1$ ) and Australia ( $n = 1$ ), as well as after aqueous extracts in New Caledonia ( $n = 2$ ) (Teschke et al 2008a). Moreover, cases of tourists developing serious toxic liver disease after consumption of kava beverages in traditional Samoan kava ceremonies were reported (Christl et al 2009). For this reason, in 2002 the herb was withdrawn from various European countries (Sarris et al 2011b), and the US Food and Drug Administration issued a safety alert about kava and its potential to cause serious liver problems (Teschke 2010a).

To address the issue in Australia, in 2002 the Therapeutic Goods Administration restricted the amount of kavalactones present in each capsule or tablet to a maximum of 125 mg kava lactones and a maximum of 3 g of dried rhizome per tea bag. Additionally, commercial products must not provide more than a daily dose of 250 mg kava lactones. (Please note that the sale and supply are prohibited in Western Australia under a 1988 law, but exceptions apply for Pacific Islander people's traditional use.)

Various authors have evaluated the case reports; however, no clear mechanism for the hepatotoxic adverse effects has emerged. Similarly, research with animal models has not provided clear evidence of hepatotoxicity, further complicating the issue.

Stickel et al (2003) report that, in an analysis of 36 cases of hepatotoxicity, the pattern of injury was both hepatocellular and cholestasis, the majority of patients were women, the cumulative dose and latency were highly variable and liver transplant was necessary in eight of the cases (Stickel et al 2003). A 2007 report by the World Health Organization (WHO) entitled *Assessment of the Risk of Hepatotoxicity with Kava Products* evaluated data from 93 case reports (WHO 2007). Of these, eight were determined to have a close association between kava usage and liver dysfunction; 53 cases were classified as having a possible relationship, but they could not be fully assessed due to insufficient data or other potential causes of liver damage; five cases had a positive rechallenge. Most of the other case reports

could not be evaluated due to lack of information. The WHO report concluded that there is 'significant concern' for a cause-and-effect relationship between kava products and hepatotoxicity, especially for organic extracts. The report noted other risk factors such as heavy alcohol intake, pre-existing liver disease, genetic polymorphisms of cytochrome P450 enzymes, excessive dosage and comedication with other potentially hepatotoxic drugs and potentially interacting drugs. Similarly, Teschke et al analysed 26 suspected cases and concluded that kava taken as recommended is associated with rare hepatotoxicity, whereas overdose, prolonged treatment and comedication may carry an increased risk (Teschke et al 2008b, Teschke 2010). However, several papers outlined strengths and weaknesses of the current methods of causality evaluation (Teschke 2009, Teschke & Wolff 2011). The latest publications have accepted a causal relationship between the use of various kava extracts, including aqueous extracts, and liver injury, and have focused on an assessment of possible causes (Teschke et al 2009).

Various possible pathogenetic factors have been discussed, including metabolic interactions with exogenous compounds at the hepatic microsomal cytochrome P450 level; genetic enzyme deficiencies; toxic constituents and metabolites derived from the kava extract, including impurities and adulterations; cyclooxygenase inhibition; P-gp alterations; hepatic glutathione depletion; solvents and solubilisers of the extracts; and kava raw material of poor quality (Teschke 2010b). More recent reports have postulated that mould hepatotoxins present in kava raw material may be the cause of hepatotoxicity (Teschke et al 2012, 2013). This could be the case given that aflatoxins have been detected in kava samples (Rowe & Ramzan 2012, Trucksess & Scott 2008).

There are abundant data of *in vitro* cytotoxicity, including apoptosis by pipermethystine and flavokavain B added to the incubation media, yet evidence is lacking of *in vivo* hepatotoxicity in experimental animals under conditions similar to human kava use. Furthermore, in commercial Western kava extracts, pipermethystine was not detectable and flavokavain B was present as a natural compound in amounts much too low to cause experimental liver injury (Lechtenberg et al 2008, Teschke et al 2011).

### A way forward?

Strict guidelines for kava standardisation have now been suggested by several researchers. They include: (1) use of a noble kava cultivar such as Borogu, at least 5 years old at time of harvest; (2) use of peeled and dried rhizomes and roots; (3) aqueous extraction; (4) dosage recommendation of  $\leq 250$  mg kavactones per day (for medicinal use); (5) systematic rigorous future research; and (6) a Pan Pacific quality control system enforced by strict policing (Teschke et al 2011).

### Lack of physical tolerance

A long-term, randomised, double-blind trial conducted over 25 weeks found that physical tolerance (effect diminishes over time) does not develop to kava extract (Volz & Kieser 1997).

### No adverse effects on cognition

Evidence from a randomised, double-blind study conducted with 84 patients has shown that treatment with kavain (one of the active constituents of kava kava) produces continuous improvements in parameters such as memory function, vigilance, fluency of mental functions and reaction time. Interestingly, these effects were reported over a relatively short period of 3 weeks (Scholing & Clausen 1977). Another randomised, double-blind trial conducted with 52 patients over 28 days not only confirmed anxiolytic activity but also found that kavain promoted subjective vitality-related performance (Lehmann et al 1989). A more recent review of 10 clinical trials further concluded that available evidence suggests that kava has no replicated significant negative effects on cognition (LaPorte et al 2011).

## SIGNIFICANT INTERACTIONS

### Alcohol

Potentiation of CNS sedative effects has been reported in an animal study; however, one double-blind, placebo-controlled study found no additive effects on CNS depression or safety-related performance (Herberg 1993). Alternatively, a study of 10 subjects found that, when alcohol and kava were combined, kava potentiated both the perceived and the measured impairment compared to alcohol alone (Foo & Lemon 1997). Caution is advised when taking kava in therapeutic doses with moderate alcohol consumption. Avoidance of high doses of kava with alcohol is advised.

### Barbiturates

Additive effects are theoretically possible. Use with caution and monitor drug dosage. However, interaction may be beneficial under professional supervision.

### Benzodiazepines

Additive effects are theoretically possible. A potential pharmacodynamic interaction between alprazolam and kava has been reported (Izzo & Ernst 2009, Shi & Klotz 2012). Use with caution and monitor drug dosage. However, interaction may be beneficial under professional supervision. The combination has been used successfully to ease symptoms of benzodiazepine withdrawal.

### Levodopa

A potential pharmacodynamic interaction between levodopa and kava was reported, leading to reduced

efficacy of levodopa in four case reports (Izzo & Ernst 2009, Shi & Klotz 2012).

### Paracetamol

Paracetamol overdose results in glutathione depletion and increased oxidative stress. A study with rat hepatocytes found that coadministration of kava with paracetamol caused further loss of cell viability by decreasing cellular adenosine triphosphate concentration and increasing reactive oxygen species formation (Yang & Salminen 2011). Avoid kava with high-dose paracetamol, as it may increase paracetamol-induced cell damage.

### L-Dopa medication

Antagonistic effects are theoretically possible, thereby reducing the effectiveness of L-dopa. Avoid concurrent use unless under professional supervision until safety is confirmed.

### Methadone and morphine

Additive effects with increased CNS depression are theoretically possible, so use with caution, although interactions may be beneficial under professional supervision.

### Substrates for CYP2E1

Inhibition of CYP2E1 has been demonstrated in vivo — serum levels of CYP2E1 substrates may become elevated — use with caution.

#### Practice points/Patient counselling

- Kava kava is a scientifically proven treatment for the symptoms of anxiety and stress states. Its anxiety-reducing effects are similar to those of 15 mg oxazepam or 9 mg bromazepam when used for more than a week; yet physical tolerance and reduced vigilance have not been observed.
- It also reduces symptoms of anxiety related to menopause when used together with HRT, and reduces withdrawal symptoms associated with benzodiazepine discontinuation.
- It has anxiolytic, sedative, antispasmodic, analgesic and local anaesthetic activities.
- Although the herb is considered to have a low incidence of adverse effects, long-term use should be carefully supervised because of the possibility of developing adverse reactions.
- Kava should also be avoided in patients with heavy alcohol intake, pre-existing liver disease, genetic polymorphisms of cytochrome P450 enzymes, excessive dosage and comedication with other potentially hepatotoxic drugs and potentially interacting drugs.

### CONTRAINDICATIONS AND PRECAUTIONS

Endogenous depression — according to Commission E (Blumenthal et al 2000).

Although clinical studies indicate no adverse effects on vigilance, the herb's CNS effects may slow some individuals' reaction times, thereby affecting ability to drive a car or operate heavy machinery. The decision as to whether people should avoid driving a car or operating heavy machinery when taking kava treatment should be considered on an individual basis.

Additionally, it should not be used by people with pre-existing liver disease and long-term continuous use should be avoided unless under medical supervision. It should be used with caution in the elderly and in those with Parkinson's disease.

### PREGNANCY USE

Safety is unknown.

### PATIENTS' FAQs

#### What will this herb do for me?

Kava is an effective herbal relaxant that reduces symptoms of anxiety and restlessness. It is also used to relieve anxiety in menopause, insomnia and symptoms of benzodiazepine withdrawal.

#### When will it start to work?

Anxiety-relieving effects are usually seen within the first few weeks of use.

#### Are there any safety issues?

Taking high doses long term has been associated with a number of side effects and should be avoided. Kava should also be avoided in patients with heavy alcohol intake, pre-existing liver disease, genetic polymorphisms of cytochrome P450 enzymes, excessive dosage and comedication with other potentially hepatotoxic drugs and potentially interacting drugs.

## L-Arginine

### BACKGROUND AND RELEVANT PHARMACOKINETICS

L-Arginine is a basic, semiessential amino acid that was discovered in 1886 in lupin seedlings and then in 1895 in mammalian protein (Boger & Bode-Boger 2001). Arginine is a precursor to a variety of compounds, including nitric oxide (NO), creatine, urea, polyamines, proline, glutamate and agmatine (Morris 2009). For humans L-arginine is considered to be a semiessential amino acid or a conditionally essential amino acid, as requirements may increase during metabolic stress or when there is insufficient endogenous L-arginine for optimal growth or tissue repair; for birds and carnivores it is an essential amino acid. It is also the most abundant nitrogen carrier in animals and humans.

Ingested arginine is rapidly cleared from the plasma, and arginine metabolism occurs via a number of pathways, although not all pathways are well defined. Arginine is involved in two major metabolic pathways: the nitric oxide synthase (NOS) pathway and the arginase pathway.

In the NOS pathway, L-arginine is converted to NO and L-citrulline. Three isoforms of NOS (neuronal, inducible and endothelial) have been discovered, each with a different function. NO is a free radical that has vasodilatory and angiogenic characteristics. It regulates nutrient metabolism, plays a role in the circulatory and respiratory systems, especially endothelial function, and exerts numerous other effects in the body.

In the arginase pathway, conversion of L-arginine into L-ornithine and urea is catalysed by the activity of arginase, with the subsequent production of polyamines such as putrescine, spermidine and spermine. Polyamines are essential for cell proliferation and differentiation, tissue growth and development, and are involved in neurogenesis (Yi et al 2009). In mammals two isoforms of arginase play key roles in the regulation of most aspects of arginine metabolism. Arginases have been investigated for their effects in vascular disease, pulmonary disease,

infectious disease, immune cell function and cancer (Morris 2009).

L-Arginine is an essential component in the urea cycle, which is the only pathway in mammals that allows elimination of continuously generated toxic ammonia. Arginine can be synthesised endogenously, mostly in the kidneys and to some degree in liver from the amino acids aspartate and citrulline by arginine synthase.

Arginine is incorporated in the synthesis of proteins, and L-arginine is also required for the production of creatine, which in its phosphorylated form plays an essential role in the energy metabolism of muscle, nerve and testis. Creatine degrades into creatinine, which is removed from the body by the kidneys. Homeostasis of plasma L-arginine is regulated by dietary arginine intake, arginine synthesis and metabolism and protein turnover.

Ingested arginine is rapidly absorbed and metabolised in the gastrointestinal tract. There is little urinary arginine excretion because it is mostly reabsorbed.

### CHEMICAL COMPONENTS

2-amino-5-guanidino-pentanoic acid

### FOOD SOURCES

Free arginine is found in dietary protein, commonly in meat, fish, poultry, milk and dairy products, and nuts and seeds (King et al 2008). Other dietary sources include barley, brown rice, buckwheat, chocolate, corn, oats, raisins and soy. It has been estimated that each gram of dietary protein provides 54 mg of L-arginine, and that 3–6 g of L-arginine is absorbed each day in adults who ingest a normal Western diet (Boger & Bode-Boger 2001, Visek 1986). Dietary lysine competes with arginine for uptake, so low-lysine diets are recommended for enhanced arginine absorption (Stargrove et al 2008).

### DEFICIENCY SIGNS AND SYMPTOMS

Elevated arginase associated with arginine deficiency has been identified in an increasing number of

diseases and conditions. Arginine deficiency syndromes may involve either T-cell dysfunction or endothelial dysfunction depending on the disease context. However the role of supplementation in ameliorating the effects of arginine deficiency requires further investigation (Morris 2012). A deficiency of arginine may affect growth and development, insulin production, lipid and protein metabolism or glucose tolerance. Arginine deficiency may be associated with poor wound healing, hair loss or breakage, liver disease, constipation or skin rash.

### MAIN ACTIONS

Arginine is involved in numerous important and diverse biochemical pathways. L-Arginine and its metabolites produce a myriad of effects in the body, including pH regulation, depolarisation of endothelial cell membranes, macronutrient metabolism, cell-mediated immunity and antitumour activity, and it is an essential intermediate in the urea cycle (Wahlqvist 2002). L-Arginine also influences the release of hormones such as corticotrophin-releasing factor, insulin, glucagon, prolactin, aldosterone and somatostatin.

#### Growth hormone and immune function

Arginine triggers the release of growth hormone, which then increases the cytotoxic activity of macrophages, natural killer cells, cytotoxic T cells and neutrophils (Wahlqvist 2002).

#### Nitric oxide production

Although the arginine–NO pathway represents only a fraction of the total arginine metabolism, it has attracted considerable interest because of the many roles that NO plays in almost all organ systems. NO is a free radical molecule that is synthesised in all mammalian cells from L-arginine by NOS (Tapiero et al 2002). NO is recognised as an ubiquitous mediator, produced by many cell types, that has diverse and complex actions in multiple organ systems (Rawlingson 2003).

As a precursor of NO, L-arginine influences functions as varied as neurotransmission, vasodilation, inflammation, host defence, cytotoxicity, airway and vascular smooth-muscle relaxation, mucociliary clearance and airway mucus secretion and regulation of gene expression (Chionglo Sy et al 2006).

#### Cardiovascular disease

Arginine seems to exert its effects in the cardiovascular system mostly through the formation of NO, although it has NO-independent haemodynamic effects as well.

Through NO-dependent actions, arginine can increase smooth-muscle cell relaxation and endothelial cell proliferation, as well as promote angiogenesis and decrease platelet aggregation, leucocyte adhesion, superoxide production, endothelin-1 release and smooth-muscle proliferation (Chionglo Sy

et al 2006). NO has also been known as endothelium-derived relaxing factor, which is responsible for maintaining vasomotor tone and systemic blood pressure. It also controls intravascular volume by enhancing renin secretion and natriuresis (Rawlingson 2003).

NO-independent actions include: increased plasmin generation or fibrinolysis; augmented release of insulin, growth hormone and glucagon; decreased blood viscosity and formation of fibrin; and decreased angiotensin-converting enzyme activity (Chionglo Sy et al 2006).

#### Antiobesity

In humans brown adipose tissue plays an important role in the oxidation of fatty acids and glucose. Dietary supplementation with L-arginine enhances brown adipose tissue growth, reduces white adipose tissue and improves metabolic profiles. As such it holds promise for preventing and treating obesity in humans (Wu et al 2012).

In a recent study of 20 obese women (aged  $\geq 18$  years and  $\leq 40$  years, body mass index  $\geq 30$  and  $\leq 40$  kg/m<sup>2</sup> and waist circumference  $\geq 89$  cm), 3 g of L-arginine was given three times a day for 12 weeks with lifestyle modification advice. At completion of study there was a significant reduction in waist circumference (mean  $\pm$  SD: 115.6  $\pm$  12.7 cm at baseline to 109.2  $\pm$  11.7 cm at 12 weeks;  $P = 0.0004$ ) and weight (mean  $\pm$  SD: 98.6  $\pm$  19.7 kg at baseline to 95.7  $\pm$  18.6 kg at 12 weeks;  $P = 0.015$ ) (Hurt et al 2014).

### CLINICAL USE

Arginine can have one of two forms, the L-form and the D-form, as do most other amino acids. The majority of research literature focuses on oral L-arginine because it has a longer half-life and better long-term effects than systemic forms and would be the preferred route (Blum et al 1999). The role of arginine in NO production has formed the basis of its application in various disease states, such as cardiovascular disease, sexual dysfunction, peripheral arterial disease, asthma and interstitial cystitis.

#### Cardiovascular disease

In the management of cardiovascular disease, arginine supplementation is noted to improve endothelial function, particularly in hypercholesterolaemia and atherosclerosis (Boger & Bode-Boger 2001). Under- or overproduction of NO is considered to be a contributing factor to cardiovascular disease, or it may be a consequence of disease, leading to active investigations into the potential for the L-arginine–NO system as a therapeutic target for a variety of conditions such as hypertension, atherosclerosis and ischaemic stroke (Rawlingson 2003).

Numerous human studies have shown that arginine supplementation improves endothelial function. Some of the studies have been performed in people with poor flow-mediated dilation, smokers, people with diabetes or after cardiac surgery.

A meta-analysis of 12 studies ( $n = 492$  subjects) investigating the effects of short-term supplementation of oral L-arginine on endothelial function reported that supplementation was effective in significantly improving vascular endothelial function only when the baseline flow-mediated dilation is low (<7%) (Bai et al 2009). In a small double-blind crossover trial 15 obese subjects with impaired glucose tolerance received a low-sugar and protein biscuit with or without 6.6 g of L-arginine in a 1600-kcal diet. Each study period lasted 2 weeks with a 2-week washout in between. During the active treatment phase recipients experienced enhanced endothelial function and improved glucose metabolism, insulin sensitivity and insulin secretion compared to the placebo phase (Monti et al 2013). In a short-term randomised, placebo-controlled, double-blind, crossover study investigating changes in smoking-induced endothelial function, oral supplementation of L-arginine (7 g/day) administered for 3 days in 10 healthy smokers (aged  $24.3 \pm 0.73$  years) resulted in significantly improved arterial performance compared to placebo (Siasos et al 2008). A double-blind randomised parallel-order study investigating the effects of long-term oral L-arginine supplementation (6.4 g/day) on endothelial dysfunction and insulin sensitivity in 64 patients after an aortocoronary bypass who had stable coronary artery disease and without diabetes reported that L-arginine supplementation significantly improved endothelial function, insulin resistance and markers of inflammation after 6 months compared to placebo (Lucotti et al 2009). In a small study of young male patients ( $n = 10$ ) with uncomplicated diabetes and control subjects ( $n = 20$ ), L-arginine supplementation of 7 g/day for 1 week resulted in improved vascular function as determined by lower-limb blood flow. Resting lower-limb blood flow was lower in the patients ( $2.66 \pm 0.3$  vs  $3.53 \pm 0.35$  mL/100 mL/min) and was restored to normal ( $2.66 \pm 0.3$  to  $4.74 \pm 0.86$  mL/100 mL/min) by supplementation with arginine (Fayh et al 2013).

Numerous animal studies have investigated the effects of L-arginine supplementation on measures of atherosclerotic lesion formation and on several markers of endothelial health and function, such as macrophage function, platelet aggregation and adhesion and response to injury. L-Arginine supplementation appears to be of benefit regarding many parameters of vascular health: in particular, experimental models indicate slowed progression of the atherosclerotic disease process (Boger & Bode-Boger 2001, Preli et al 2002), although there is controversy as to whether pre-existing lesions are affected by L-arginine supplementation.

Human clinical trials have shown mixed results. A review of oral L-arginine supplementation identified 17 clinical studies that investigated its effects on vascular health (Preli et al 2002). The duration of supplementation varied from 3 days to 6 months, and doses varied from 6 g to 36 g daily, usually in divided doses. Studies were grouped into those

investigating effects on small vessels, large vessels, coronary blood flow, adhesion molecule expression and monocyte adhesion, platelet aggregation and adhesion, limb ischaemia, exercise tolerance and myocardial infarction.

Of the 17 studies reviewed, 12 produced positive results and showed inhibition of platelet aggregation and adhesion, decreased monocyte adhesion resulting in decreased atherogenesis, improved endothelium-dependent vasodilation or greater painfree and total walking distance in intermittent claudication. In chronic heart failure patients, improvements in forearm blood flow, walking distance and subjective symptoms were reported. In hypercholesterolaemia, all four studies reviewed produced positive results, suggesting that this subgroup may be particularly responsive to therapy with oral L-arginine. The studies showing favourable effects involved subjects with or at risk of vascular disease, whereas two of the five studies showing no beneficial effect on vascular health were conducted with healthy volunteers who did not have endothelial dysfunction. Overall there are subgroups of patients who may gain vascular health benefits from supplementary arginine, particularly patients with less advanced disease (Boger 2008).

### **Hyperlipidaemia**

Treatment with 9 g arginine daily for 6 months improved endothelial function and patient symptom scores in 26 adults with coronary artery disease (Lerman et al 1998). Similarly, in a study of 27 young hypercholesterolaemic adults, improved endothelial dilation was reported as a result of arginine supplementation (21 g/day) for 1 month (Clarkson et al 1996). Decreased serum total cholesterol levels were reported in a study of 45 healthy elderly adults who were treated with 30 g arginine aspartate/day (equivalent to 17 g arginine) for 2 weeks (Hurson et al 1995).

### **Hypertension**

Both oral and intravenous administration of L-arginine may reduce blood pressure. A meta-analysis of 11 randomised, double-blind, placebo-controlled studies ( $n = 387$  subjects) reported oral L-arginine supplementation (4–24 g/day) significantly lowers both systolic (by 5.39 mmHg; 95% confidence interval [CI]  $-8.54$  to  $-2.25$ ,  $P = 0.001$ ) and diastolic (by 2.66 mmHg; 95% CI  $-3.77$  to  $-1.54$ ,  $P < 0.001$ ) blood pressure compared to placebo (Dong et al 2011).

It is believed that supplementation with L-arginine stimulates NO biosynthesis, which leads to reduction of oxidative stress. In a randomised placebo-controlled study, 54 participants (24 women and 30 men) received either L-arginine (2 g tid or 4 g tid) or placebo for 28 days. In patients with mild arterial hypertension L-arginine significantly increased total antioxidant status and the plasma level of asymmetric dimethylarginine (Jabecka et al 2012).

Intravenous administration of L-arginine reduces blood pressure in both healthy subjects and patients with vascular disease. In a randomised, placebo-controlled, crossover study by [West et al \(2005\)](#), the benefit of oral arginine supplementation (12 g/day for 3 weeks) was investigated in 16 middle-aged men with hypercholesterolaemia. In contrast to the results of other studies, where arginine was administered intravenously, L-arginine supplementation did not affect lipids, glucose or inflammatory biomarkers; however, there was a reduction in homocysteine and blood pressure. Supplementation in normotensive people is not necessarily advantageous. In a randomised study of 19 healthy subjects, 6–12 g/day of L-arginine for 4 weeks resulted in a non-significant decrease in systolic and diastolic blood pressure ([Ast et al 2011](#)).

### Pregnancy

A recent meta-analysis of five placebo-controlled studies that investigated the effects of L-arginine supplementation on blood pressure during pregnancy reported that diastolic blood pressure was reduced (mean decrease of 3.07 mmHg;  $P = 0.004$ ) and there was an increase in gestational age at delivery (mean increase of 1.23 weeks;  $P = 0.002$ ) with arginine supplementation, but there was no effect on systolic pressure ( $P = 0.19$ ) ([Zhu et al 2013](#)).

Similarly, another recent systematic review and meta-analysis of seven randomised controlled trials with 916 patients administered different dosages (3–30 g) and administration routes (oral and intravenous) reported that L-arginine was effective in reducing pre-eclampsia or eclampsia incidence and prolonging pregnancy. Two of the studies reported adverse effects that included nausea, vomiting and headache in 1–10% of the subjects and one study reported diarrhoea during oral L-arginine treatment ([Gui et al 2014](#)).

### Myocardial infarction

Some studies have reported that orally administered arginine improves cardiovascular function and reduces myocardial ischaemia in coronary artery disease, whereas others have noted increased mortality. A meta-analysis of two studies with 927 patients with acute myocardial infarction reported that oral supplementation of L-arginine had no significant effect on clinical outcomes in these patients with unstable coronary artery disease, although in an overall pooled estimate there was a reduction (7%) in mortality in the supplemented group compared with the control group (105/459, 22.9% vs 111/455, 24.4%; not significant) ([Sun et al 2009](#)).

In a randomised, controlled study by [Schulman et al \(2006\)](#) 153 patients with acute ST-segment elevation myocardial infarcts were given 9 g arginine (as arginine hydrochloride) a day or placebo for 6 months; however, this study was terminated while in progress, as a significant increase in death rate was noted (8.6% in the group given arginine versus zero in the placebo group;  $P = 0.01$ ). The

supplementary arginine was implicated by the authors, but this assumption was not verified.

In a large, multicentre, randomised, double-blind, placebo-controlled study, 792 patients with coronary artery disease were included within 24 h of the onset of acute myocardial infarction; the arginine group received  $3 \times 3$  g L-arginine a day for 1 month. The results showed very little difference between the two groups with respect to various metabolic and clinical markers, although the arginine-supplemented group had favourable trends. However, positive results were seen in a subgroup of patients with hypercholesterolaemia ([Bednarz et al 2005](#)).

### Angina

Not all studies report efficacy of arginine supplementation for the treatment of angina. A randomised, controlled study of 40 men with stable angina receiving 15 g arginine on a daily basis for 2 weeks did not show benefits for endothelium-dependent vasodilation, oxidative stress or exercise performance ([Walker et al 2001](#)). However, in a randomised controlled study, 10 patients with stable angina who were given 12 g arginine daily for 6 weeks demonstrated increased exercise tolerance benefits, decreased lactate accumulation and decreased heart rate ([Doutreleau et al 2006](#)).

### Congestive heart failure

Studies report mixed findings regarding the benefits of supplemental arginine in congestive heart failure, although taking L-arginine orally, in combination with conventional treatment, seems to improve glomerular filtration rate, creatinine clearance and sodium and water elimination after saline loading.

A study of 21 patients with congestive heart failure who were given 9 g arginine daily for 7 days reported prolonged exercise capability ([Bednarz et al 2004](#)). However, in general, improvements in exercise tolerance, quality of life and peripheral vascular resistance are not consistently obtained. Oral arginine treatment did not have beneficial effects in endothelial function for 20 heart-failure patients who received 20 g/day for 4 weeks ([Chin-Dusting et al 1996](#)).

### Peripheral arterial disease

Dietary supplementation of L-arginine has been reported to improve endothelium-dependent vasodilation, limb blood flow and walking distance in peripheral arterial disease. In one study ([Oka et al 2005](#)), 80 patients with peripheral arterial disease and intermittent claudication were randomly assigned oral doses of L-arginine in 3-g increments up to 9 g daily in three divided doses over a period of 12 weeks. No major differences were noted, although there was a trend for an improvement in walking speed in patients receiving L-arginine, and the group that was treated with 3 g L-arginine daily also demonstrated a moderate improvement in walking distance. On the other hand, in a

randomised, controlled study of 133 patients with peripheral arterial occlusive disease who received L-arginine supplementation of 3 g daily for 6 months, no benefit was reported regarding vascular function and there was a significant decrease in the absolute walking distance (Wilson et al 2007).

### Diabetes

Abnormal insulin modulation of L-arginine transport may contribute to vascular dysfunction in diabetes (Rajapakse et al 2013). Reduced arginine plasma levels have been noted in patients with diabetes mellitus, and reports indicate that endothelial function may be improved in such patients by supplementary arginine. Arginine may also counteract lipid peroxidation, thus reducing the long-term complications of diabetes. In a small study of 10 women with type 2 diabetes mellitus, improved endothelial function was noted after they were given 9 g arginine daily for 1 week (Regensteiner et al 2003).

In a recent long-term randomised, double-blind, parallel-group, placebo-controlled study of 144 subjects with impaired glucose tolerance and metabolic syndrome, arginine supplementation (6.4 g/day) for 18 months, including a follow-up at 12 months, did not reduce the incidence of diabetes, although the probability of normal glucose tolerance increased significantly because of improved insulin sensitivity and  $\beta$ -cell function (Monti et al 2012).

In a randomised placebo-controlled trial 60 patients with visceral obesity and 20 healthy lean control subjects received either 9 g of L-arginine or placebo for 3 months. Arginine treatment significantly decreased homeostasis model assessment-insulin resistance and insulin concentration in patients with visceral obesity, with no impact on tumour necrosis factor- $\alpha$  concentration (Bogdanski et al 2012).

However, in a small study of 38 patients with type 2 diabetes and atherosclerotic peripheral arterial disease of lower extremities and 12 healthy controls, L-arginine supplementation ( $3 \times 2$  g/day) for 2 months had no effect on fasting glucose and HbA<sub>1c</sub>, but there was a significant increase in NO production and total antioxidant status (Jablecka et al 2012).

### Erectile dysfunction

Supplementary arginine has been investigated for its effect on erectile function, given the role of NO in the corpus cavernosum; the research in this area has mixed findings.

In a randomised double-blind, placebo-controlled, two-way crossover study, 26 patients were given 'on demand' 8 g L-arginine aspartate combined with 200 mg of adenosine monophosphate or placebo 1–2 h before sexual intercourse for the intermittent treatment of mild to moderate erectile dysfunction. In the active treatment phase participants experienced significant improvements in all International Index of Erectile Function domains, with the

exception of the Sexual Desire and Orgasmic domains (Neuzillet et al 2013).

In a large prospective randomised, double-blind placebo-controlled study, a high dose of arginine (5 g/day) was administered for 6 weeks to 50 men with organic erectile dysfunction and significant improvement in sexual function was reported only in men with abnormal NO metabolism (Chen et al 1999). However, in a randomised, placebo-controlled, crossover oral study of 32 patients with mixed-type impotence who were treated with  $3 \times 500$  mg L-arginine/day for 17 days, the results showed the supplement was no more effective than the placebo (Klotz et al 1999). Taking L-arginine orally in high doses, 5 g daily, seems to improve subjective assessment of sexual function in men with organic erectile dysfunction, but taking lower doses might not be effective. A combination of arginyl aspartate (equivalent to 1.7 g of L-arginine a day) with pycnogenol was administered to 40 men, aged 25–45 years, for 3 months; by the third month up to 92% of the men reported improved erectile function without any side effects (Stanislavov & Nikolova 2003).

### Cancer

In a randomised prospective study, 37 ambulatory postsurgical patients (mean age  $67.4 \pm 13.1$  years) with head and neck cancer and with recent weight loss (>5% during previous 3 months) received an oral supplement with omega-3 fatty acids and arginine ( $2 \times 227$  mL or  $3 \times 227$  mL supplement containing either 8.4 or 12.6 g L-arginine and 1.2 or 1.8 g eicosapentaenoic acid and 0.8 or 1.2 g docosahexaenoic acid) for 12 weeks postdischarge from hospital. Both doses of the supplement were beneficial and resulted in improved levels of biomarkers, such as albumin, prealbumin and lymphocyte levels, and the higher-dose supplement also led to improved weight gain (de Luis et al 2013).

### Chemotherapy adjunct

There are conflicting reports about the value of arginine supplementation during chemotherapy. As some studies have also used other supplementary constituents, it is difficult to attribute any benefits solely to arginine (Appleton 2002). Importantly, arginine has been implicated in promoting cancer growth, since polyamines can act as growth factors for cancers, and this might be of concern in long-term arginine treatment. Precautionary measures regarding L-arginine administration should be considered in cancer patients, although in recent years immunomodulating formulas containing supplementary arginine have been used safely (Aiko et al 2008, Marik & Zaloga 2008).

### Necrotising enterocolitis

A small parallel-group double-blind randomised study of 83 very-low-birth-weight neonates ( $\leq 1500$  g) and gestational age  $\leq 34$  weeks reported that enteral arginine supplementation (1.5 mmol/kg/day bid)

between the third and 28th day of life ( $n = 40$ ) compared to placebo ( $n = 43$ ) resulted in significantly lower incidence of necrotising enterocolitis stage III (2.5% vs 18.6%,  $P = 0.030$ ) (Polycarpou et al 2013).

### Interstitial cystitis

The results of taking L-arginine for the management of interstitial cystitis are mixed. In a double-blind placebo-controlled crossover study (Cartledge et al 2000), 16 patients were randomised to receive L-arginine (2.4 g/day) or a placebo for 1 month. Although some patients reported improvement in their symptoms, the effects were only small and probably not clinically significant. A randomised, double-blind, placebo-controlled study with 53 patients who received 1500 mg L-arginine or a placebo orally for 3 months reported less pain and urgency in some of the patients (Korting et al 1999). A small study in which patients were treated with either 3 g or 10 g of supplementary arginine did not report any symptom improvements (Ehrén et al 1998). Overall, taking L-arginine orally may reduce symptoms, especially pain associated with interstitial cystitis, in only some patients.

### Enhancing immune function

The results of the utility of supplemental arginine in immunonutrition are mixed. Numerous enteral formulas contain additional arginine for use in catabolic conditions and critical illness; most enteral feeds provide about 12–13 g per 1000 kcal.

A systematic review investigated the impact in critical illness of intramuscular formulas containing various supplementary nutrients such as arginine (ranging from 6.5 to 15 g arginine/L) and glutamine compared with a control diet. Analysis of 24 studies (3013 patients) found that intramuscular diets with supplementary arginine, with or without various supplementary nutrients, did not result in improved outcomes in intensive care, trauma and burn patients (Marik & Zaloga 2008).

### Wound healing

A number of studies have reported that dietary L-arginine supplementation enhances wound healing and immunity. A randomised controlled study with 29 older adults receiving 15 g arginine daily for 4 weeks reported improved immune function (Moriguti et al 2005). Similarly, improved wound healing was reported in another randomised controlled study, in which 17 g arginine as arginine aspartate (30 g/day) was administered daily for 14 days to 30 healthy elderly people (Kirk et al 1993). Improved wound healing was noted in a randomised controlled trial of experimental surgical wounds in 36 healthy adults who were given 17–25 g oral arginine per day (Barbul et al 1990).

### Renal failure

There are mixed reports about the benefit of supplemental L-arginine in the management of chronic

renal failure. There was no improvement in renal function in a randomised, double-blind, placebo-controlled study of 24 patients who were given 200 mg/kg (14 g/70 kg) arginine daily for 6 months (De Nicola et al 1999). A study of 76 renal transplant patients who were given 9 g arginine a day and canola oil as a source of omega-3 fatty acids for 3 years noted reduced infections and transplant rejections (Alexander et al 2005).

### Sports

A recent randomised, double-blind, placebo-controlled study investigating the acute effect of L-arginine supplementation (6 g) in 15 men during recovery from three sets of resistance exercise regarding biceps strength performance, indicators of NO production and muscle blood volume and oxygenation reported that supplementation significantly increased muscle blood volume but there was no difference between groups regarding the other measures (Alvares et al 2012). Similarly, in a randomised, double-blind crossover study investigating the effects of acute supplementation with L-arginine alpha-ketoglutarate (3000 mg) on muscular strength and endurance in eight resistance-trained and eight untrained men, it was reported that supplementation did not provide an ergogenic benefit regardless of the training status of the participants (Wax et al 2012).

In a further randomised, double-blind, placebo-controlled crossover study, 6 g arginine did not alter biomarkers of NO synthesis, oxygen cost of exercise or exercise tolerance in 15 healthy subjects (Vanhatalo et al 2013).

## OTHER USES

### HIV — general support

Supplementary arginine may have a beneficial role in the care of HIV infection and AIDS. A few studies have already been conducted investigating the effects of a combination of arginine with vitamins, minerals and glutamine; body weight was reported to increase, but other findings were mixed (Appleton 2002).

### Asthma

Arginine supplementation may be beneficial to patients with asthma, although there are reports that such supplementation may also cause exacerbation of airway inflammation (Coman et al 2008). At present, it is unclear whether L-arginine supplementation results in any clinically significant benefit to patients with asthma.

### Cystic fibrosis

In a small, double-blind, placebo-controlled crossover study of 10 patients with cystic fibrosis, arginine supplementation of 200 mg/kg administered for 6 weeks resulted in increased NO production (Grasemann et al 2005).

## Dementia

Increased cognitive function and reduced lipid peroxidation were noted in 16 elderly patients with senile dementia who were administered arginine (1.6 g/day) (Ohtsuka & Nakaya 2000).

## Subfertility

It has been well documented that arginine-deficient diets in adult men result in markedly decreased sperm counts. Infertile men given 500 mg arginine hydrochloride per day for 6–8 weeks were reported to have increased sperm counts, although such supplementation had no effect if the baseline sperm counts were less than 10 million/mL (Appleton 2002). Results of a single study note that supplementation of 16 g of arginine per day improved ovarian response and pregnancy rate in poor responders to in vitro fertilisation (Battaglia et al 1999).

## DOSAGE RANGE

### General guide

- Overall, L-arginine is well tolerated in doses <30 g administered orally, intravenously or via the intra-arterial route (Boger & Bode-Boger 2001). It is best taken in divided doses to improve overall absorption, reaching 1.5–6 g daily.
- In a risk assessment by Shao and Hancock (2008), the following recommendations have been made: no observed adverse effect level and lowest observed adverse effect level >42 g/day L-arginine; observed safe level 20 g/day. ULS 20 g/day.

### According to clinical studies

- Angina pectoris: oral 12 g/day (uncertain efficacy).
- Coronary artery disease: 9 g/day.
- Erectile dysfunction: 5 g/day (in men with abnormal NO metabolism).
- Hyperlipidaemia: 30 g/day (uncertain efficacy).
- Wound healing: 17 g/day.

## TOXICITY

Overall, arginine administration is considered safe for humans and animals (Wu & Meininger 2000). However, it must be noted that vasodilation and hypotension can result from the overproduction of NO due to excess administration of arginine.

## ADVERSE REACTIONS

L-Arginine supplementation has been used safely and has been associated with only minor side effects in clinical studies lasting from a few days to months (Shao & Hathcock 2008). Orally, L-arginine can cause abdominal pain and bloating, diarrhoea and gout. Gastrointestinal disturbances have been reported as a result of arginine supplementation, although the studies have been of a mixed nature and involved a range of patients (Grimble 2007), whereas these effects have not been reported in controlled studies.

There has been only limited consideration of safety aspects of supplemental arginine, even though

numerous animal studies have been conducted examining a wide range of diseases (Shao & Hathcock 2008). In humans only one study has used a high oral arginine dose of 42 g on a daily basis without any adverse effects being noted (Shao & Hathcock 2008). In patients with argininosis, high doses (500 mg/kg body weight) of arginine may elevate liver enzymes (Nagamani et al 2012).

## SIGNIFICANT INTERACTIONS

No controlled studies are available to determine the significance of the proposed interactions, so they remain speculative.

### Antihypertensive medicines

Theoretically, additive hypotensive effects may occur — use with caution. Potential benefits under professional supervision.

### Nitrates

Theoretically, additive vasodilation and hypotensive effects may occur — use with caution.

### L-Lysine

A limited number of research studies report that high doses of arginine could be unfavourable, as arginine may compete with lysine uptake by tissues; caution is needed if considering the administration of both amino acids, since supplemental arginine has been reported to affect proliferation of the herpes simplex virus (Griffith et al 1981).

### Sildenafil

Theoretically, additive vasodilation and hypotensive effects may occur — use with caution. Potential benefits under supervision.

## CONTRAINDICATIONS AND PRECAUTIONS

Intravenous arginine needs to be administered with care, as overdose may result in adverse consequences such as severe hyponatraemia (Shao & Hathcock 2008), and high doses with high osmolality can cause local irritation and phlebitis (Boger & Bode-Boger 2001).

Other side effects that can occur as a result of administering arginine are metabolic acidosis associated with arrhythmias, and hyperkalaemia and increases in blood nitrogen urea in patients with liver disease and/or renal impairment (Boger & Bode-Boger 2001).

Hyperkalaemia and hypophosphataemia in patients with diabetes have also been reported (Boger & Bode-Boger 2001). Supplementary arginine may also be contraindicated in patients with systemic septic shock and hypotension due to NO production (Feihl et al 2001).

Caution is necessary in using high doses of 30 g/day in cancer patients, as even short-term use for 3 days may be linked to increased tumour growth.

### PREGNANCY USE

At present there is insufficient reliable information available about the safety of L-arginine during pregnancy and for nursing mothers. Dietary intake levels are likely to be safe.

### Practice points/Patient counselling

- L-Arginine is a conditionally essential amino acid for humans; requirements may be increased during metabolic stress or when there is insufficient endogenous L-arginine for optimal growth or tissue repair.
- Arginine deficiency can affect growth and development, insulin production, lipid and protein metabolism and glucose tolerance. Clinical symptoms include poor wound healing, hair loss or breakage, liver disease, constipation and skin rashes.
- The role of arginine in NO production forms the basis of its application in cardiovascular disease, peripheral arterial disease, sexual dysfunction, asthma and interstitial cystitis.
- Oral arginine supplementation shows promise in the treatment of angina, hyperlipidaemia, congestive heart failure, improving vascular health (reducing atherogenesis) and interstitial cystitis; however, results are not consistent.
- Oral arginine supplementation has shown benefits in erectile dysfunction and promoting wound healing.
- Arginine supplementation should be used with caution in people with cancer, kidney and/or liver impairment, schizophrenia, herpes simplex virus or a history of myocardial infarction.

### PATIENTS' FAQs

#### What will this supplement do for me?

Arginine supplementation is used in cardiovascular disease, peripheral arterial disease, sexual dysfunction, wound healing and several other conditions. Its effects will depend on the dose used and indication for use.

#### When will it start to work?

This depends on the dose used and indication for use.

#### Are there any safety issues?

Arginine supplementation should be used with caution in people with cancer, kidney and/or liver impairment, schizophrenia, herpes simplex virus or a history of myocardial infarction. There are also several drug interactions that should be considered before use.

## Lavender

**HISTORICAL NOTE** Lavender, both the whole plant and its essential oils, has a long history of traditional use for a range of medical conditions. Lavender was used as an antiseptic in ancient Arabian, Greek and Roman medicines. Its generic name comes from the Latin *lavare*, to wash, and it was used as a bath additive as well as an antiseptic in the hospitals and sick rooms of ancient Persia, Greece and Rome (Blumenthal et al 2000), and as an antibacterial agent in World War I (Cavanagh & Wilkinson 2005). In the 17th century, Culpeper described lavender as having 'use for pains in the head following cold, cramps, convulsions, palsies and faintings' (Battaglia 1995). Lavender was also used traditionally to scent bed linen and to protect stored clothes from moths. This was such a well-accepted practice that the phrase 'laying up in lavender' was used metaphorically to mean 'putting away in storage' (Kirk-Smith 2003).

Lavender is now widely used in perfumes, potpourri, toiletries and cosmetics, to flavour food, as well as therapeutically. However, research produces a conflicting evidence base for lavender for a range of reasons, including the fact that the species of lavender is not always identified, that lavender is frequently adulterated and

that little research has been conducted using species other than *Lavandula angustifolia*, which is also known as true lavender. *Lavandula angustifolia* is commonly adulterated with related species that vary in their chemical constituents. Spike lavender yields more oil, but is of lower quality than true lavender, and has a different chemical make-up. Lavandin is a hybrid of spike lavender and true lavender.

## COMMON NAME

Lavender

## OTHER NAMES

Common lavender, English lavender, French lavender, garden lavender, Spanish lavender, spike lavender, true lavender

## BOTANICAL NAME/FAMILY

*Lavandula angustifolia* (synonyms: *L. officinalis*, *L. vera*, *L. spica*); *L. dentata*; *L. latifolia*; *L. pubescens*; *L. stoechas*, *L. multifida* (family Labiatae)

## PLANT PARTS USED

Flowers, leaves and stems

## CHEMICAL COMPONENTS

Most lavender is extracted by steam distillation, but it can also be extracted using supercritical carbon dioxide extraction. Time and pressure affect the oil yield and antioxidant activity of lavender oil and both increase with pressure and time (Danh et al 2012).

Lavender flowers contain between 1% and 3% essential oil. The oil is a complex mixture of many different compounds, the amounts of which can vary between species. The most abundant compounds include linalyl acetate (30–55%), linalool (20–35%), cineole, camphor, coumarins and tannins (5–10%) (Schulz et al 1998), together with 1,8-cineole, thymol and carvacrol (Aburjai et al 2005) and borneol (Danh et al 2012). Perillyl alcohol and D-limonene have been shown to exert anticancer effects (see Clinical note). More recently, 39 constituents, accounting for 99% of total constituents, were extracted from *Lavandula multifida* (Rhaffari et al 2007). The main constituents were phenols such as thymol (32%), carvacrol (27.77%) and *p*-cymene (15.72%), and  $\gamma$ -terpinene (9.54%). Phenols are not commonly found in lavender. These constituents give the oil significant antibacterial activity similar to ampicillin and tetracycline in a dose-dependent manner (Rhaffari et al 2007).

## MAIN ACTIONS

The pharmacological actions of various lavender extracts, essential oil and several of its constituents have been investigated. The true therapeutic benefit of the essential oil is difficult to ascertain as it is often combined with other oils or administered together with massage and other therapies such as acupressure, making interpretation of study results difficult.

### Sedative/anxiolytic

The methanolic and aqueous extracts of *Lavandula officinalis* demonstrate potent sedative and hypnotic

### Clinical note — Perillyl alcohol and anticancer effects

Perillyl alcohol and D-limonene are monoterpenes found in lavender (also in cherries, mint and celery seeds) that have shown chemotherapeutic and chemoprotective effects in a wide variety of in vitro and animal models (Shi & Gould 2002) and are currently being examined in human clinical trials (Gould 1997, Kelloff et al 1999). Perillyl alcohol treatment has resulted in 70–99% inhibition of ‘aberrant hyperproliferation’, a late-occurring event preceding mammary tumorigenesis in vivo (Katdare et al 1997) and, together with limonene, perillyl alcohol has been shown to induce the complete regression of rat mammary carcinomas by what appears to be a cytostatic and differentiation process (Shi & Gould 1995). Perillyl alcohol has also been shown to inhibit human breast cancer cell growth in vitro and in vivo (Yuri et al 2004) and inhibit the expression and function of the androgen receptor in human prostate cancer cells (Chung et al 2006).

A variety of mechanisms has been proposed to explain these effects. The compounds may act via interfering with Ras signal transduction pathways that regulate malignant cell proliferation (Hohl 1996) and have been found to promote apoptosis in pancreatic adenocarcinoma cells (Stayrook et al 1997) and liver tumours in vivo (Mills et al 1995). Perillyl alcohol, together with D-limonene, has been found to preferentially inhibit HMG-CoA reductase in tumour cells (Elson et al 1999), as well as inhibit ubiquinone synthesis and block the conversion of lathosterol to cholesterol, which may add to its antitumour activity (Ren & Gould 1994). Limonene is oxidised by the CYP2C9 and CYP2C19 enzymes in human liver microsomes (Miyazawa et al 2002a) and there are reported sex-related differences in the oxidative metabolism of limonene by liver microsomes in rats (Miyazawa et al 2002b).

Although in vitro and animal studies have demonstrated the ability of perillyl alcohol to inhibit tumorigenesis in the mammary gland, liver and pancreas, the results are not yet conclusive and one animal study testing perillyl alcohol detected a weakly promoting effect early in nitrosamine-induced oesophageal tumorigenesis in rats (Liston et al 2003). In initial phase II clinical trials, perillyl alcohol administered orally, four times daily, at a dose of 1200 mg/m<sup>2</sup> had no clinical antitumour activity on advanced ovarian cancer (Bailey et al 2002), metastatic androgen-independent prostate cancer (Liu et al 2003) or metastatic colorectal cancer (Meadows et al 2002).

activities *in vivo*, thereby providing a pharmacological explanation for its therapeutic use in anxiety and insomnia (Alnamer et al 2012). Hritcu et al (2012) demonstrated that *L. angustifolia* ssp *angustifolia* and *L. hybrida* administered daily for 7 days significantly reduced anxiety, inhibited depression and improved spatial memory in male Wistar rats.

### Lavender oil

The sedative properties of the essential oil and its main constituents (linalool and linalyl acetate) have a dose-dependent effect in mice and have been shown to reverse caffeine-induced hyperactivity in mice (Buchbauer et al 1991, Lim et al 2005), as well as reduce stress, as indicated by modulation of adrenocorticotrophic hormone (ACTH), catecholamine and gonadotrophin levels in experimental menopausal rats (Yamada et al 2005), and reduce cortisol responses in infant Japanese macaques (Kawakami et al 2002). Inhalation of lavender oil has also been shown to produce a dose-dependent anticonvulsant effect in both rats and mice (Yamada et al 1994).

In human trials, inhalation of lavender has been shown to induce relaxation and sedation (Schulz et al 1998) and to alter EEG responses (Diego et al 1998, Dimpfel et al 2004, Lee et al 1994, Sanders et al 2002, Yagyu 1994), enhance sleep and improve alertness on waking (Hirokawa et al 2012), as well as significantly decrease heart rate and increase high-frequency spectral components to produce calm and vigorous mood states in healthy volunteers (Kuroda et al 2005). Intermittent exposure to lavender over 30 minutes increased the proportion of deep and slow wave sleep in men and women (Goel et al 2005). In addition, Goel et al's subjects reported feeling more alert in the morning after inhaling lavender oil in the evening. Conversely, Sakamoto et al (2005) reported higher concentration levels in the afternoon in people receiving lavender at night compared to controls.

Transdermal absorption of linalool without inhalation produced a decrease in systolic blood pressure and a smaller decrease of skin temperature with no effects on subjective evaluation of wellbeing in healthy human subjects (Heuberger et al 2004), and another study found that lavender scent was associated with lower fatigue following an anxiety-provoking task (Burnett et al 2004). Lavender inhalation compared to sweet almond oil reduced autonomic arousal (e.g. heart and respiratory rates and blood pressure) and improved self-reported mood, supporting studies that reported on the relaxing effects of lavender (Sayorwan et al 2012).

Shaw et al (2011) also demonstrated anxiolytic effects in various parts of the hypothalamus and the central amygdala in rat brains, but the effect was not as significant as benzodiazepines. Shaw et al attributed the effects to linalool and linalyl acetate and recommended further study using single chemicals extracted from lavender. Similarly, Chioca et al (2011) demonstrated an anxiolytic effect of a

combination of *L. angustifolia* and *Citrus sinensis* administered via a vapouriser to Swiss mice without affecting locomotor activity and suggested the activity was not mediated through the GABA-A/benzodiazepine complex.

These positive studies are contrasted by studies with negative findings. Lavender aromatherapy did not significantly improve scores on the Hospital Anxiety and Depression Scale or the Somatic and Psychological Health Report (SPHERE) in a RCT of 313 patients undergoing radiotherapy (Graham et al 2003), and a study of 169 subjects, including both depressed and non-depressed subjects, showed that lavender increased fatigue, tension, confusion and total mood disturbance, and decreased vigour (Goel & Grasso 2004).

Lavender combined with sweet marjoram, patchouli and vetiver essential oils in a cream and applied as a massage five times per day for 4 weeks to 56 residents with moderate to severe dementia in an aged care facility demonstrated a significant but small improvement in Mini-Mental tests, increased alertness and less resistance, compared to the use of a massage cream without essential oils (Bowles et al 2002). The calming effects could be due to the large proportion of esters in *L. angustifolia* (26–56%) (Walsh et al 2011), but it is not clear which lavender species were used in the studies cited.

### Antimicrobial

Various *in vitro* data suggest that lavender oil has antibacterial activity (Dadalioglu & Evrendilek 2004, Larrondo et al 1995), including against methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococcus (VRE) (Nelson 1997), antifungal activity (Inouye et al 2001), including against *Aspergillus nidulans* and *Trichophyton megatrophites* (Daferera et al 2000) and mitocidal activity (Perrucci et al 1996, Refaat et al 2002), with both lavender and linalool having fungistatic and fungicidal activities against *Candida albicans* strains at high concentrations and inhibiting germ tube formation and hyphal elongation at low concentrations, suggesting that it may be useful for reducing fungal progression and the spread of infection in host tissues (D'Auria et al 2005). Lavender has been shown to be active alone and to work synergistically with tea tree oil against the fungi responsible for tinea and onychomycosis (Cassella et al 2002). However, effective vapour concentrations have not yet been established for aromatherapy use.

The fungistatic properties of linalool have led to the suggestion that it could be used to complement environmental measures in preventing fungal contamination in storage areas of libraries (Rakotonirainy & Lavedrine 2005).

### Carminative

Linalool, one of lavender's major components, demonstrated spasmolytic activity when tested on an *in vitro* preparation of guinea-pig ileum smooth muscle (Lis-Balchin & Hart 1999).

### Antineoplastic effects

In vitro and animal studies suggest that perillyl alcohol and D-limonene (see [Clinical note](#)) may have useful chemotherapeutic and chemoprotective effects in a range of cancers, including cancers of the colon, liver, lung, breast, pancreas and prostate, as well as in melanoma ([Micromedex 2003](#)). These results have not yet been confirmed in human studies.

### OTHER ACTIONS

When applied topically, lavender oil has rubefacient properties ([Fisher & Painter 1996](#)) and is thought to have analgesic, antihistaminic and anti-inflammatory activities. A small study comparing the effects of a bath containing lavender oil, synthetic lavender oil and distilled water in reducing perineal discomfort after childbirth found lower mean discomfort scores in the lavender group; however, the differences between groups were not significant ([Cornwell & Dale 1995](#)).

Traditionally, lavender oil is considered to have a balancing effect on the CNS, acting as an aromatic stimulant or calming agent.

Extracts of *L. multifida* have been found to have topical anti-inflammatory activity in mice, with some extracted compounds having activity comparable to that of indomethacin ([Sosa et al 2005](#)). At high concentrations (0.1%), lavender oil has also been found to suppress TNF-alpha-induced neutrophil adherence ([Abe et al 2003](#)). Lavender has also demonstrated powerful antioxidant activity ([Gulcin et al 2004](#)), as well as antimutagenic activity ([Evandri et al 2005](#)) and antiplatelet and antithrombotic properties demonstrated both in vitro and in vivo ([Ballabeni et al 2004](#)).

### Insect bites

In vitro and animal studies suggest that lavender oil inhibits immediate-type allergic reactions by inhibition of mast cell degranulation ([Kim & Cho 1999](#)).

### CLINICAL USE

Increasingly, clinical studies have been conducted with lavender oil in an oral dose form as well as externally applied essential oil and inhaled as an aromatherapy application. In particular, its potential therapeutic effect as an anxiolytic agent has gained much more attention than previously.

### Anxiety

A number of controlled trials and observational studies suggest that inhalation of ambient lavender oil has a relaxing effect and is able to reduce anxiety and improve mood, concentration and sleep. It has been studied as a stand-alone treatment and in combination with other essential oils. Recent clinical research also shows that oral administration of lavender oil (Silexan) is an effective treatment for mild to moderate anxiety and is generally well tolerated. This product has been authorised for use in Germany

for the treatment of states of restlessness during anxious mood ([Uehleke et al 2012](#)).

A 2012 systematic review of 15 randomised controlled trials (RCTs) ( $n = 1565$ ) investigated various forms of lavender (inhaled as aromatherapy, essential oil combined with massage, oil added to bath and oral capsules) used with different cohorts (healthy, stress induced) and applied as acute treatment or as multiple doses/exposures. It concluded that limited specific effects of lavender inhalation and massage on anxiety measures are available and while reductions in anxiety measures were observed, methodological issues limit the extent to which firm conclusions can be drawn. Alternately, the evidence available regarding the use of oral lavender oil is positive, supporting its use in anxiety ([Perry et al 2012](#)).

More specifically, RCTs using oral lavender oil capsules have reported beneficial effects in reducing mild to moderate anxiety ([Bradley et al 2009](#), [Kasper et al 2010](#), [Uehleke et al 2012](#), [Woelk & Schlafke 2010](#)). All studies used a commercial product known as Silexan.

[Woelk et al \(2010\)](#) compared Silexan to lorazepam and found both groups significantly reduced anxiety as measured by the Hamilton Anxiety Rating Scale (HAM-A). While both treatments were well tolerated, there were marginally more side effects in the lavender group which were generally gastrointestinal disturbances. [Kasper et al \(2010\)](#) also tested the lavender oil capsules (Silexan) in this randomised double blind study, which used treatments for 10 weeks in volunteers with subsyndromal anxiety disorder (according to DMS-IV or ICD-10). Active treatment produced a significant reduction in anxiety levels ( $P < 0.01$ ) compared to controls as measured by the HAM-A. Additionally, [Bradley et al \(2009\)](#) tested the same preparation (Silexan) in subjects with generalised anxiety disorder (GAD) over a 6-week treatment period and compared it to lorazepam. The mean of the HAM-A-total score decreased clearly and to a similar extent in both groups (by  $11.3 \pm 6.7$  points (45%) in the silexan group and by  $11.6 \pm 6.6$  points (46%) in the lorazepam group, from  $25 \pm 4$  points at baseline in both groups. Both treatments were also comparable for a number of other outcomes such as SAS (Self-rating Anxiety Scale), PSWQ-PW (Penn State Worry Questionnaire), SF 36 Health Survey Questionnaire and Clinical Global Impressions of severity of disorder (CGI item 1, CGI item 2, CGI item 3), and the results of the sleep diary. It appeared to be most effective in cases of induced mild anxiety compared to more severe anxiety.

In 2012, [Uehleke et al \(2012\)](#) reported from an open label study that Silexan significantly increased mental wellbeing (SF-36) by 48.2% ( $P < 0.001$ ), efficiency of sleep ( $P = 0.018$ ) and mood ( $P = 0.03$ ) and significantly reduced waking-up frequency ( $P = 0.002$ ), waking-up duration ( $P < 0.001$ ) and morning tiredness ( $P = 0.005$ ). At baseline, patients suffered from restlessness (96%), depressed mood (98%),

sleep disturbances (92%) or anxiety (72%). Of those, response rates were 62%, 57%, 51% and 62% respectively showing improvements during treatment ( $P < 0.001$ ). The dose used was 80 mg/day Silexan over 6 weeks. The study involved 50 male and female patients with neurasthenia, post-traumatic stress disorder or somatisation disorder. For all patients, mean von Zerssen's Depression Scale score decreased by 32.7% and Symptom Checklist-90-Revised Global Severity Index by 36.4% as compared to baseline ( $P < 0.001$ ).

### Essential oil used externally

At least eight RCTs have investigated the effect of lavender oil inhalation with four trials reporting a significant decrease in anxiety for at least one outcome measure (Braden et al 2009, Kritsidima et al 2010, Kutlu et al 2008, Motomura et al 2001), whereas four other RCTs found no significant effect (Howard & Hughes 2008, Muzzarelli et al 2006, Sgoutas-Emch et al 2001, Toda & Morimoto 2008). A systematic review of these RCTs concluded that lavender oil inhalation and massage can reduce anxiety symptoms; however, the methodological shortcomings of the existing RCTs means a definitive conclusion cannot be made (Perry et al 2012).

More recently, a study conducted in an intensive care unit (ICU) involving 56 percutaneous coronary intervention (PCI) patients found that inhaling a combination of essential oils (lavender, roman chamomile and neroli with a 6:2:0.5 ratio) 10 times before PCI and another 10 times after PCI significantly lowered anxiety ( $P < 0.001$ ) and improved sleep quality ( $P = 0.001$ ) compared with conventional nursing interventions. The latter were not described (Cho et al 2013).

### Veterinary use

Lavender oil has also been studied for veterinary applications. The ambient odour of lavender reduced travel-induced excitement in dogs, according to a study involving 32 dogs with a history of travel-induced excitement in owners' cars (Wells 2006). Dogs exposed to lavender spent significantly more time resting and sitting, and less time moving and vocalising during the experimental condition.

Lavender aromatherapy has also been found to produce increased resting and reduced movement and vocalisation in dogs housed in a rescue shelter (Graham et al 2005). Daily essential oil baths using *L. angustifolia* for 14 days led to lower stress and trait anxiety in both the experimental and the control groups, but a larger effect occurred in the lavender group ( $n = 37$ ) (Morris 2008).

### Insomnia

In Australia, lavender essential oil is the most popular aromatherapy oil, outselling the second most popular (orange) oil by more than seven times (Kheery (In Essence) pers. commun. 2002). It is often combined with bergamot and cedarwood oils for relieving

anxiety and stress and combined with marjoram to induce sleep. A recent systematic review of four RCTs suggests lavender could be beneficial to promote sleep in people with insomnia compared to controls, but the differences in outcome measures, administration methods, other methodological inadequacies such as short duration of the studies and small sample size make it difficult to make definitive conclusions (Fismer & Pilkington 2012). It is most often used as part of an aromatherapy approach, applied topically or inhaled via ambient dispersion.

Since then, a study utilising a combination of essential oils (lavender, roman chamomile and neroli with a 6:2:0.5 ratio) with 56 ICU patients found that it significantly improved sleep quality ( $P = 0.001$ ) compared with conventional nursing intervention (Cho et al 2013).

Commission E supports the use of oral lavender in mood disturbances such as restlessness and insomnia (Blumenthal et al 2000).

### Depression and mood enhancement

According to a 4-week double-blind, RCT, oral lavender tincture (1:5 in 50% alcohol) taken as a dose of 60 drops/day was not as effective as imipramine for treating depression; however, a combination of lavender tincture and imipramine taken together was actually more effective than imipramine used alone and provided quicker improvement (Akhondzadeh et al 2003).

Another RCT of 80 non-depressed women tested the addition of lavender oil to a bath and found this procedure had a general mood-enhancing effect and produced a reduction in pessimism (Morris 2002). Similarly, improved mood and perceived anxiety were reported in a controlled trial of 122 ICU patients who received a massage with lavender oil (Dunn et al 1995).

### Cardiovascular effects

Lavender aromatherapy reduced serum cortisol and improved coronary flow velocity reserve (CFVR) in healthy men, suggesting that lavender aromatherapy has relaxation effects and may have beneficial acute effects on coronary circulation (Shiina et al 2008). CFVR was measured with non-invasive transthoracic Doppler echocardiography (TTDE). CFVR was assessed at baseline and immediately after lavender aromatherapy (4 drops of essential oil diluted with 20 mL of hot water and inhaled for 30 minutes). Simultaneously, serum cortisol was measured.

Another study of healthy young women found that lavender aromatic treatment induced not only relaxation but also increased arousal level in these subjects as measured by continuous electrocardiographic (ECG) monitoring before and after (10, 20, 30 minutes) the lavender fragrance stimuli (Duan et al 2007). Increases in the parasympathetic tone were observed after the lavender fragrance stimulus, seen as increases in the heart function component

and decreases in the low frequency (LF)/high frequency (HF). Additional measurement with positron emission tomography demonstrated the regional metabolic activation in the orbitofrontal, posterior cingulate gyrus, brainstem, thalamus and cerebellum, as well as the reductions in the pre/post-central gyrus and frontal eye field.

#### Hypertension — in combination

Seong et al (2013) demonstrated significant differences in systolic blood pressure between treatment and control groups in favour of the treatment group. The study involved 40 male soldiers with >140 mmHg of systolic or >90 mmHg diastolic blood pressure readings who were undergoing preliminary training and not taking antihypertensive medication. The active group used a combination of *L. angustifolia*, ylang ylang, marjoram and neroli for 2 weeks which was administered via inhalation using an aroma stone and aroma necklace. Hypertension was diagnosed using the American Society of Hypertension guidelines.

#### Dementia care

Managing difficult behaviours in aged care facilities is very challenging. A number of researchers have shown reductions in agitated behaviour using lavender in massage, baths, vaporisers and on bedclothes. These studies generally show positive effects; however, they are difficult to interpret because of the individual nature of behaviour and odour effects on individuals, as well as the methodological differences among the studies.

A placebo-controlled study found that lavender aromatherapy effectively reduced agitated behaviour in 15 patients with severe dementia (Holmes et al 2002), but it had no effect on reducing agitation in another controlled trial of seven severely demented patients (Snow et al 2004), nor was there an effect on reducing resistive behaviour in 13 people with dementia in a residential aged care facility (Gray & Clair 2002). Similarly, a crossover randomised trial of 70 Chinese older adults with dementia demonstrated that lavender inhalation for 3 weeks significantly decreased agitated behaviours (Lin et al 2007). As this patient population is particularly vulnerable to side effects of psychotropic medications, aromatherapy using lavender may offer an attractive alternative option.

In another controlled trial, a 2-week lavender aromatherapy hand massage program produced significant improvements in emotion and aggressive behaviour in elderly people with Alzheimer's type dementia (Lee 2005).

#### Reducing falls

Lavender administered in patches ( $n = 73$ ) appears to reduce falls rates in residential aged care facilities compared to standard case ( $n = 72$ ) when falls and falls incidence was monitored over 360 days (Sakamoto et al 2012). There were significantly fewer falls in the lavender group compared with controls.

Likewise, the incident rate was lower: 1.04/person/year compared to 1.40/person per year. In addition, The Cohen-Mansfield Agency Inventory (CMAI) score was lower in the lavender group.

#### Improved concentration

In an RCT, exposure to lavender aromatherapy during breaks resulted in significantly higher concentration levels during the afternoon period when concentration was found to be lowest in a control group (Sakamoto et al 2005). Lavender oil aromatherapy has also been found to reduce mental stress and increase arousal rate (Motomura et al 2001), to elicit a subjective sense of 'happiness' (Vernet-Maury et al 1999) and to produce increased relaxation, less depressed mood and faster and more accurate mathematical computations (Field et al 2005). In an RCT, lavender aromatherapy tended to enhance calculating speed and calculating accuracy in female but not male subjects (Liu et al 2004); however, results from another study suggest that lavender reduced working memory and impaired reaction times for both memory and attention-based tasks compared with controls (Moss et al 2003).

#### IN COMBINATION

A controlled study of dementia patients found that a blend of lavender, sweet marjoram, patchouli and vetiver essential oils in a cream massaged five times/day for 4 weeks onto the bodies and limbs of 56 aged care facility residents with moderate-to-severe dementia produced a small but significant improvement in the Mini-Mental State Examination associated with increased mental alertness and awareness and resistance to nursing care procedures compared with massage with cream alone (Bowles et al 2002).

#### Migraine headache

Inhalation of lavender essential oil for 15 minutes significantly reduced the severity of migraine headache, based on a Visual Analogue Scale, compared with controls ( $P < 0.0001$ ). The placebo-controlled study of 47 patients with a definite diagnosis of migraine headache showed that out of 129 headache attacks, 92 episodes responded entirely or partially to lavender compared to 32 out of 64 headaches responding to placebo. In other words, the percentage of responders was significantly higher in the lavender group than the placebo group ( $P = 0.001$ ) (Sasannejad et al 2012).

#### Dyspepsia and bloating

Although there have been no clinical trials to investigate its use, lavender is commonly recommended for gastrointestinal disorders as a carminative and antifatulent to soothe indigestion, colic, dyspepsia and bloating (Blumenthal et al 2000). Based on the antispasmodic actions of a key constituent, linalool, lavender may be useful in these conditions. No controlled clinical studies could be located to determine its effectiveness for these indications.

### Alopecia — in combination

An RCT of scalp massage using thyme, rosemary, lavender and cedarwood essential oils in 86 patients with alopecia areata found a significant improvement in hair growth after 7 months (Hay et al 1998). Although the efficacy of lavender as a stand-alone treatment was not clarified with this trial, it is known that the herb has some antibacterial and antifungal activity that may play a role. In a single case study, topical application of lavender, together with other essential oils, was reported to assist in treating scalp eczema (De Valois 2004).

### Perineal discomfort following childbirth

An RCT in 635 women following childbirth found that using lavender oil in bath water was safe and pleasant and that there was a tendency towards lower discomfort scores between the third and fifth day (Dale & Cornwell 1994). In that study, 6 drops of pure lavender oil was added to the bath. Vakilian et al (2011) demonstrated less perineal redness using lavender essential oil compared to povidone-iodine in 120 primiparous Pakistani women who had an episiotomy. Lavender was administered in a sitz bath.

Likewise, Sheikhhan et al (2012) demonstrated lavender 'essence' reduced perineal discomfort following episiotomy in 60 post partum primiparous women in a hospital setting in Iran. Lavender was administered in a sitz bath twice a day for 5 days. The women were randomly allocated to a treatment of control group and self-rated discomfort using a visual analogue scale. Nurses rated the appearance of the perineum for redness and discharge 4-hourly and 12-hourly for 5 days. However, it is not clear what lavender essence was, or even whether it was an essential oil.

### Dysmenorrhoea and PMS

Ten minutes of aromatic inhalation with lavender significantly decreased depressive mood and feelings of dejection ( $P = 0.045$ ) and confusion ( $P = 0.049$ ) according to the Profile Of Moods (POMs) scale among women with mild to moderate subjective premenstrual symptoms. The randomised, crossover study of 17 women ( $20.6 \pm 0.2$  years) examined exposure to aromatic stimulation on two separate occasions (lavender and control) in the late-luteal phases. The beneficial effects lasted up to 35 minutes after exposure. Additionally, a 10-minute inhalation of the lavender scent significantly increased parasympathetic nervous system activity in comparison with water according to measures taken after 10–15 minutes and again after 20–25 minutes (Matsumoto et al 2013).

#### IN COMBINATION

Aromatherapy applied topically in the form of an abdominal massage using 2 drops of lavender (*Lavandula officinalis*), 1 drop of clary sage (*Salvia sclarea*) and 1 drop of rose (*Rosa centifolia*) in 5 cc of almond oil significantly decreased the severity of menstrual cramps,

according to a randomised, placebo-controlled study (Han et al 2006). The study involved 67 female college students who rated their menstrual cramps to be greater than 6 on a 10-point visual analogue scale, who had no systemic or reproductive diseases and who did not use contraceptive drugs.

### Acute external otitis — in combination

A randomised study of 70 subjects demonstrated that application of a combination herbal drop consisting of *Syzygium aromaticum*, *L. angustifolia* and *Geranium robertianum* (Lamigex 1 drop) was as effective as Ciprofloxacin 0.3% drops after a week of treatment. Three drops were applied every 12 hours for a week ( $n = 70$ : 35 in each group). Tenderness, itching, erythema, oedema and discharge were all improved by the end of the treatment period ( $P > 0.05$ ). Additionally, the rate of pain relief was the same with both treatments when evaluated on day 3 and day 7 ( $P > 0.05$ ). Importantly, the number of positive cultures tested for micro-organisms were the same for both groups, indicating successful antibiotic effects (Panahi et al 2012).

### Pain reduction

It has been suggested that the relaxing effects may be useful in the treatment of chronic pain (Buckle 1999), and this is supported by a study reporting that while lavender did not elicit a direct analgesic effect, it did alter affective appraisal of the pain experience with retrospective impression of pain intensity and pain unpleasantness from experimentally induced heat, pressure and ischaemic pain being reduced after treatment with lavender aromatherapy (Gedney & Glover 2004).

In an RCT, eight sessions of acupressure using lavender essential oil over 3 weeks was found to be effective in relieving pain, neck stiffness and stress in 32 adults with sub-acute non-specific neck pain (Yip & Tse 2006). Alternatively, one RCT involving 42 subjects found that the addition of lavender essential oil did not appear to increase the beneficial effects of massage for patients with advanced cancer (Soden et al 2004).

### OTHER USES

Lavender has a long history of use as a sedative, an antidepressant, an antimicrobial agent, a carminative (smooth muscle relaxant), a topical analgesic agent for burns and insect bites (Cavanagh & Wilkinson 2002) and an insect repellent. Lavender has also been used to treat migraines and neuralgia, as an astringent to treat minor cuts and bruises, and is used externally for strained muscles, as well as acne, eczema and varicose ulcers (Fisher & Painter 1996). It is also used in a gargle for loss of voice.

### DOSAGE RANGE

Probably no other herb is available in as many forms as lavender.

- Infusion (tea): 1.5 g dried flowers in 150 mL water, which is 1–2 teaspoons lavender flowers or

leaves in one cup of boiling water steeped for 5–10 minutes and strained before drinking.

- Internal: 1–4 drops (20–80 mg) on a sugar cube.
- Liquid extract (1:2): 2–4.5 mL/day.
- External use: mix 20 drops of oil with 20 mL of carrier oil such as almond oil. May be applied undiluted to insect bites or stings.
- As a bath additive: 20–100 g lavender flowers are commonly steeped in 2 L boiling water, strained, and then added to the bathwater. Alternatively 5–7 drops are added to the bath and stirred to mix the oil into the water.
- Aromatherapy: use 2–4 drops of lavender oil in a suitable oil diffuser or on a pillowcase to assist sleep.

Lavender oil is quickly absorbed by the skin and constituents linalool and linalyl acetate have been detected in the blood 5 minutes after administration. Blood levels peak after 19 minutes and are negligible by 90 minutes.

### According to clinical studies

Anxiety, restlessness and depression: Silexan 80 mg/day

### TOXICITY

McGuffin (1997) lists lavender as a Class I herb, a classification which represents herbs that can be 'safely consumed when used appropriately'. The acute oral toxicity dose (LD<sub>50</sub>) in rats for lavender and linalool are 5 g/kg and 2.8 g/kg, respectively and the acute dermal toxicity in rabbits is 5 g/kg and 5.6 g/kg, respectively (Kiefer 2007). These doses would translate to approximately 350 g lavender oil or 1.5 cups. Although there are very few specific reports of toxicity, it is suggested that no more than 2 drops be taken internally.

### ADVERSE EFFECTS

#### Topical use

The prevalence of dermatitis and skin allergies to essential oils, including lavender, increases with the duration of exposure, representing a cumulative risk: 1.1–13.9% over 13 years (Wu et al 2011). Dermatitis appears to be a cumulative occupational risk for aromatherapists applying essential oils in massage over long periods of time.

There is a potential for irritant or allergenic skin reactions with the topical use of lavender oil, as it has been found to be cytotoxic to human skin cells in vitro (endothelial cells and fibroblasts) at a concentration of 0.25% v/v, possibly due to membrane damage. The activity of linalool was found to reflect the cytotoxicity of the whole oil, whereas the cytotoxicity of linalyl acetate was found to be higher than that of the oil, suggesting suppression of its activity by an unknown factor in the oil (Prashar et al 2004). Three case reports have been published of gynaecomastia developing in boys aged four, seven and ten following regular topical use of lavender-containing products (soap, shampoo and

lotions) (Henley et al 2007). Henley et al postulated that lavender has oestrogenic and antiandrogenic effects on several different cell lines. The implications for clinical practice and aromatherapy are unknown.

Skin sensitivity to lavender might develop with increased exposure and prolonged use (Sugiura et al 2000).

### Oral use

Controlled studies with Silexan, a commercial lavender oil product manufactured for oral consumption, report that mild gastrointestinal symptoms are the most common side effect.

#### Practice points/Patient counselling

- The active part of lavender is the volatile oil, which has relaxing, sedative, antispasmodic and antiseptic activity.
- Lavender can be taken as a tincture or tea, or the oil can be applied topically, used in baths or inhaled from a diffuser.
- It is advised that topical preparations be tested on a small area of skin before widespread application.
- Lavender has traditionally been used for sleep disorders, anxiety and nervous stomach, as well as to treat minor cuts, burns, bruises and insect bites and is commonly found in cosmetics and toiletries.
- Ambient lavender induces a relaxation response in healthy people, the elderly with dementia, and agitation and also dogs with travel-induced excitement. It also may improve mood in women with mild to moderate PMS symptoms, enhance memory and concentration, reduce the severity of migraine headache.
- Abdominal massage with lavender oil (in combination with several others) has been shown to reduce menstrual cramps to a better degree than a non-aromatherapy oil.
- Recent studies with a commercial oral lavender preparation supports its use for insomnia.

### SIGNIFICANT INTERACTIONS

Controlled studies are rarely available; however, the American Society for Pharmacology and Experimental Therapeutics (Doroshenko et al 2013) found repeated doses of 160 mg/day of an oral lavender oil preparation Silexan did not significantly inhibit or induce the CYP 1A2, 2C9, 2C19, 2D6, or 3A4 liver enzymes in vivo studies.

### Pharmaceutical sedatives

Theoretically, lavender can potentiate the effects of sedatives, so observe patients taking this combination closely — beneficial interaction possible under professional supervision.

## Antidepressants

Lavender tincture may have additive effects when used with these medicines — beneficial interaction possible.

### PREGNANCY USE

No restrictions known for external use. Safety of internal use has not been scientifically established.

### PATIENTS' FAQs

#### What will this herb do for me?

Lavender oil is often used together with other essential oils to assist relaxation, sleep disturbances, digestive problems and as first aid for minor skin conditions. Ambient lavender can improve mood in women with mild to moderate PMS, reduce the severity of migraine headache, induce a relaxation response in healthy people and older people with dementia and agitation, and also calms dogs during travel. Used as part of an aromatherapy massage, it also has antispasmodic activity. There is also research that a commercial lavender oil capsule has benefits in insomnia and when lavender is administered in patches, reduces falls rates in residential aged care.

#### When will it start to work?

As a relaxant, effects may be felt on the first day of use, but depends on the dose and dose form used.

#### Are there any safety issues?

Topical lavender oil is considered generally safe although skin irritation can occur whereas oral lavender (Silexan) has been associated with gastrointestinal discomfort in some people.

L

## Lemon balm

**HISTORICAL NOTE** Lemon balm was used in ancient Greece and Rome as a topical treatment for wounds. In the Middle Ages it was used internally as a sedative and, by the 17th century, English herbalist Culpeper claimed it could improve mood and stimulate clear thinking (Myers 2007). Nowadays, it is still used to induce a sense of calm and help with anxiety, and it is also added to cosmetics, insect repellents, furniture polish and food.

### COMMON NAME

Lemon balm

### OTHER NAMES

Balm mint, bee balm, blue balm, common balm, cure-all, dropsy plant, garden balm, sweet balm

### BOTANICAL NAME/FAMILY

*Melissa officinalis* (family Lamiaceae)

### PLANT PART USED

Aerial parts

### CHEMICAL COMPONENTS

Flavonoids, phenolic acids, tannins, triterpenes, essential oil and sesquiterpenes. Of note, the herb contains citronellal, caffeic acid, eugenol, rosmarinic acid, choline, ursolic acid and oleanolic acid (Wake et al 2000, Yoo et al 2011). Caftaric acid, *p*-cumarinic acid, ferulic acid, luteolin and apigenin have also been identified (Hanganu et al 2008). Growing and harvesting methods have a major influence on the

amount of volatile oil present in the leaves. It has been found that the oil content in the herb is highest in the top third and lowest in the bottom two-thirds (Mrljanova et al 2002).

#### Clinical note

Long before the current biologically based theory of cholinergic abnormalities in Alzheimer's dementia emerged, Western European medicine systems traditionally used several herbs that are now known to exert cholinergic activity (such as sage and lemon balm) for their dementia-treating properties.

### MAIN ACTIONS

#### Anxiolytic, sedative

Over the years, a number of studies involving rodents have suggested specific anxiolytic or sedative effects (Abuhamdah et al 2008, Ibarra et al 2010,

Kennedy et al 2002, Soulimani et al 1991, Taiwo et al 2012). A number of possible active components of the dried leaf and essential oil of the herb may be responsible for these effects, such as eugenol and citronellol, which bind to gamma-aminobutyric acid-A (GABA-A) receptors and increase the affinity of GABA to receptors (Aoshima & Hamamoto 1999).

A 2009 in vitro study found a methanol extract of lemon balm caused inhibition of rat brain GABA transaminase, the enzyme responsible for GABA degradation (Awad et al 2009). This effect was attributed to rosmarinic acid, a major constituent of lemon balm that has been shown to possess anti-anxiety properties in vivo (Pereira et al 2005).

### Antidepressant activity

A rodent study investigated the antidepressant-like activity of an aqueous extract and the essential oil of lemon balm using a forced-swim test model. Both the aqueous extract and the essential oil demonstrated significant antidepressant effects. The antidepressant effect of the aqueous extract was similar to that of the reference drug imipramine. The aqueous extract also demonstrated a sedative effect not seen in the essential oil. The mechanism of the antidepressant effect of the aqueous extract and essential oil of lemon balm is unknown and requires further investigation (Emamghoreishi & Talebian-pour 2009).

### Antiviral

A lemon balm extract was found to have significant virucidal effects against herpes simplex virus-1 (HSV-1) within 3 and 6 hours of treatment in vitro and in animal tests (Dimitrova et al 1993). The volatile oils from *Melissa officinalis* have also been shown to inhibit the replication of HSV-2 in vitro (Allahverdiyev et al 2004).

A hydroalcoholic extract of lemon balm showed a significant virucidal effect against HSV-2 activity in vitro, and demonstrated a concentration-dependent inhibition of viral replication, with a maximum effect of 60% inhibition of viral replication achieved at 0.5 mg/mL (Mazzanti et al 2008).

An aqueous extract of lemon balm, as well as isolated phenolic compounds caffeic acid, *p*-coumaric acid and rosmarinic acid, exhibits strong antiviral activity against HSV-1 in vitro. Rosmarinic acid had the strongest effects; however the complete lemon balm extract demonstrated superior activity at lower doses than any of the isolated compounds, suggesting a synergistic effect (Astani et al 2012).

Two more studies have demonstrated the antiviral effects of lemon balm against HSV in plaque reduction assays. One study used an essential oil preparation, while the other used an aqueous extract (Nolkemper et al 2006, Schnitzler et al 2008). Both studies demonstrated > 90% inhibition of plaque formation for HSV-1 and HSV-2, and in one study an aciclovir-resistant strain of HSV-1 was reduced

by 85% (Nolkemper et al 2006). Both studies also found that lemon balm affected HSV before adsorption, but had no effect on viral replication.

Lemon balm has demonstrated a virucidal effect against HIV-1 in T-cell lines and macrophages in vitro (Geuenich et al 2008). Inhibitory activity against HIV-1 reverse transcriptase has also been shown (Yamasaki et al 1998).

### Antibacterial and antifungal

Lemon balm extract exhibited activity against bacteria, filamentous fungi and yeasts in vitro (Larrondo et al 1995). Lemon balm extracts have demonstrated moderate to strong antibacterial activity against *Sarcina lutea*, *Staphylococcus aureus* and *Bacillus cereus* in vitro (Canadanovic-Brunet et al 2008).

It is likely that the constituent eugenol is chiefly responsible, as it has well-established antibacterial activity against organisms such as *Escherichia coli* and *S. aureus* (Walsh et al 2003).

An in vitro study found that lemon balm essential oil exhibited a higher degree of antibacterial activity than lavender oil against Gram-positive strains, while both oil samples demonstrated a high activity against *Candida albicans*. Lemon balm oil displayed poor activity against Gram-negative bacteria. This study identified citral (a mixture of neral and geranial, 16.10%), citronellal (3.76%) and trans-caryophyllene (3.57%) as the chief antimicrobial constituents in lemon balm essential oil (Hancianu et al 2008).

An aqueous extract of lemon balm inhibited *Candida albicans* mycelial growth in vitro. However, green tea, cassia and lemon grass preparations demonstrated even greater antifungal activity against *C. albicans* (Taguchi et al 2010).

### Cholinergic

Lemon balm appears to increase activity in the cholinergic system in the brain; this is necessary for memory and attention. Lemon balm exhibits central nervous system acetylcholine receptor activity, with both nicotinic and muscarinic-binding properties (Perry et al 1996, Wake et al 2000). In vitro data have demonstrated that lemon balm has a moderate affinity to the GABA-A benzodiazepine receptor site (Salah & Jager 2005). The essential oil has demonstrated reversible inhibition of GABA-induced currents in rat cortical neurons (Huang et al 2008) and inhibitory activities on both acetylcholinesterase and butyrylcholinesterase (Chaiyana & Okonogi 2012, Orhan et al 2008). Isolated compounds from lemon balm, including *cis*- and *trans*-rosmarinic acid, have shown a very high inhibitory activity against acetylcholinesterase in vitro (Dastmalchi et al 2009). These studies indicate that lemon balm may have a role to play in the treatment of Alzheimer's disease and epilepsy. However, a 2003 randomised, double-blind, placebo-controlled, crossover trial demonstrated that lemon balm did not inhibit cholinesterase. The trial demonstrated improved cognitive function and mood and concluded that for

these reasons it was a valuable adjunct to Alzheimer's therapy (Kennedy et al 2003).

### Anti-inflammatory, analgesic

The plant extract exerts analgesic activity at high doses in vivo (Soulimani et al 1991). A rodent study documented the dose-related analgesic effect of ethanolic extracts of lemon balm and rosmarinic acid produced via activation of cholinergic and inhibition of L-arginine-nitric oxide pathways (Guginski et al 2009).

Two constituents in lemon balm have documented anti-inflammatory activity, achieved through different mechanisms of action. Rosmarinic acid, a naturally occurring constituent found in *Melissa officinalis*, inhibits several complement-dependent inflammatory processes (Englberger et al 1988, Peake et al 1991). Eugenol, another important component, inhibits cyclooxygenase-1 (COX-1) and -2 activities in vitro (Huss et al 2002, Kelm et al 2000).

Presently, little clinical research has been conducted to determine whether topical application of lemon balm preparations have an anti-inflammatory effect.

To date, one randomised, placebo-controlled study of 40 healthy subjects investigated the anti-inflammatory activity of a topical lemon balm application for ultraviolet (UV)-induced erythema and found it was ineffective as used in the study. Test areas on the upper back were irradiated with 1.5-fold of the UV-B minimal erythema dose. A formulation of lemon balm was applied under occlusion to the irradiated areas and to a non-irradiated area on the contralateral side (Beikert et al 2013).

### Antispasmodic

Both the whole volatile oil and its main component citral have demonstrated antispasmodic ability on isolated rat ileum (Sadraei et al 2003). Similarly, both the aqueous extract and rosmarinic acid component demonstrated vasorelaxant properties on isolated rat aorta (Ersoy et al 2008). An in vivo study has shown both an extract of lemon balm and the herbal formulation ColiMil (chamomile, fennel and lemon balm) may delay gastric emptying (Capasso et al 2007). The group treated with lemon balm exhibited 36% inhibition, chamomile 28% and fennel 9% as compared to 45% for the ColiMil group, suggesting a synergistic action.

### Antioxidant

Lemon balm has shown antioxidant activity in several studies (Apak et al 2006, Canadanovic-Brunet et al 2008, Dastmalchi et al 2008, Ferreira et al 2006, Hohmann et al 1999, Koksai et al 2011, Lopez et al 2007, Marongiu et al 2004, Spiridon et al 2011). According to a 2003 study, concentrations of antioxidants within lemon balm are >75 mmol/100 g (Dragland et al 2003). Co-administration of an aqueous extract of lemon balm in manganese-treated mice resulted in a significant decrease in activity of the antioxidant enzymes

superoxide dismutase and catalase in the hippocampus, striatum, cortex and cerebellum; and decreased oxidative stress marker levels in the hippocampus and striatum (Martins et al 2012). Lemon balm has demonstrated superior antioxidant activity compared to chamomile and lemongrass, and an aqueous extract of lemon balm has been found to have greater antioxidant potential than methanolic and ethanolic extracts (Pereira et al 2009).

### Cardiovascular effects

Aqueous extracts of lemon balm have been shown to slow cardiac rate but not alter the force of contraction in isolated rat hearts (Gazola et al 2004). An aqueous extract of lemon balm was found to exhibit a vasodilatory effect on isolated rat aortic rings via the nitric oxide pathway (Ersoy et al 2008).

### Hypolipidaemic

Lemon balm has been found to reduce blood cholesterol and lipid levels in rabbits fed a high-cholesterol diet (Karimi et al 2010). Interestingly, in a similar study using rats fed a high-fat and alcohol diet, the lemon balm extract also increased glutathione levels and reduced lipid peroxidation in the liver, demonstrating a hepatoprotective effect (Bolken et al 2005).

The hypolipidaemic effects of lemon balm essential oil were investigated in vitro and in vivo using lipid-loaded HepG2 cells and human APOE2 transgenic mice, respectively. The HepG2 cells treated with lemon balm essential oil demonstrated increased bile acid synthesis, and decreased expression of HMG-CoA reductase and cellular triglyceride and cholesterol concentrations (Jun et al 2012).

The APOE2 transgenic mice treated with lemon balm essential oil for 2 weeks did not demonstrate a significant reduction in total cholesterol; however plasma triglyceride concentrations decreased by 36%, and the mouse livers showed increased expression of cholesterol metabolism genes. The authors suggest that longer-term treatment of APOE2 transgenic mice with lemon balm essential oil may have had hypocholesterolaemic effects (Jun et al 2012).

### IN COMBINATION

In a 2008 study, mice fed a high-fat diet were supplemented with Ob-X, a herbal compound containing lemon balm, white mulberry and injin. At 12 weeks, mice supplemented with Ob-X had significantly decreased serum triglycerides and total cholesterol levels; significantly lower adipose tissue mass and body weight gain; and less hepatic lipid accumulation compared to mice fed a high-fat diet alone (Lee et al 2008). In two follow-up studies, Ob-X was found to inhibit angiogenesis and adipogenesis in vitro and in vivo (Hong et al 2011, Yoon & Kim 2011).

Dietary supplementation with 1% powdered clove flower combined with 0.2% lemon balm extract in broiler chickens had no influence on plasma low-density lipoproteins, serum cholesterol, total lipids, triglycerides or high-density lipoproteins. However, blood concentrations

of vitamin E and sulfhydryl groups were found to increase (Petrovic et al 2012).

### Promotes neurogenesis

Lemon balm enhances the neurogenic ability of cells of the hippocampal dentate gyrus in vivo: this is of relevance because this area is affected in several neurological disorders, including Alzheimer's disease. The study found administration of lemon balm extract resulted in increased GABA levels in the hippocampal dentate gyrus of mice, due to less GABA breakdown due to inhibition of GABA transaminase, the enzyme responsible for GABA degradation. Lemon balm was found to significantly increase cell proliferation and neuroblast differentiation in the mouse dentate gyrus. This is thought to be due to the increased GABA levels potentiating the survival of new cells, as GABA agonists have been found to increase maturation and survival of proliferating neuronal cells (Yoo et al 2011).

### Hypoglycaemic

The hypoglycaemic potential of lemon balm essential oil was investigated in type 2 diabetic mice. Administration of 0.015 mg/day of lemon balm essential oil for 6 weeks resulted in significantly reduced blood glucose levels and triglyceride concentrations, improved glucose tolerance and significantly increased serum insulin levels. This action is mediated via activation of GCK, a key enzyme in the control of glucose homeostasis, and inhibition of G6Pase and PEPCK, two key enzymes in the gluconeogenesis pathway in the liver (Chung et al 2010).

### Anticarcinogenic, antimutagenic

Ethanollic extracts of lemon balm have demonstrated both antigenotoxic and antimutagenic activity in mice (de Carvalho et al 2011). Antitumour activity has also been demonstrated (Chlabicz & Galasinski 1986, Dudai et al 2005, Galasinski 1996, Galasinski et al 1996, Saraydin et al 2012). Extracts of lemon balm were found to inhibit growth of cervix epithelial carcinoma cells and breast adenocarcinoma cells in vitro (Canadanovic-Brunet et al 2008).

Ethanollic and aqueous extracts of lemon balm demonstrated cytotoxic activity against human colon cancer cells in vitro. The ethanollic extract was found to reduce cell proliferation to values close to 40% and cell viability to 13% after 72 hours of treatment. Cytotoxic activity was largely attributed to rosmarinic acid (Encalada et al 2011).

Isolated extract of corchorifatty acid B (CFAB) from ethanollic preparations of lemon balm demonstrated antimelanogenic activity in both human melanocytes and mouse melanoma B16 cells. The inhibition of cellular pigmentation is likely to be induced by rapid degradation of tyrosinase, the rate-limiting enzyme for melanin production (Fujita et al 2011).

### OTHER ACTIONS

Lemon balm inhibits the binding of thyroid-stimulating hormone to thyroid plasma membranes in vitro and the extrathyroidal enzymic T4-5'-deiodination to triiodothyronine (Aufmkolk et al 1984a). Methanolic extracts of lemon balm exhibit moderate amoebicidal activity in vitro (Malatyali et al 2012).

Lemon balm extracts have demonstrated antiglycative activity in vitro. Ethanollic extracts of lemon balm exhibited the highest inhibitory effects on the formation of advanced glycation end products, which induce cell and tissue damage and are known to promote diabetic complications, atherosclerosis, Alzheimer's disease and ageing (Miroliaei et al 2011).

### CLINICAL USE

In clinical practice, lemon balm is often prescribed in combination with other herbal medicines. As a reflection of this, many clinical studies have investigated the effects of lemon balm as an ingredient of a herbal combination, making it difficult to determine the efficacy of this herb individually.

### Anxiety

A small, double-blind, placebo-controlled, randomised, crossover trial involving 18 healthy volunteers investigated the effects of a whole extract of standardised *Melissa* extract (Pharmaton, Lugano, Switzerland) in two different doses (300 and 600 mg) and found a significant reduction in stress in the volunteers taking the larger dose; however alertness was also reduced at the higher dose (Kennedy et al 2004).

A prospective, open-label, 15-day pilot study evaluated the efficacy of a product called Cyracos, a standardised hydroalcoholic lemon balm extract containing >7% rosmarinic acid and >15% hydroxycinnamic acid derivatives, in 20 participants with mild to moderate anxiety disorders and sleep disturbances. Participants took 600 mg of active treatment per day in two divided doses. Anxiety levels were evaluated using the Free Rating Scale for Anxiety, and the Hamilton Rating Scale for Depression was used to assess insomnia. Cyracos reduced anxiety by 18%, anxiety-associated symptoms by 15% and insomnia by 42%. While significant improvements in associated symptoms of anxiety and insomnia were seen, these findings need to be replicated in a larger clinical trial that includes a placebo arm and double blinding (Cases et al 2011).

Commission E approves the use of lemon balm in the treatment of anxiety and restlessness (Blumenthal et al 2000).

### IN COMBINATION

A combination of lemon balm and valerian (*Valeriana officinalis*) was examined for acute effects on anxiety in a double-blind, placebo-controlled, randomised, crossover experiment of 24 individuals (Kennedy et al 2006).

Three separate concentrations of the standardised product (600 mg, 1200 mg, 1800 mg) were given on separate days after a 7-day wash-out period. Any changes to mood and anxiety were assessed predose and at 1-, 3- and 6-h intervals. Interestingly, the lower dose (600 mg) was shown to decrease anxiety levels whereas the highest dose (1800 mg) increased anxiety. The exact effect of lemon balm in this preparation is hard to determine.

### Cognitive function

Lemon balm has been used for centuries to improve cognitive function and encouraging results from a 2002 clinical study confirm that it can influence memory.

The randomised, double-blind crossover study involving 20 healthy young volunteers found that single doses of lemon balm (Pharmaton, Lugano Switzerland) were able to modulate both mood and cognitive performance in a dose- and time-dependent manner (Kennedy et al 2002). In this study, treatment with the lowest dose (300 mg) increased self-rated 'calmness' within 1 hour whereas the 600 mg and 900 mg doses produced significant effects on memory task performance, observable at both 2.5 hours and 4 hours after administration. The highest tested dose (900 mg) was found to significantly reduce alertness within 1 hour, suggesting a dose-response effect.

### Alzheimer's disease

A randomised, double-blind, placebo-controlled trial demonstrated the efficacy and safety of *M. officinalis* in 42 patients aged 65–80 years with mild to moderate Alzheimer's disease: patients were given 60 drops/day for 4 months (Akhondzadeh et al 2003). The treatment consisted of a plant extract prepared as 1:1 in 45% alcohol and standardised to contain at least 500 mcg citral/mL. After week 4, the difference between placebo and active treatment was significant and became highly significant at the end point (week 16) ( $P < 0.0001$ ) on the Alzheimer's disease assessment scale. By week 8, the difference was also significant on the clinical dementia rating scale and highly significant by week 16 ( $P < 0.0001$ ).

Aromatherapy with lemon balm may not be as effective as oral use of the extract, according to a double-blind randomised controlled trial which compared lemon balm aromatherapy to donepezil or placebo aromatherapy in the treatment of agitation in people with Alzheimer's dementia. Participants were required to wear nose clips for the aromatherapy treatment to ensure that full blinding was maintained. The Pittsburgh Agitation Scale (PAS) and Neuropsychiatric Inventory (NPI) were completed at baseline, 4-week and 12-week follow-up. Of 114 participants, 94 completed the week 4 assessment and 81 completed the assessment at week 12. No significant differences were found between aromatherapy, donepezil and placebo either at week 4 or 12. However, the lack of

significant differences between groups was due to an 18% improvement in the PAS and a 37% improvement in the NPI over 12 weeks in all three groups. The authors suggest that this may be attributed to potential non-specific benefits of touch and interaction in the treatment of agitation in people with Alzheimer's disease (Burns et al 2011).

In another study, lemon balm essential oil used as aromatherapy and applied twice daily to face and arms under double-blind placebo-controlled conditions was found to be a safe and effective treatment for clinically significant agitation in people with severe dementia (Ballard et al 2002). The trial, which involved 71 subjects, found that after 1 month's treatment, patients were less agitated, less socially withdrawn and spent more time in constructive activities than those in the placebo group. Quality-of-life ratings also improved.

### Insomnia

In clinical practice, lemon balm is often prescribed in combination with other herbs such as valerian in the treatment of insomnia. As a reflection of this, a randomised, double-blind multicentre study investigated the effects of a commercial valerian and lemon balm herbal combination (Songha Night) in 98 healthy subjects (Cerny & Schmid 1999). Treatment was administered over a 30-day period and consisted of three tablets taken half an hour before bedtime, providing a total dose of 1–6 g valerian and 1–2 g lemon balm. Herbal treatment was found to significantly improve sleep quality and was well tolerated.

Another randomised, double-blind crossover study found that the same combination of valerian and lemon balm taken over 9 nights was as effective as triazolam in the treatment of insomnia (Dressing et al 1992). The dose used was equivalent to 1.4 g dried valerian and 0.9 g dried lemon balm.

As with all herbal combination studies, it is difficult to determine the contribution each individual herb made to the end result. As such, these studies are encouraging but the role of lemon balm as a stand-alone treatment for insomnia remains unclear.

Commission E approves the use of lemon balm in the treatment of insomnia (Blumenthal et al 2000).

### Gastrointestinal conditions associated with spasm and nervousness

To date, lemon balm's activity in gastrointestinal conditions has only been studied in combination with other herbs.

A pilot study investigated the effects of Carmint, containing lemon balm, spearmint and coriander, in 32 patients with irritable bowel syndrome (Vejdani et al 2006). Patients were randomly assigned Carmint or placebo, plus loperamide or psyllium (based on their irritable bowel syndrome subtype) for 8 weeks. The severity and frequency of abdominal pain and bloating were significantly lower in the Carmint group as compared to placebo at the end

of the 8 weeks. A larger follow-up trial is needed to confirm these results.

A 15-day open study involving 24 subjects with chronic non-specific colitis investigated whether a combination of lemon balm, St John's wort, dandelion, marigold and fennel could provide symptom relief (Chakurski et al 1981). Excellent results were obtained by the end of the study, with herbal treatment resulting in the disappearance of spontaneous and palpable pains along the large intestine in 95.83% of patients. A double-blind study using a herbal tea prepared from chamomile, lemon balm, vervain, licorice and fennel in infantile colic has also been conducted. A dose of 150 mL offered up to three times daily was found to eliminate symptoms of colic in 57% of infants, whereas placebo was helpful in only 26% after 7 days' treatment (Weizman et al 1993).

A randomised, double-blind, placebo-controlled trial was conducted to examine the effectiveness of ColiMil (lemon balm, chamomile and fennel) in 93 breastfed infants with colic (Savino et al 2005). The infants were randomised into two groups to receive either ColiMil or placebo, both twice a day at 5 p.m. and 8 p.m. before feeding (2 mL/kg/day) for 7 days. A reduction in crying time was observed in 85.4% subjects in the active treatment group as compared to 48.9% for placebo ( $P < 0.005$ ). This is a significant result, especially considering the treatment period was only 7 days. No side effects were reported. Commission E supports the use of lemon balm for functional gastrointestinal conditions (Blumenthal et al 2000).

#### IN COMBINATION

A randomised, double-blind, placebo-controlled trial investigated the use of two herbal preparations in the treatment of somatoform disorders. A total of 182 patients with somatisation disorder and undifferentiated somatoform disorder were randomised into three treatment groups: (1) butterbur, valerian, passionflower and lemon balm; (2) valerian, passionflower and lemon balm; or (3) placebo, for a 2-week treatment period. Primary outcomes measured were anxiety (visual analogue scale) and depression (Beck's Depression Inventory). Clinical Global Impression was measured as a secondary outcome. Both herbal treatment groups showed significant improvement in anxiety and depression, yet the four-herb preparation was significantly superior to the three-herb preparation. There were no serious adverse events. While these results are promising, it is impossible to determine the individual efficacy of lemon balm in the treatment of somatoform disorders due to the herbal combinations used in each active treatment arm (Melzer et al 2009).

#### Herpes simplex type 1 — external use

The topical use of lemon balm preparations for HSV infection is very popular in Europe. Results from a randomised double-blind study in 66 subjects with a history of recurrent herpes labialis (>3 episodes/year) found that standardised lemon balm ointment

(700 mg crude herb per gram) applied four times daily for 5 days significantly shortened healing time, prevented infection spread and produced rapid symptom relief (Koytchev et al 1999). Decreased symptoms and increased rate of healing were also observed in another double-blind study of lemon balm cream in 116 subjects (Woelbling & Leonhardt 1994).

Positive results were seen again in a 2008 double-blind randomised controlled trial of 60 patients with recurrent herpes simplex. In the study, volunteers applied either placebo or a lemon balm ointment five times daily for 5–10 minutes during herpes outbreaks until full recovery. The lemon balm ointment was found to significantly reduce healing time and the area of the lesion between day 1 and day 5 compared to placebo. No significant change was seen in the severity or duration of pain (Zolfaghari et al 2008).

#### Oxidative stress

A clinical trial involving 55 radiology staff found that a lemon balm infusion (1.5 g/100 mL) taken orally twice daily for 30 days resulted in significant increases in plasma levels of catalase, superoxide dismutase and glutathione peroxidase, and reductions in plasma DNA damage, myeloperoxidase and lipid peroxidation (Zeraatpishe et al 2011).

Another clinical trial evaluated the ability of lemon balm to reduce oxidative stress levels in 30 participants occupationally exposed to aluminium. Participants ingested an oral lemon balm infusion (1.5 g/100 mL) twice daily for 30 days. There was a significant increase in plasma levels of total antioxidant capacity and total thiol molecules, and a significant decrease in triglyceride, cholesterol and aspartate transaminase (AST). Lipid peroxidation levels did not differ before and after treatment (Fazli et al 2012).

#### OTHER USES

Animal studies have identified dose-dependent anti-ulcerogenic activity for lemon balm extract, which has been histologically confirmed. This activity is associated with a reduced acid output and an increased mucin secretion, an increase in prostaglandin E<sub>2</sub> release and a decrease in leukotrienes (Khayyal et al 2001).

A combination of lemon balm, cinnamon and nettle (1.5, 0.5 and 0.25 g/100 mL) was investigated in 35 patients with non-alcoholic fatty liver disease. An infusion of the combined herbs was consumed twice a day for 30 days. Plasma liver markers, including alanine transferase (ALT), AST and alkaline phosphatase (ALP), were measured before and after treatment. There was a significant decrease in ALT. AST and ALP also declined; however these decreases were not significant. While these results are encouraging, it is difficult to determine the degree to which lemon balm contributed to the outcome due to the use of a herbal combination (Malekirad et al 2012).

## DOSAGE RANGE

- Fresh herb: 1.5–4.5 g two–three times daily.
- Infusion: 1.5–4.5 g in 150 mL water.
- Fluid extract (1:1) (g/mL): 6–12 mL/day.
- Ointment: 700 mg/g ointment applied four times daily for herpes simplex infection.

## According to clinical studies

- Anxiety: Cyracos (a standardised hydroalcoholic lemon balm extract containing >7% rosmarinic acid and >15% hydroxycinnamic acid derivatives) 600 mg daily in divided doses; 600 mg daily of standardised *Melissa* extract (Pharmaton, Lugano, Switzerland)
- Alzheimer's dementia: 60 drops/day of *Melissa* extract (standardised to contain at least 500 mg citral/mL) taken internally.
- Herpes simplex infection: *Melissa* ointment applied five times daily.

## TOXICITY

Not known.

## ADVERSE REACTIONS

Lemon balm is well tolerated according to one double-blind, randomised crossover study (Kennedy et al 2002).

## SIGNIFICANT INTERACTIONS

Controlled clinical studies are not available, so interactions are speculative and based on evidence of activity.

## Barbiturates

Increased sedative effects: one animal study (Soulimani et al 1991) found that concomitant administration of lemon balm extract with pentobarbitone produced an increased sedative effect — observe patients taking this combination.

## Cholinergic drugs

Additive effects are theoretically possible and may be beneficial — observe patients taking this combination.

## CONTRAINDICATIONS AND PRECAUTIONS

Hypothyroidism — one in vitro study found that an extract of *M. officinalis* inhibited both the extrathyroidal enzymic T4-5'-deiodination to triiodothyronine and the T4-5'-deiodination (Aufmkolk et al 1984b). At high doses (900 mg) oral *Melissa* extract was shown to reduce alertness, so caution is required if using this treatment together with alcohol, as it may potentiate sedative effects (Kennedy et al 2002).

## PREGNANCY USE

Safety has not been scientifically established and is unknown.

## Practice points/Patient counselling

- Lemon balm has been used traditionally to treat insomnia, irritability, restlessness, anxiety and dementia. It is also used to relieve gastrointestinal symptoms associated with spasms and nervousness.
- Used topically as a cold sore treatment, it significantly reduces symptoms, shortens the healing period and prevents infection spread. It may be suitable both as an active treatment and as a preventive agent in cases of chronic recurrent herpes simplex infections.
- Lemon balm may have some anti-inflammatory and antispasmodic activity.
- The essential oil is used in aromatherapy to relieve anxiety and promote calm and a sense of wellbeing.
- Clinical studies have demonstrated that, when taken internally, *Melissa* extract reduces stress and anxiety and can improve cognitive function.

## ! PATIENTS' FAQs

### What will this herb do for me?

Lemon balm has several different actions and is used for a number of different conditions. Taking the herb internally may help reduce anxiety and improve mood and mental concentration. When taken together with valerian, it can relieve insomnia. It may also relieve stomach spasms associated with nervousness, or in chronic, non-specific colitis when taken as part of a specific herbal combination. *Melissa* cream applied four to five times daily to herpes simplex infections can reduce symptoms, accelerate healing and reduce the chance of the infection spreading.

### When will it start to work?

Approximately 1 month's treatment with the essential oil is required for calming effects on agitation in dementia to be seen. Taken internally with valerian, effects on sleep may be seen after 9 days' use. Improved memory occurred within 2.5 hours, according to one study; however, it is not known if and when effects are seen in dementia. *Melissa* cream has been shown to significantly reduce symptoms of herpes simplex within 2 days, when applied four times daily. Orally, 4–8 weeks of use with *Melissa* extract is required to see significant changes in Alzheimer's dementia, whereas improved cognitive function is seen after a single dose in healthy people.

### Are there any safety issues?

One study using lemon balm in tablet form found that it was well tolerated. Drug interactions are theoretically possible and this herb should be used cautiously in people with hypothyroidism.

## L-Glutamine

**HISTORICAL NOTE** Glutamine and glutamate were originally described in the mid 19th century and their functions began to be examined in the early 20th century. The role of glutamine in the immune system and gastrointestinal tract has been investigated since the 1980s.

### BACKGROUND AND RELEVANT PHARMACOKINETICS

L-Glutamine is a conditionally essential amino acid found in all life forms and the most abundant amino acid in the human body. During conditions of

metabolic stress characterised by catabolism and negative nitrogen balance, such as trauma (including surgical trauma), prolonged stress, glucocorticoid use, excessive exercise, starvation, infection, sepsis, cancer and severe burns, the body is unable to

synthesise L-glutamine in sufficient quantities to meet biological needs and it becomes essential to have an exogenous intake (Miller 1999, PDRHealth 2006a).

L-Glutamine is absorbed from the lumen of the small intestine by active transport (Meng et al 2003) and is then transported to the liver via the portal circulation and enters the systemic circulation, where it is distributed to various tissues and transported into cells via an active process. Elimination occurs via glomerular filtration and it is almost completely reabsorbed by the renal tubules. Some metabolism of L-glutamine takes place in the enterocytes and hepatocytes and it is involved in various metabolic activities, including the synthesis of L-glutamate (catalysed by glutaminase), proteins, glutathione, pyrimidine and purine nucleotides and amino sugars. L-glutamate is converted to L-glutamine by glutamine synthase in the presence of ammonia, adenosine triphosphate (ATP) and magnesium or manganese.

L-Glutamine is synthesised endogenously from other amino acids, predominantly branched-chain amino acids and glutamate, and stored in skeletal muscles, where it comprises around 60% of the free amino acids and makes up 4–5% of muscle protein. In times of metabolic stress, glutamine is released into the circulation and transported to tissues in need (Kohlmeier 2003, Miller 1999, PDRHealth 2006a).

L-Glutamine is not very soluble or stable in solution, especially upon heating for sterilisation, and as a result, until recently, was not included in total parenteral nutrition (TPN). The more soluble and stable glutamine dipeptides are now commonly used as the delivery forms in TPN solutions and some nutritional supplements (Kohlmeier 2003, PDRHealth 2006b).

### Common forms available

The terms L-glutamine and glutamine are often used interchangeably. L-glutamine is the amide form of L-glutamic acid and contains 15.7% nitrogen (Kohlmeier 2003). It is also known as 2-aminoglutaric acid, levoglutamide, (S)-2,5-diamino-5-oxopentanoic acid and glutamic acid 5-amide. Glutamic acid is a non-essential amino acid and glutamine is the aminated form of glutamic acid. Glutamic acid is found in many foods, such as grain cereals (barley, wheat, flax, sorghum, rye), nuts and seeds, dairy foods and meat. L-glutamic acid is commonly used as a supplement in sports nutrition. Salts and carboxylate anions of glutamic acid are known as glutamates (such as sodium glutamate, potassium glutamate). Glutamate is involved in cellular metabolism and it is an abundant neurotransmitter.

Two synthetic glutamine dipeptides that may be used in TPN are L-alanyl-L-glutamine and glycyl-L-glutamine. D-Glutamine, the stereoisomer of L-glutamine, has no known biological activity (Kohlmeier 2003, PDRHealth 2006b).

Since the late 1960s, L-glutamine has been manufactured for pharmaceutical use using a fermentation broth. The manufacture of high-quality, low-cost L-glutamine requires a strain of microorganism with good production efficiency and minimum byproducts. Impurities can then be removed from the broth using a nanofiltration membrane to obtain a fine crystalline powder (Kusumoto 2001, Li et al 2003).

### FOOD SOURCES

Typical dietary intake of L-glutamine is 5–10 g/day (Miller 1999). Sources include animal and plant proteins, vegetable juices (especially cabbage), eggs, wheat, soybeans and fermented foods, such as miso and yoghurt (Kohlmeier 2003, PDRHealth 2006a).

### DEFICIENCY SIGNS AND SYMPTOMS

Although traditionally considered a non-essential amino acid, L-glutamine is now considered 'conditionally essential' during periods of metabolic stress characterised by catabolism and negative nitrogen balance.

Critical illness, stress and injury can lead to a significant decrease in plasma levels of L-glutamine which, if severe, can increase the risk of mortality (Boelens et al 2001, Wischmeyer 2003).

Prolonged protein malnutrition may cause growth inhibition, muscle wasting and organ damage (Kohlmeier 2003). In the absence of sufficient plasma glutamine, the body will break down skeletal muscle stores, and gut integrity (gut mucosal barrier function) and immunity will be compromised. Because L-glutamine is utilised during exercise, a more recent phenomenon of deficiency has been explored and glutamine depletion has been linked with 'overtraining syndrome'.

### MAIN ACTIONS

L-Glutamine has many important biological functions within the human body. It is an important fuel for the intestinal mucosal cells, hepatocytes and rapidly proliferating cells of the immune system, particularly lymphocytes and monocytes, assists in the regulation of acid balance, thus preventing acidosis, acts as a nitrogen shuttle protecting the body from high levels of ammonia, and is involved in the synthesis of amino acids (including L-glutamate), gamma-aminobutyric acid (GABA), glutathione (an important antioxidant), purine and pyrimidine nucleotides, amino acid sugars in glycoproteins and glycans, and nicotinamide adenosine dinucleotide (NAD). It is also involved in protein synthesis and energy production (Boelens et al 2001, Kohlmeier 2003, Miller 1999, Niihara et al 2005, Patel et al 2001, PDRHealth 2006a).

### Gastrointestinal protection/repair

According to in vitro and in vivo research, L-glutamine aids in the proliferation and repair of intestinal cells (Chun et al 1997, Rhoads et al 1997, Schepach et al 1996) and is the preferred

respiratory fuel for enterocytes (and also utilised by colonocytes) (Miller 1999). It is thus vital for maintaining the integrity of the intestinal lining and preventing the translocation of microbes and endotoxins into the body. In addition, L-glutamine helps to maintain secretory immunoglobulin A (IgA), which functions primarily by preventing the attachment of bacteria to mucosal cells (PDRHealth 2006a, Yu et al 1996).

According to evidence from animal studies, it may also assist in preventing atrophy following colostomy (Paulo 2002) and irradiation (Diestel et al 2005), and intestinal injury by inhibiting intestinal cytokine release (Akiyu et al 2003). L-glutamine depletion induces apoptosis by triggering intercellular events that lead to cell death (Paquette et al 2005), resulting in altered epithelial barrier competence (increased intestinal permeability), bacterial translocation and increased mortality. Under experimental conditions, L-glutamine may assist in maintaining intestinal barrier function by increasing epithelial resistance to apoptotic injury, reducing oxidative damage, attenuating programmed cell death and promoting re-epithelialisation (Masuko 2002, Ropeleski et al 2005, Scheppach et al 1996) and may thus reduce bacterial and endotoxin translocation (Chun et al 1997).

### Immunomodulation

L-Glutamine has demonstrated immunomodulatory activity in animal models of infection and trauma, as well as trauma in humans. L-Glutamine acts as the preferred respiratory fuel for lymphocytes, is essential for cell proliferation, and can enhance the function of stimulated immune cells.

Extracellular glutamine concentration affects lymphocyte, interleukin-2 and interferon- $\gamma$  proliferation, cytokine production, phagocytic and secretory macrophage activities and neutrophil bacterial killing (Miller 1999, Newsholme 2001, PDRHealth 2006a). In humans, L-glutamine may enhance both phagocytosis and reactive oxygen intermediate production by neutrophils (Furukawa et al 2000) and support the restoration of type-1T lymphocyte responsiveness following trauma (Boelens et al 2004). In a randomised trial, there was a reduced frequency of pneumonia, sepsis and bacteraemia in patients with multiple traumas who received glutamine-supplemented enteral nutrition (Houdijk et al 1998).

In addition, effects on the gastrointestinal tract may contribute significantly to immune defence by maintaining gut-associated lymphoid tissue and secretory IgA (preventing the attachment of bacteria to the gut mucosa) and maintaining gut integrity (thus preventing the translocation of microbes and their toxins, especially Gram-negative bacteria from the large intestine) (Miller 1999, Yu et al 1996).

### Antioxidant

As a precursor to glutathione (together with cysteine and glycine), L-glutamine can assist in ameliorating

the oxidation that occurs during metabolic stress. Glutathione protects epithelial cell membranes from damage, and its depletion can negatively affect gut barrier function and result in severe degeneration of colonic and jejunal epithelial cells (Lantomasi 1994, Ziegler et al 1999). In animal studies, it has also been shown to inhibit fatty acid oxidation, resulting in a reduction in body weight and alleviation of hyperglycaemia and hyperinsulinaemia in mice fed a high-fat diet (Opara et al 1996).

### Anabolic/anticatabolic

As L-glutamine is stored primarily in skeletal muscles and becomes conditionally essential under conditions of metabolic stress, the anticatabolic/anabolic properties of supplemented L-glutamine are likely due to a sparing effect on skeletal muscle stores.

Following strenuous exercise, glutamine levels are depleted by approximately 20%, resulting in immunodepression (Castell 2003, Castell & News-holme 1997, Rogero et al 2002). As a result supplemental L-glutamine may be of benefit in athletes to prevent the deleterious effects of glutamine depletion associated with 'overtraining syndrome'. Evidence supporting a direct ergogenic effect is currently lacking.

### Cardioprotective

In vitro, L-glutamine has been shown to assist in the maintenance of myocardial glutamate, ATP and phosphocreatine, and in the prevention of lactate accumulation (Khogali et al 1998). In addition to its antioxidant properties and effects on hyperglycaemia and hyperinsulinaemia (Opara et al 1996), this may suggest a possible role as a cardioprotective agent.

A recent randomised, double-blind, placebo-controlled study by Lomivorotov et al (2013) reported no cardioprotective benefit of perioperative use of N<sub>2</sub>-L-alanyl-L-glutamine (0.4 g/kg/day of 20% solution of N<sub>2</sub>-L-alanyl-L-glutamine [Dipeptiven, Fresenius Kabi, Germany]) in 32 patients with type 2 diabetes who underwent cardiopulmonary bypass surgery compared to the control group of 32 patients who received 0.9% NaCl.

However glutamine supplementation was reported to be cardioprotective in the first 24 hours postoperatively, as assessed by dynamics of troponin I in a study of patients with ischaemic heart disease who underwent cardiopulmonary bypass surgery. The perioperative glutamine-supplemented group of 25 patients (0.4 g/kg glutamine [Dipeptiven, 20% solution] per day) was compared to 25 patients in the control group who were administered a placebo (0.9% NaCl) (Lomivorotov et al 2011) and the dynamics of troponin I were assessed at 30 minutes, and at 6, 24 and 48 hours after surgery.

In a small, randomised double-blind study, 14 patients who required cardiopulmonary bypass surgery were placed in two groups. One group of 7 patients received oral alanyl-glutamine (25 g twice daily) for 3 days prior to surgery and the other

group served as a control and received maltodextrin. The glutamine-supplemented group was reported to have significantly reduced myocardial injury and clinical complications (Sufit et al 2012).

#### **Clinical note — Total parenteral nutrition**

L-Glutamine is not very soluble or stable in solution, especially upon heating for sterilisation. As a result, until recently it was not included in TPN, resulting in compromised glutamine status in patients for whom reduced immune status and increased intestinal permeability could potentially increase the risk of morbid infection and mortality. The more soluble and stable synthetic glutamine dipeptides (L-alanyl-L-glutamine and glycyl-L-glutamine) have now been developed as delivery forms of L-glutamine for use in TPN. The dipeptide forms can also be used orally and have demonstrated a potential for greater bio-availability than glutamine alone (Macedo Rogero et al 2004).

Numerous studies have now been conducted using glutamine dipeptides in TPN and have shown benefit in preventing deterioration of gut permeability and preserving mucosal structure (Hall et al 1996, Jiang et al 1999, PDRHealth 2006a, van der Hulst et al 1993). In addition, animal studies suggest that glutamine-enriched TPN may attenuate the suppression of CYP3A and CYP2C usually associated with TPN (Shaw et al 2002). The addition of glutamine to TPN in preterm infants also appears to hasten improvements in hepatic function (Wang et al 2013).

In a meta-analysis of European and Asian randomised controlled trials (RCTs) in elective surgery patients, 13 studies (pooled  $n = 355$ ) met inclusion criteria and demonstrated a significant reduction in infectious complication and length of hospital stay (weighted mean difference [WMD] of 3.86 days) (Jiang et al 2004). Conversely, a small study using glutamine (10 g) as part of home parenteral nutrition for 6 months did not reveal any significant effects compared to placebo for infective complications (36% vs 55%;  $P = 0.67$ ), nutritional status, intestinal permeability or quality of life. It should be noted that plasma glutamine concentrations were also not affected in this study (Culkin et al 2008).

### **Neurotransmission**

Disturbances of glutamine metabolism and/or transport may contribute to changes in glutamatergic or GABAergic transmission associated with different pathological conditions of the brain, such as epilepsy, hepatic encephalopathy and manganese encephalopathy. Glutamine appears to affect neurotransmission by interacting with the N-methyl-D-aspartate class of glutamine receptors (Albrecht et al 2010).

## **CLINICAL USE**

### **Deficiency: prevention and treatment**

During periods of increased need, L-glutamine is considered conditionally essential. Glutamine depletion can result in increased intestinal permeability, microbial translocation across the gut barrier, impaired wound healing, sepsis and multiple organ failure (Miller 1999). Experimental studies have proposed a number of benefits for patients with conditions that increase glutamine requirements. The suggested mechanisms include effects on proinflammatory cytokine expression, gut integrity, enhanced ability to mount a stress response and improved immune cell function, and studies have shown potential benefit with regard to mortality, length of hospital stay and infection.

To date, the results of studies using glutamine dipeptides in TPN have proven to be very promising in treating patients for whom enteral feeding is impossible. Benefits from studies of enteral glutamine supplementation have tended to be less pronounced, but preliminary trials have demonstrated benefits in some conditions, especially at high doses (e.g. 30 g/day enterally) (Wischmeyer 2003).

### **Critical care settings**

A systematic review found trends to suggest that parenteral and enteral glutamine supplementation may reduce mortality, the development of infection and organ failure in critical illness; however, poor study design and possible publication bias limit what conclusions can be drawn from the current data (Avenell 2006).

A recent meta-analysis of 14 RCTs ( $n = 587$ ) found that people given parenteral nutrition supplemented with glutamine dipeptide had a shorter length of hospital stay and a significant decrease in infectious complications (relative risk [RR] = 0.69;  $P = 0.02$ ) compared to the group receiving standard parenteral nutrition (Wang et al 2010).

Similarly, in a recent meta-analysis by Bollhalder et al (2013) that included 40 RCTs, parenteral glutamine supplementation was associated with a significant reduction in infections (RR = 0.83) and a non-significant reduction in short-term mortality (RR = 0.89) and length of stay, although a significant reduction in mortality was not verified, in contrast to previous meta-analyses.

Likewise, a more recent meta-analysis by Chen et al (2014) that included 15 studies of 2862 critically ill patients in a number of settings, including surgical intensive care unit (ICU) subgroup and parenteral nutrition subgroup, reported that, compared to control groups, glutamine supplementation significantly reduced the incidence of hospital-acquired infections (RR 0.85; 95% confidence interval [CI] 0.74–0.97;  $P = 0.02$ ). However, in 14 studies with 2777 patients, there was no benefit in overall mortality or length of hospital stay, although the mortality rate was significantly higher (RR 1.18; 95% CI

1.02–1.38;  $P = 0.03$ ) in high glutamine dosage subgroup (above 0.5 g/kg/day).

### Abdominal surgery and trauma

Parenteral supplementation of glutamine in critically ill patients has been shown to improve survival rate and minimise infectious complications, costs and length of hospital stay; however, the role of enteral glutamine supplementation remains controversial (Al Balushi et al 2013).

A meta-analysis of nine RCTs involving 373 patients was performed to assess the clinical and economical validity of glutamine dipeptide supplementation to parenteral nutrition in patients undergoing abdominal surgery. The review concluded that glutamine dipeptide has a positive effect in decreasing postoperative infectious morbidity (odds ratio [OR] = 0.24,  $P = 0.04$ ), shortening the length of hospital stay (WMD = -3.55, 95%  $P < 0.00001$ ) and improving postoperative cumulative nitrogen balance (WMD = 8.35,  $P = 0.002$ ). No serious adverse effects were identified (Zheng 2006).

Enteral supplementation has not been shown to be as effective in abdominal trauma. In one trial, 120 patients with peritonitis or abdominal trauma were randomised to receive either enteral glutamine (45 g/day for 5 days) in addition to standard care ( $n = 63$ ) or standard care alone ( $n = 57$ ). No statistically significant benefits were noted in the treatment group for serum malondialdehyde or glutathione levels, infectious complications, survival rate or duration of hospital stay (Kumar et al 2007).

### Trauma

Enteral glutamine has been shown to be protective to the gut in experimental models of shock and thus improve clinical outcomes. In a pilot study, enteral glutamine was administered during active shock resuscitation (0.5 g/kg/day during the first 24 hours) and continued for 10 days through the early postinjury period. The treatment was found to be safe and improved gastrointestinal tolerance (vomiting, nasogastric output, diarrhoea and distension). ICU and hospital length of stay were comparable (McQuiggan et al 2008). In a randomised trial using glutamine-enriched enteral nutrition in patients with multiple traumas, there was a reduction in the incidence of pneumonia, sepsis and bacteraemia (Houdijk et al 1998). Parenteral supplementation of alanyl-glutamine dipeptide may also result in better insulin sensitivity in multiple-trauma patients (Bakalar et al 2006).

### Burns

Acute burn injury results in depletion of plasma and muscle glutamine, which contributes to muscle wasting, weight loss and infection. In critical illness, supplementation has been shown to minimise these effects and reduce the rate of mortality and length of stay (Windle 2006). In a double-blind controlled trial, 48 severely burned patients (total burn surface area 30–75%, full-thickness burn area 20–58%) were

randomised into treatment ( $n = 25$ ; 0.5 g/kg/day glutamine granules for 14 days with oral or tube feeding) or control group ( $n = 23$ ; glycine placebo). The results indicated that significantly reduced plasma glutamine and damaged immunological function occurred and supplementation with glutamine granules increased plasma glutamine concentration and reduced the degree of immunosuppression. Glutamine improved immunological function (especially cellular immunity), wound healing and length of hospital stay ( $46.59 \pm 12.98$  days vs  $55.68 \pm 17.36$  days,  $P < 0.05$ ) (Peng et al 2006).

According to animal studies, oral glutamine supplementation may reduce bacterial and endotoxin translocation after burns by maintaining secretory IgA in the intestinal mucosa (Yu et al 1996). Systematic reviews and practice guidelines generally support glutamine supplementation in critical illness; however, in large or severe burns or inhalation injury there may be a prolonged critical illness phase (>4 weeks). Further research focusing on enteral and parenteral glutamine supplementation and long-term use is required (Windle 2006).

A recent meta-analysis of glutamine supplementation in critically ill patients with burns reported a reduction in mortality in hospital and complications due to Gram-negative bacteraemia (Lin et al 2013). The meta-analysis included four RCTs which involved 155 patients. The total burn surface area ( $P = 0.34$ ) was similar in both glutamine and control groups at baseline; however, treatment with glutamine induced a significant decrease in the number of patients with Gram-negative bacteraemia (OR 0.27;  $P = 0.04$ ) and hospital mortality (OR = 0.13;  $P = 0.004$ ), and there was no statistical difference for the length of hospital stay.

### Infants

Enteral and parenteral glutamine supplementation in preterm infants has been shown to have some beneficial effects on neonatal morbidity and mortality; however, these results are controversial (Korkmaz et al 2007).

In a short-term study of preterm infants (birth weight  $\leq 1500$  g) who received either enteral glutamine supplementation ( $n = 36$ ; 300 mg/kg/day adjusted over time according to the current weight) or placebo ( $n = 33$ ) between 8 and 120 days of life, the glutamine-supplemented group had significantly higher mean weight, length, head circumference, left upper mid-arm circumference and left mid-thigh circumference than the control group at the end of the fourth month. The effects appeared to occur in a time-dependent pattern (Korkmaz et al 2007). Another study reported that oral supplementation (0.25 mg/kg body weight) with glutamine did not improve growth or intestinal permeability (lactulose:mannitol ratio: 0.29 [95% CI 0.23–0.35] and 0.26 [95% CI: 0.21–0.32]) in malnourished Gambian infants (Williams et al 2007). It should be noted, however, that this dose is exceptionally low compared to other trials. The dose, route of

administration and length of supplementation require further elucidation in larger-scale trials before full assessment can be made.

Experimental data have suggested that, by stimulating the rate of recovery of the villi and lipid-synthesising enzymes, L-glutamine treatments could improve the efficacy of enteral feeding in infants recovering from bowel damage (Ahdieh et al 1998). However, a recent Cochrane review concluded insufficient data were available from RCTs to determine whether glutamine supplementation confers clinically significant benefits for infants with severe gastrointestinal disease (Wagner et al 2012).

Some authors have suggested that early glutamine supplementation may also provide longer-term benefits. Enteral glutamine supplementation (300 mg/kg/day) between 3 and 30 days of life has been shown to lower the incidence of atopic dermatitis (OR 0.13; 95% CI 0.02–0.97) but not the incidence of bronchial hyperreactivity and infectious diseases (upper respiratory, lower respiratory and gastrointestinal) during the first year of life (van den Berg et al 2007). Follow-up of 52 very preterm babies who received glutamine supplementation in their first month of life revealed that there was an increase in white matter, hippocampus and brainstem volumes at school age, and this was mediated by a decrease in serious neonatal infections (de Kieviet et al 2012).

Despite the many encouraging results, a recent Cochrane review of 11 RCTs (five trials of enteral glutamine supplementation and six trials of parenteral glutamine supplementation) that included 2771 preterm infants reported that glutamine supplementation did not have a significant effect on mortality or major neonatal morbidities, including the incidence of invasive infection and necrotising enterocolitis (Moe-Byrne et al 2012).

### Strenuous exercise

Following strenuous exercise, glutamine levels are depleted approximately 20%, resulting in immunodepression (Castell 2003, Castell & Newsholme 1997, Rogero et al 2002). However the role of glutamine supplementation in preventing postexercise effects on immune function is controversial (Gleeson 2008). The type of training is important to note, as although previous reports suggest decreased glutamine concentrations in overtrained athletes, progressive endurance training may lead to steady increases in plasma glutamine levels (Kargotich et al 2007).

The provision of glutamine after exercise has been shown to improve immune status (Castell & Newsholme 1997). In a study of 200 elite runners and rowers given a glutamine or placebo drink immediately after and again 2 hours after strenuous exercise, 151 participants returned questionnaires reporting the incidence of infection over the subsequent 7 days. The percentage of athletes reporting no infections was considerably higher in the glutamine group (81%,  $n = 72$ ) compared to the placebo group (49%,  $n = 79$ ,  $P < 0.001$ ) (Castell et al 1996).

During recovery from strenuous exercise, rates of lymphocyte apoptosis, hyperammonaemia and whole-body proteolysis may be affected by glutamine supplementation. In a small study of nine triathletes, glutamine supplementation (four tablets of 700 mg of hydrolysed whey protein enriched with 175 mg of glutamine dipeptide dissolved in 250 mL water) partially prevented lymphocyte apoptosis induced by exhaustive exercise, possibly by a protective effect on mitochondrial function (Cury-Boaventura et al 2008). Both intermittent and continuous-intensity exercises increase ammonia, urate, urea and creatinine in the blood stream. Chronic glutamine supplementation (100 mg/kg body weight) given immediately before exercise may partially protect against elevated ammonia but not urate, urea or creatinine (Bassini-Cameron et al 2008). The addition of glutamine (300 mg/kg body weight) to an oral carbohydrate (1 g/kg/h) and essential amino acid (9.25 g) solution had no effect on postexercise muscle glycogen resynthesis or muscle protein synthesis, but may suppress a rise in whole-body proteolysis during the later stages of recovery (Wilkinson et al 2006).

Conversely, a trial assessing the possible ergogenic effects of glutamine supplementation (300 mg/kg body weight) to improve high-intensity exercise performance in trained males was unable to determine a beneficial effect (Haub et al 1998). Currently, the use of glutamine to enhance exercise performance is speculative at best and the cost of the high doses indicated must be considered. Further large-scale research is required to elucidate any potentially beneficial effects.

Care should be taken in people with diabetes as a small study revealed an increase in postexercise overnight hypoglycaemia in adolescents with type 1 diabetes who received a glutamine drink (0.25 g/kg/dose) pre-exercise and at bedtime (Mauras et al 2010).

### Gut repair

Preliminary research on enteral (as well as parenteral) glutamine supplementation suggested promise for the use of glutamine in gut repair by: (1) protecting the intestinal mucosa from damage and promoting repair, thus improving intestinal permeability and reducing subsequent microbial and endotoxin translocation, promoting glutathione and secretory IgA; and (2) improving gut immunity. However, while there is some evidence for the use of glutamine in TPN (Hall et al 1996), clinical evidence using oral supplementation is less convincing. As *in vitro* data suggest that the colonic mucosa receives its nutrients preferentially from the luminal (not vascular) side (Roediger 1986), it has been suggested that glutamine should be more effective when delivered by the enteral route (Kouznetsova et al 1999). This has yet to be determined in clinical trials.

L-Glutamine enemas, twice daily for 7 days, have been shown to reduce mucosal damage and inflammation in experimental models of colitis in rats

(Kaya et al 1999); however, preliminary trials in humans using parenteral glutamine (da Gama Torres et al 2008) and oral supplementation in malnourished preterm infants (Williams et al 2007) have not confirmed benefits for intestinal permeability.

Postoperative administration of TPN supplemented with a combination of glutamine and recombinant human growth hormone in patients following portal hypertension surgery prevented intestinal mucous membrane atrophy and preserved intestinal integrity, although the role of glutamine is unclear (Tang et al 2007). In a 1998 randomised, double-blind, placebo-controlled, 4-week trial of 24 HIV patients with abnormal intestinal permeability using 0, 4 or 8 g/day of glutamine, the authors reported a dose-dependent trend towards improved intestinal permeability and enhanced intestinal absorption with glutamine supplementation and recommended further studies to be carried out with higher doses (e.g. 20 g/day) over a longer study period (Noyer et al 1998). It is difficult to extrapolate the findings of this study to the wider community for the purpose of gut repair as there are factors involved in HIV/AIDS that may increase the biological demand for glutamine. Longer-term studies may provide more convincing results; however, it is possible that glutamine only stabilises gut barrier function under certain conditions and more research is required to elucidate these.

### Crohn's disease

In a controlled trial, consecutive patients in remission from Crohn's disease with an abnormal intestinal permeability were randomised to receive oral glutamine or whey protein (0.5 g/kg ideal body weight/day). After 2 months intestinal permeability and morphology had improved significantly in both the glutamine and whey groups (Benjamin et al 2012). Previously a 4-week study on 18 children with active Crohn's disease fed a glutamine-enriched polymeric diet (Akobeng et al 2000) was unable to demonstrate benefits.

### HIV

L-Glutamine has been shown to improve glutathione levels and significantly increase lean body mass in HIV patients (Patrick 2000); however, not all studies confirm this latter effect (Huffman & Walgren 2003). A recent study of 12 treated patients (six men and six women, 22–45 years old) and 20 healthy controls (10 men and 10 women, 20–59 years old) who were randomly assigned to 7-day dietary supplements containing *N*-acetylcysteine (1 g/day) or glutamine (20 g/day), with a 7-day washout period ingesting their usual diet, reported an increase in total glutathione by glutamine supplementation (Borges-Santos et al 2012). Improvements in intestinal absorption have also been reported in HIV patients receiving isonitrogenous doses of alanyl-glutamine (24 g/day for 10 days) (Leite et al 2013). Combined therapy with arginine and the leucine metabolite beta-hydroxy-beta-

methylbutyrate has been shown to reverse lean tissue loss in HIV and cancer patients (Rathmacher et al 2004).

During initial HIV infection, the rapid turnover and proliferation of immune cells increase glutamine requirements and later the repeated episodes of infection, fever and diarrhoea may lead to further depletion. As a result, the doses used in the trial mentioned above (4 g and 8 g) may have been insufficient to meet the increased requirement in such patients (Noyer et al 1998).

Highly active antiretroviral therapy may be associated with diarrhoea and other gastrointestinal side effects. In a prospective, randomised, double-blind crossover study, HIV-infected patients with nelfinavir-associated diarrhoea (for >1 month) received L-glutamine (30 g/day) or placebo for 10 days. Glutamine supplementation resulted in a significant reduction in the severity of nelfinavir-associated diarrhoea (Huffman & Walgren 2003). A prospective 12-week trial of 35 HIV-positive men experiencing diarrhoea as a result of nelfinavir or lopinavir/ritonavir therapy was also conducted using probiotics and soluble fibre. When glutamine (30 g/day) was added to the regimen of non-responders at week 4, the response rate improved (Heiser et al 2004).

### Cancer prevention

In addition to being the major fuel source for rapidly proliferating intestinal and immune cells, L-glutamine is the main fuel source for many rapidly growing tumours and, as a result, tumour growth is associated with a depletion in glutamine and glutathione stores and a depression of natural killer (NK) cell activity (Fahr et al 1994, Miller 1999). The increased intestinal permeability, immune suppression and oxidative damage that may result may further compromise the body's ability to deal with the tumour. While concerns exist, and are supported by *in vitro* evidence, that glutamine supplementation may feed the tumour, animal studies suggest that glutamine supplementation may assist in decreasing tumour growth by enhancing NK cell activity (Fahr et al 1994, Miller 1999). Animal studies have demonstrated that glutamine supplementation prevents the promotion of tumour cells in an implantable breast cancer model (Kaufmann et al 2003). The exact effects in different human tumour cell lines require further elucidation.

### Gastrointestinal effects

A number of studies have reported that adding glutamine to chemotherapy appears to reduce the incidence and severity of oral mucositis, a frequent complication of mucotoxic cancer therapy, which causes significant oral pain, increased infection risk and impaired functioning (Peterson et al 2007). For instance, oral glutamine (30 g/day) appears to reduce the incidence of fluorouracil/leucovorin-induced mucositis/stomatitis (9% vs 38% in the control group;  $P < 0.001$ ) (Choi et al 2007).

**Clinical note — Cancer therapy**

Side effects of chemotherapy and radiation therapy can significantly affect the quality of life of patients undergoing treatment for cancer. A number of trials have demonstrated the benefits of glutamine supplementation for improving side effects such as oral pain and inflammation, increased gut permeability and reduced lymphocyte count.

The provision of 15 g of oral glutamine three times daily appears to significantly reduce the incidence of severe radiation-induced diarrhoea (Kucuktulu et al 2013). Similarly, in a retrospective randomised experimental study of 46 patients with lung cancer who were treated with thoracic radiotherapy, the severity of acute radiotherapy-induced oesophagitis was significantly reduced ( $P < 0.0001$ ) in those who were given 30 g prophylactic oral glutamine powder daily (Tutanc et al 2013).

Reduced oral pain and inflammation have also been observed in patients receiving radiation and chemotherapy during bone marrow transplantation taking oral glutamine (1 g four times daily) (Miller 1999). In a retrospective study involving 41 patients with stage III lung carcinoma treated with thoracic irradiation, prophylactic supplementation with powdered glutamine (10 g/8 h) was found to be associated with a 27% lower incidence of grade 2 or 3 acute radiation-induced oesophagitis (ARIE), a 6-day delay in ARIE (22 days vs 16 days) and weight gain during radiotherapy (Topkan et al 2009).

In another study, L-glutamine (4 g twice daily, swish and swallow) was given to 12 patients receiving doxorubicin, one receiving etoposide, and one receiving ifosfamide, etoposide and carboplatinum from day 1 of chemotherapy for 28 days or for 4 days past the resolution of any postchemotherapy mucositis. Oral supplementation with glutamine significantly decreased the severity of chemotherapy-induced stomatitis (Skubitz & Anderson 1996). In a small study, parenteral glutamine supplementation was shown to protect the gastrointestinal mucosa against fluorouracil/calcium-folate chemotherapy-induced damage (Decker-Baumann et al 1999). Yoshida et al (1998, 2001) have also shown that 30 g/day L-glutamine for 28 days attenuates the increased gut permeability and reduced lymphocyte count observed in patients undergoing cisplatin and fluorouracil therapy for oesophageal cancer.

In a small phase I trial ( $n = 15$ ), glutamine was co-administered in an attempt to escalate the dose of a chemoradiotherapy regimen (weekly paclitaxel and carboplatin with concurrent radiation therapy). The addition was deemed unsuccessful due to multiple severe toxicities, including haematological toxicities and oesophagitis (Jazieh et al 2007). The role

of glutamine in reducing taxane-associated dysgeusia (taste alteration) appears limited (Strasser et al 2008).

In a double-blind, placebo-controlled, randomised trial, oral glutamine (18 g/day) or placebo was given to 70 chemotherapy-naïve patients with colorectal cancer 5 days prior to their first cycle of fluorouracil (450 mg/m<sup>2</sup>) in association with folinic acid (100 mg/m<sup>2</sup>), which was administered intravenously for 5 days. Glutamine treatment was continued for 15 days and was shown to reduce the negative effects on intestinal absorption and permeability induced by the chemotherapy and to potentially reduce diarrhoea (Daniele et al 2001). L-Glutamine may also reverse the decrease in goblet cells induced by fluorouracil (Tanaka & Takeuchi 2002).

More recent studies have further investigated the utility of glutamine supplementation in different patient groups receiving various modes of nutrition support and a variety of glutamine dosages.

A randomised study of 70 patients (Chattopadhyay et al 2014) reported that oral glutamine (10 g in 1 L of water 2 hours before radiotherapy treatment for 5 days/week on treatment days only;  $n = 35$ ) reduced the severity and duration of oral mucositis in head and neck cancer patients receiving primary or adjuvant radiation therapy compared to patients in the control group ( $n = 35$ ) who did not receive the glutamine.

A recent systematic review of 131 studies that included 10,514 participants evaluated the effectiveness of a range of prophylactic agents, including glutamine supplementation for oral mucositis in patients with cancer receiving treatment, compared with other potentially active interventions, placebo or no treatment, and reported that there was some benefit with intravenous glutamine (Worthington et al 2011).

However a more recent systematic review investigating natural agents in the management of oral mucositis has made a recommendation against the use of intravenous glutamine in patients receiving high-dose chemotherapy prior to haematopoietic stem cell transplant (level II evidence) (Yarom et al 2013).

In particular an earlier study by Pytlík et al (2002) had reported that intravenous glutamine made mucositis worse and was significantly associated with more relapses ( $P = 0.02$ ) and higher mortality ( $P = 0.05$ ).

In contrast, Gibson et al (2013) reported in their systematic review that new research did not support earlier observations of toxicity associated with glutamine supplementation and therefore they were unable to make a clinical guideline regarding glutamine supplementation for gastrointestinal mucositis, whereas the previous guideline was not to use systemic glutamine.

In regard to use in children, the evidence is less clear. A recent systematic review by Qutob et al (2013) investigated the evidence for the use of agents regarding the prevention of oral mucositis in

children and concluded that, due to conflicting results, certain agents such as oral or enteral glutamine should be avoided until their efficacy is confirmed by further research.

### Chemotherapy-induced diarrhoea

Chemotherapy-induced diarrhoea is a significant adverse effect during treatment with chemotherapy. A recent meta-analysis of eight RCTs (five studies with glutamine administered intravenously and three studies where glutamine was taken orally) included 298 patients (147 patients who received glutamine supplementation [16–40 g/day] and 151 patients who received a placebo), and reported a statistically significant reduction in the duration of diarrhoea in the glutamine-supplemented group, although there was no significant difference in the severity of diarrhoea between the groups (Sun et al 2012).

In a small randomised double-blind, placebo-controlled pilot study of 33 patients with rectal cancer, 30 g of glutamine was given in three doses per day for 5 weeks during preoperative radiochemotherapy and the placebo was given as 30 g of maltodextrin. There was no difference between groups in the frequency and severity of diarrhoea during radiochemotherapy ( $P = 0.5$  and  $P = 0.39$  respectively) (Rotovnik Kozjek et al 2011).

### Chemotherapy-induced peripheral neuropathy

Chemotherapy-induced peripheral neuropathy is a significant adverse effect associated with neurotoxic chemotherapy (especially taxanes, platinum compounds and vinca alkaloids). In a review, two studies were identified that suggested beneficial effects. In one study, oral glutamine was found to be effective in reducing peripheral neuropathy associated with high-dose paclitaxel, resulting in a reduction in numbness, dysaesthesias and motor weakness, as well as a smaller loss of vibratory sensation (Amara 2008). Another study found that the addition of oral glutamine (15 g twice daily for 7 consecutive days every 2 weeks, starting on the day of oxaliplatin infusion) resulted in a significant reduction in the incidence and severity of peripheral neuropathy, less interference with activities of daily living (16.7% versus 40.9%) and less need for oxaliplatin dose reduction due to adverse effects (7.1% vs 27.3%). The addition of glutamine did not affect response to chemotherapy or survival (Wang et al 2007).

### Other benefits

In one report, L-glutamine (10 g three times daily), given 24 hours after receiving paclitaxel, appeared to prevent the development of myalgia and arthralgia associated with treatment (PDRHealth 2006a). In children with solid tumours receiving chemotherapy, oral glutamine supplementation (4 g/m<sup>2</sup>/day) may improve nutritional and immunological parameters and reduce requirements for antibiotics (Okur et al 2006). Glutamine may also increase tumour methotrexate concentration and

tumouricidal activity and reduce side effects and mortality rates (Miller 1999, PDRHealth 2006a).

## OTHER USES

### Growth and development

In a prospective randomised, double-blind, placebo-controlled 1-year study of 120 young Brazilian shantytown children aged from 2 months to 9 years who were given glutamine alone (16 g daily for 10 days at start of the study) or a combination of glutamine + zinc + vitamin, improved intestinal barrier function was seen, as measured by the percentage of lactulose urinary excretion and the lactulose:mannitol absorption ratio. Glutamine treatment significantly improved weight-for-height z-scores compared to the placebo-glycine control group (Lima et al 2014).

### Radiation injury

In a recent double-blind study the beneficial effects of oral glutamine supplementation on radiation injury were investigated in women undergoing radiation therapy for breast cancer. In the 8-week study, 17 patients were randomised to receive either the supplementary glutamine (0.5 g/kg/day;  $n = 9$ ) or a placebo (dextrose, 25 g/day;  $n = 8$ ) three times daily during 6 weeks of radiation therapy. The patients were followed for 2 years for assessment of radiation injury using the Radiation Therapy Oncology Group scales. The study reported reduced acute radiation morbidity and pain in the glutamine-supplemented group (Rubio et al 2013).

### Alcoholism

Preliminary studies suggested a potential for glutamine to reduce alcohol cravings; however, these effects have not yet been studied in controlled trials on humans (PDRHealth 2006a). More recently, in vitro research has suggested that glutamine supplementation may inhibit the deleterious effects of alcohol on the tight junctions of the gut mucosa and in turn reduce the increased risk for gastrointestinal cancers in alcoholics (Basuroy et al 2005, Seth et al 2004).

### Acute pancreatitis

The enteral administration of L-glutamine (15 mg/kg/day) to rats with acute pancreatitis resulted in a reduction in necrosis and infectious complications by decreasing the bacterial translocation rate (Avsar et al 2001).

### Sickle cell disease

Orally administered L-glutamine improves the NAD redox potential of sickle red blood cells. Investigations of blood samples taken from five adult patients with sickle cell anaemia who had been on L-glutamine (30 g/day) therapy for at least 4 weeks consistently resulted in improvement of sickle red blood cell adhesion to human umbilical vein endothelial cells compared to the control group. The

authors conclude that these results suggest positive physiological effects for L-glutamine in sickle cell disease (Niihara et al 2005).

### Other conditions

Glutamine is a popular supplement in naturopathic practice and sometimes used for conditions that may be associated with compromised intestinal permeability, such as food allergies, leaky gut syndrome and malabsorption syndromes, including diarrhoea. It may also be used for conditions such as dermatitis and general fatigue, based on the theory that compromised intestinal permeability provides the opportunity for undigested food particles (especially proteins) to enter the systemic circulation and gives rise to an unwanted immune response that manifests as a skin reaction or as lethargy.

### DOSAGE RANGE

Naturally-occurring food proteins contain 4–8% of their amino acid residues as glutamine and so the daily consumption is usually less than 10 g/day (Hall et al 1996).

Supplemental L-glutamine is available for oral and enteral use (in capsules, tablets and powder form) and in a dipeptide form for parenteral use.

While solubility and stability are primarily factors for TPN solutions, several factors should also be considered when using oral supplements, as powder forms are often mixed into a solution to enable easy administration of higher doses: 1 g of L-glutamine dissolves in 20.8 mL of water at 30°C (PDRHealth 2006a) and is stable for up to 22 days if stored at 4°C (Hornsby-Lewis et al 1994). Ideally, powdered formulas should be consumed immediately after mixing.

- Gut repair: 7–21 g taken orally as a single dose or in divided doses.
- Cancer therapy: 2–4 g twice daily swished in the mouth and swallowed (up to 45 g has been used in trials and given orally in divided doses).
- Critical illness: 5 g/500 mL of enteral feeding solution.
- HIV: 30 g/day taken orally as a single dose or in divided doses.
- Infection: 12–30.5 g in an enteral feeding solution.
- Infants: 300 mg/kg/day added to breast milk or to preterm formula.

### ADVERSE REACTIONS

Toxicity studies in rats fed up to 5% of their diet in L-glutamine showed no toxic events (Tsubuku et al 2004) and glutamine dose-response studies have demonstrated ‘good tolerance without untoward clinical or biochemical effects’ (Ziegler et al 1999). Based on the available published human clinical trial data, glutamine intakes up to 14 g/day appear to be safe in normal healthy adults. Higher levels have been tested without adverse effects and may be safe; however, the data for intakes above 14 g are not sufficient for a confident conclusion of long-term safety (Shao & Hathcock 2008).

Most adverse reactions are mild and uncommon; they include gastrointestinal complaints such as constipation and bloating (PDRHealth 2006a). No evidence of harm has been observed in the studies conducted to date (Wischmeyer 2003).

A report exists of mania in two hypomanic patients after self-medication with up to 4 g/day glutamine (Membane 1984). As glutamine is a precursor of GABA, this may provide a possible explanation.

Two cases of a transient increase in liver enzyme levels have also been reported (Hornsby-Lewis et al 1994).

## SIGNIFICANT INTERACTIONS

### Radiation and chemotherapy

Benefits have been observed for the use of L-glutamine during radiation and chemotherapy (see ‘Clinical note — Cancer therapy’, above).

### Indomethacin/NSAIDs

Concomitant use of L-glutamine (7 g three times daily) and indomethacin may ameliorate the increased intestinal permeability caused by indomethacin. The inclusion of misoprostol may also have a synergistic effect with this combination (Hond et al 1999, PDRHealth 2006a, Tanaka & Takeuchi 2002) — beneficial interaction possible.

### Human growth hormone

In patients with severe short-bowel syndrome, concomitant use of L-glutamine and human growth hormone may enhance nutrient absorption (PDRHealth 2006a).

### CONTRAINDICATIONS AND PRECAUTIONS

It is contraindicated in patients with hypersensitivity to glutamine or hepatic disease or any condition where there is a risk of accumulation of nitrogenous wastes in the blood, thus increasing the risk of ammonia-induced encephalopathy and coma.

It should only be used in people with chronic renal failure under professional supervision.

### PREGNANCY USE

Safety in pregnancy has not been established; however, doses in line with normal dietary intake (approximately 10 g/day) are unlikely to be cause for concern.

### PATIENTS' FAQs

#### *What will this supplement do for me?*

L-Glutamine is an amino acid that is used by the immune systems and intestinal cells as a fuel source. People with critical illnesses, stress, burns, injury or having undergone surgery or undertaking strenuous physical exercise require an increased intake to

restore glutamine levels to normal and avoid loss of muscle mass and compromised immune function. It also promotes gastrointestinal repair and may improve tolerance to some anticancer treatments.

#### **When will it start to work?**

This will depend on the indication for which it is being used.

#### **Are there any safety issues?**

Glutamine appears to be a safe supplement; however, it should not be used by people who are hypersensitive to this compound, those with liver disease or any condition where there is a risk of accumulation of nitrogenous wastes in the blood (e.g. Reye's syndrome).

It should be used only by people with chronic renal failure under professional supervision.

## Licorice

**HISTORICAL NOTE** Licorice root has been used in Europe since prehistoric times, and its medicinal use is well documented (Fiore et al 2005). References to licorice date back to approximately 2500 BC on Assyrian clay tablets and Egyptian papyri. It has been used as both a food and a medicine since ancient times. The genus name, meaning ‘sweet root’, is attributed to the 1st-century Greek physician Dioscorides. The herb is also popular in traditional Chinese and Ayurvedic medicines (Blumenthal et al 2000).

### OTHER NAMES

Liquorice, licorice root, Chinese licorice, sweet root, gan cao, kanzo, kanzoh, radix glycyrrhizae, yashimadhu, yasti-madhu, alcacuz.

### BOTANICAL NAME/FAMILY

*Glycyrrhiza glabra* L. (family Leguminosae)

There are around 30 species of *Glycyrrhiza* spp., so *G. glabra* should be differentiated from other medicinally used herbs such as: *G. uralensis* (synonyms: Chinese licorice, gan cao, licorice root, sweet root), *G. inflata* (synonyms: gan cao, zhigancao), *G. pallidiflora*, *G. glandulifera*, *G. pallida*, *G. typica* and *G. violacea*, although some studies do not always clearly state which form is used. In addition, there are three varieties of *G. glabra*: var. *violacea* (Persia, Turkey), var. *gladulifera* (Russia) and var. *typica* (Spain, Italy) (Asl & Hosseinzadeh 2008).

### PLANT PARTS USED

Root and stolon

### CHEMICAL COMPONENTS

Licorice contains several triterpenoid saponins (4–20%), the most studied of which is glycyrrhizin (GL, also known as glycyrrhizic acid or glycyrrhizic acid), which is a mixture of potassium and calcium salts of glycyrrhetic acid (GA). Other triterpenes include: liquiritic acid, glycyrrhetol, glabrolide and isoglabrolide (Asl & Hosseinzadeh 2008).

Other important constituents include: flavonoids (isoflavonoids, liquiritin, isoliquiritin, liquiritigenin,

### Clinical note — GL, GA and side effects

GL is mainly absorbed after presystemic hydrolysis to GA (18-β-glycyrrhetic acid [glycyrrhetic acid; the aglycone of GL]). On excretion via the bile it may be reconstituted to GA by commensal bowel flora and then reabsorbed (Gunnarsdottir & Johannesson 1997, Hattori et al 1983, Ploeger et al 2001). GL and GA are associated with the side effects encountered with high-dose or long-term licorice use, such as elevated blood pressure and fluid retention. In people with prolonged gastrointestinal transit time, GA can accumulate after repeated intake. As GA is 200- to 1000-fold more powerful in inhibiting 11-β-hydroxysteroid dehydrogenase (11HSD) than GL, this may lead to more significant mineralocorticoid effects (Ploeger et al 2001). In order to minimise the risk of side effects, practitioners often use a deglycyrrhizinised form of licorice (DGL).

While *G. glabra*, *G. uralensis* and *G. inflata* are often seen as similar remedies, there are some differences in the constituents, such as the phenolic contents (Mills & Bone 2000).

formononetin, glabridin, rhamnoliquiritin, neoliquiritin and the chalcones [isoliquiritigenin, licochalcone A and B]); sterols (β-sitosterol, dihydrostigmasterol); polysaccharides (arabinogalactans); coumarins (liqoumarin, glabrocoumarone A and B, herniarin,

umbelliferone, glycerin, glycocoumarin, licofurano-coumarin, licopyranocoumarin and glabrocoumarin); phenols, fatty acids, glabrol; amines; glucose, sucrose; resin; and volatile oil. 5,8-Dihydroxy-flavone-7-O-beta-D-glucuronide, glychionide A, 5-hydroxy-8-methoxyl-flavone-7-O-beta-D-glucuronide, glychionide B, hispaglabridin A, hispaglabridin B, 4'-O-methylglabridin and 3'-hydroxy-4'-O-methylglabridin, glabroisoflavanone A and B and glabroisoflavanone B have also been isolated (Asl & Hosseinzadeh 2008, Blumenthal et al 2000).

*Glycyrrhiza glabra* should be differentiated from other species such as *G. inflata* and *G. uralensis*. While the constituent properties of *G. glabra* resemble that of *G. inflata*, they are not similar to *G. uralensis*. Furthermore, there are species-specific typical constituents including glabridin (*G. glabra*), licochalcone A (*G. inflata*) and glycykoumarin (*G. uralensis*) that may influence the pharmacological effects (Kondo et al 2007). Additionally, among different samples of *G. glabra* there may be significant differences in the content of active constituents and biological activity (Statti et al 2004). The lack of standardisation of herbs such as licorice provides a challenge for demonstrating reproducible efficacy in clinical settings.

## MAIN ACTIONS

### Mineralocorticoid effect

The GA constituent in licorice (and its metabolite 3-monoglucuronyl-glycyrrhetic acid) inhibits the enzyme 11HSD (Kato et al 1995), which catalyses the conversion of cortisol into its inactive metabolite, cortisone. This results in delayed excretion and prolonged activity of cortisol. Additionally, GL and GA bind to mineralocorticoid and glucocorticoid receptors and may displace cortisol from its carrier molecule, transcortin (Nissen 2003).

### Pseudohyperaldosteronism

As cortisol levels rise, they stimulate mineralocorticoid receptors in the distal renal tubule (Walker et al 1992). This creates pseudohyperaldosteronism, which has the same clinical features as primary aldosteronism, including sodium retention, fluid retention and oedema, hypertension, hypokalaemia and metabolic alkalosis (Armanini et al 1996, Haldal & Midtvedt 2002, Kato et al 1995, van Uum et al 1998, Walker & Edwards 1994).

A case report suggests that the symptoms occur despite low plasma levels of aldosterone (Nobata et al 2001). Decreased plasma renin activity (Bernardi et al 1994, Epstein et al 1977) and increased cortisol levels result in vasoconstriction of vascular smooth muscle (Dobbins & Saul 2000, Walker et al 1992), which may further exacerbate the hypertensive effects. This may be of particular significance in patients with prolonged intestinal transit time where GA levels can accumulate (Ploeger et al 2001).

### Anti-inflammatory

The anti-inflammatory action of beta-glycyrrhetic acid ( $\beta$ -GA), a major metabolite of GL, is largely mediated by cortisol, an endogenous hormone with anti-inflammatory action (Teelucksingh et al 1990). It inhibits glucocorticoid metabolism and therefore potentiates its effects.

Synergistic activity between GL and other constituents of licorice in suppressing the expression of inflammatory mediators nitric oxide and inducible nitric oxide synthase has also been identified (Uto et al 2012).

Attenuation of pro-inflammatory cytokine release by licorice or licorice constituents has been reported in a number of animal models (Chu et al 2013, Xie et al 2009).  $\beta$ -GA was shown to significantly suppress LPS-induced interleukin-12, as well as the expression of surface molecules CD80, CD86, major histocompatibility complex (MHC) class I and MHC class II molecules in dendritic cells in vitro (Kim ME et al 2013). The T-helper type 1 immune response was also reduced in response to  $\beta$ -GA.

Several studies have found that GA inhibits the activity of 11HSD and hepatic delta-4-5-beta-steroid reductase, preventing the conversion of cortisol to its inactive metabolite, cortisone (Kageyama et al 1997, MacKenzie et al 1990, Soma et al 1994, Whorwood et al 1993). As such, cortisol activity is prolonged and levels may rise, thereby increasing its anti-inflammatory effects. It may also inhibit classical complement pathway activation (Asl & Hosseinzadeh 2008). For these reasons, licorice has also been investigated for its ability to potentiate the effects of steroid medications (Teelucksingh et al 1990).

This mechanism alone does not fully account for the anti-inflammatory effects of licorice as oral doses of GL also appear to exert an effect in adrenalectomised rats (Gujral et al 2000). GL (10 mg/kg IP 5 min prior to carrageenan) exerts potent anti-inflammatory effects in mice by preventing the activation of nuclear factor (NF)- $\kappa$ B and STAT-3 (Menegazzi et al 2008). The DGL also exerts anti-inflammatory effects, and steroid-like activity has also been attributed to the liquiritin constituent (Bradley 1992).

### Anti-allergic

The anti-allergic effects of licorice are mainly due to GL,  $\beta$ -GA and liquiritigenin, which can relieve IgE-induced allergic reactions, inhibit passive cutaneous anaphylactic reactions and scratching behaviour in mice (Shin et al 2007). A mouse model of asthma GL (5 mg/kg) markedly inhibited airway constriction and hyperreactivity, lung inflammation and infiltration of eosinophils in the peribronchial and perivascular areas. It decreased interleukin (IL)-4, IL-5 and ovalbumin-specific IgE levels (Ram et al 2006). This finding was supported by a more recent study, where GL (10 mg/kg) prevented chronic histopathological lung changes in a mouse

model of asthma, including basement membrane thickness, and goblet and mass cell number (Hocaoğlu et al 2011). These effects may prove beneficial for the treatment of allergic conditions such as asthma and dermatitis; however, further research is required.

### Mucoprotective

Early investigation into the mucoprotective qualities of licorice led to the development of the anti-inflammatory and anti-ulcer medications, carbenoxolone (a hemisuccinate derivative of GA), and enoxolone (an analogue of carbenoxolone) used to treat gastric and oesophageal ulcer disease. Researchers have suggested that it may exert its mucoprotective effects by increasing mucosal blood flow as well as mucus production, and by interfering with gastric prostanoid synthesis (Guslandi 1985). Animal studies indicate that licorice preparations such as DGL improve the environment in the stomach by increasing mucus production, thereby allowing for proliferation of tissue and healing to occur. DGL increases mucus production by increasing the number of fundus glands and the number of mucus-secreting cells on each gland (van Marle et al 1981).

The increase in mucus production seen with carbenoxolone and licorice appears to occur in a number of epithelial tissues other than the digestive tract. It has been reported in the lungs and also bladder, according to *in vivo* studies (Mooreville & Fritz 1983), and in the trachea, accounting for its expectorant properties (Bradley 1992).

### Anti-ulcer effects

Licorice demonstrates the ability to promote mucosal repair and reduce symptoms of active ulcer (Larkworthy & Holgate 1975).

The anti-ulcer effects of licorice are due to inhibition of 15-hydroxyprostaglandin dehydrogenase (which converts prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) and F<sub>2α</sub> to their inactive forms) and delta-13-PG reductase. Licorice-derived compounds therefore increase the local concentration of PGs that promote mucus secretion and cell proliferation in the stomach, leading to healing of ulcers (Baker 1994).

Anti-inflammatory activity (as described above) further contributes to the herb's symptom-relieving action.

### Antiviral

Both oral and injectable dose forms of licorice have been tested and found to have activity against a range of viruses. In human trials, GL and its derivatives reduce the liver sequelae associated with hepatitis B and C viruses; animal studies demonstrate a reduction in viral activity for herpes simplex virus, encephalitis and influenza A virus pneumonia; and *in vitro* studies reveal antiviral activity against HIV-1, severe acute respiratory syndrome (SARS) related coronavirus, respiratory syncytial virus, arboviruses, vaccinia virus, hand foot and mouth-related enterovirus and coxsackievirus, and vesicular

stomatitis virus (Fiore et al 2008, Wang J et al 2013). The effects appear to be mediated by the constituents GL and GA (Jeong & Kim 2002). The proposed mechanisms for these antiviral effects include 'reduced transport to the membrane and sialylation of hepatitis B virus surface antigen, reduction of membrane fluidity leading to inhibition of fusion of the viral membrane of HIV-1 with the cell, induction of interferon gamma in T-cells, inhibition of phosphorylating enzymes in vesicular stomatitis virus infection and reduction of viral latency' (Fiore et al 2008). It should be noted that current studies focus largely on GL, which is converted in the gut to GA and may not produce the same results as those demonstrated for GL *in vitro*.

### SARS-associated coronavirus

*In vitro* studies have shown GL to inhibit SARS-CV (clinical isolates FFM-1 and FFM-2) replication by inhibiting adsorption and penetration of the virus in the early steps of the replicative cycle. GL was most effective when given both during and after the adsorption period. High concentrations of GL (4000 mg/L) were found to completely block replication of the virus (Cinatl et al 2003). The ability of GL to reduce platelet accumulation in the lungs (Yu et al 2005) may also support this use and provide a possible therapeutic option for further investigation.

### HIV

Preliminary evidence indicates that intravenous administration of GL may reduce replication of HIV. High-dose GL (1600 mg/day) was most effective in reducing HIV type 1 p24 antigen and increasing lymphocytes (Hattori et al 1989). *In vitro*, GL has the potential to inhibit viral replication in cultures of peripheral blood mononuclear cells from HIV-infected patients infected with a non-syncytium-inducing variant of HIV (Sasaki et al 2002–03).

### Influenza

Animal studies have shown that GL offers protection against influenza virus in mice through stimulation of interferon-gamma production by T-cells (Utsunomiya et al 1997). While GL treatment has been shown to reduce the number of human lung cells infected with influenza A virus, this effect was limited to up to two viral replication cycles (Wolkerstorfer et al 2009). This study suggests that the antiviral activity of GL is via cell membrane interactions, reducing endocytotic activity and subsequent viral particle uptake.

### Epstein-Barr virus

*In vitro* studies suggest that GL may interfere with an early step of the Epstein Barr Virus replication cycle (possibly penetration) (Lin JC 2003).

### Herpes simplex virus 1

In Kaposi sarcoma-associated herpes virus (KSHV), GL reduced the synthesis of a viral latency protein

and induced apoptosis of infected cells (Cohen 2005) terminating KSHV latent infection of B-lymphocytes (Bradbury 2005). Early in vitro studies found that GL inactivated herpes simplex virus irreversibly (Pompei et al 1979). Animal studies show that intraperitoneal administration of GL reduces HSV-1 viral replication and improves survival from herpetic encephalitis in mice (Sekizawa et al 2001). Whether GL may act against other latent herpes viruses or be suitable for clinical use against KSHV requires further elucidation (Bradbury 2005).

### Antibacterial

A number of constituents in licorice, including phenolic compounds (glicophenone and glicoisoflavonone), licochalcone A and isoflavones, were found to have antibacterial effects on methicillin-resistant *Staphylococcus aureus* (MRSA) and methicillin-sensitive *Staphylococcus aureus* in vitro (Hatano et al 2000). GA has been shown to exhibit bactericidal activity against MRSA at concentration above 0.223 microM, and induced reduced expression of virulence genes *saeR* and *hla* at concentrations below this (Long et al 2013).

Glabridin has been identified as a potentially active agent against *Mycobacterium tuberculosis* (H(37)Ra and H(37)Rv strains), Gram-positive and Gram-negative bacteria (Gupta et al 2008). Additionally ether-water extracts of licorice have been found to have antibacterial activity against *E. coli*, *B. subtilis*, *E. aerogenes*, *K. pneumoniae* and *S. aureus* (Onkarappa et al 2005).

### Antifungal

Licochalcone A and glabridin, but not GA, showed antifungal activity against *Candida albicans* in vitro (Messier & Grenier 2011). At high doses (100 mcg/mL), both licochalcone A and glabridin inhibited hyphal formation, with licochalcone A also inhibiting biofilm formation by 35–60% from 0.2 mcg/mL. It should be noted that glabridin and licochalcone A also induced toxicity in oral epithelial cells from 10 mcg/mL and 20 mcg/mL respectively.

### Anti-parasitic

18βGA has been shown to possess anti-malarial properties both in vivo and in silico, *Plasmodium berghei*-infected mice showing  $6.68 \pm 2.19$ ,  $1.49 \pm 1.04$  and  $0 \pm 0\%$  parasitaemia on day 8 following 62.5, 125 and 250 mg/kg doses respectively (control:  $20.57 \pm 3.13\%$ ) (Kalani et al 2013).

A preliminary study found that glabridin inhibited growth of *Plasmodium falciparum* in vitro, with the trophozoite stage of the erythrocytic cycle most sensitive to the compound (Cheema et al 2014). Due to an observed induction of apoptosis and increased markers of oxidative stress, it is thought these mechanisms underlie glabridin's anti-parasitic effect.

### Expectorant

Expectorant effects may be attributed to the ability of licorice to stimulate tracheal mucus secretion,

facilitating the elimination of mucus from the respiratory tract (Bradley 1992).

### Antitussive

In animal studies licorice produces a persistent antitussive effect, which is mediated by liquiritin apioside in the earlier phase and liquiritin and liquiritigenin (a metabolite of liquiritin apioside) in the later phase (Kamei et al 2005). Isoliquiritigenin has also been shown to induce tracheal relaxation in guinea pig models (Liu et al 2008).

### Antioxidant

In vitro research has identified seven antioxidant compounds from an acetone extract of licorice: four isoflavans (hispaglabridin A, hispaglabridin B, glabridin and 4'-O-methylglabridin), two chalcones (isoprenylchalcone derivative and isoliquiritigenin) and an isoflavone (formononetin) (Vaya et al 1997). Isoflavones from licorice were also shown to be effective in protecting mitochondrial function against oxidative stresses (Haraguchi et al 2000).

Flavanoids isolated from *Glycyrrhiza inflata* and *Glycyrrhiza uralensis* (namely licochalcone B, licochalcone A, echinatin, glycy coumarin, glyurallin B and 5-(1,1-dimethylallyl)-3,4,4'-trihydroxy-2-methoxychalcone) were tested in vitro for antioxidant activity (Fu et al 2013). Strong radical scavenging activity was shown by licochalcone B, echinatin and glycy coumarin, and potent inhibition of lipid peroxidation compared to control was shown in all compounds except echinatin.

### Reduces lipid peroxidation
