## Disclaimer

Complementary medicine and pharmacology are ever-changing fields. Standard safety precautions must be followed but, as new research and clinical experience broaden our knowledge, changes in treatment become necessary or appropriate. The authors and publisher have, in so far as it is possible, taken every care to ensure that the information contained within the text is as accurate and as up-to-date as possible. Readers are, however, advised always to check available product information with the herb, supplement or drug manufacturer to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the treating person to determine dosages and the best treatment for the patient. Neither the publisher nor the editors assume any responsibility for any injury and/or damage to persons or property.

indicates a herb or supplement action with particular significance for pregnant women.

indicates a warning or cautionary note regarding the action of a herb or supplement.

indicates FAQs about the herb or supplement.

About the cover image (Gustoimages/Science Photo Library): Passion flower (*Passiflora incarnata*), Passion flower (*Passiflora incarnata*) flower head. As well as being cultivated for use as a decoration due to its impressive flowers, the passion flower is also used medicinally. It has a sedative effect and can be used as a hypnotic (sleep inducer) and an anti-spasmodic (relaxes involuntary muscles). When used as a compress, passion flower can ease minor skin irritations. It is usually used as an infusion or as a tincture (alcohol extract).

# ORGANISATION OF THIS BOOK

This fourth edition of *Herbs and Natural Supplements: an evidence-based guide* is organised into four sections. The first volume provides a basic introduction to complementary medicine in general and then, more specifically, to herbal medicine, clinical nutrition, aromatherapy and food as medicine. It is hoped that many of your general questions will be answered here. In this first volume, we have also included the chapters relating to clinical practice and explore the relatively new fields of integrative medicine and wellness as it relates to health. These areas are gaining popularity around the globe and complementary medicine philosophy and treatments are often an integral part of the approach. We have also included chapters with a focus on safety because the wise clinical use of all interventions must be based on a benefit versus risk assessment. There are general chapters discussing the safety of herbs and natural supplements and drug interactions, and then specific chapters focusing on safety in pregnancy, before surgery and for people undertaking treatment for cancer. These topics are discussed in both a theoretical and a practical way to clarify the key concerns and produce some general guidelines that can be used to inform practice.

The second part of this volume consists of ready-reference appendices, the largest of which is a table outlining the interactions possible between the complementary medicines reviewed and pharmaceutical drugs. Although investigation into this area is still in its infancy, we have provided a brief

explanation for each possible interaction and a general recommendation based on what is currently known or suspected. It is intended as a guide only, to be used to inform practice when clinicians take a medical and medication history; obviously it should be interpreted within the individual patient's context. It is anticipated that this section will continue to change in future editions as more clinical studies are published and theoretical predictions are tested.

The second volume comprises of 132 evidence-based reviews of some of the most popular herbs and natural supplements available over the counter. Exhaustive reviews of the peer-reviewed literature have been undertaken by the author team to update, modify and expand information from the previous edition. Common names, chemical components, main actions, clinical uses, dosage range and safety issues are included for each herbal medicine. For nutritional supplements, background information and pharmacokinetics, food sources, deficiency signs and symptoms and the new Australian and New Zealand recommended daily intakes (RDIs) are also included where appropriate. Although technical language is frequently used, there is also a summary in non-technical language (Practice Points/Patient Counselling) and answers to key questions patients may have about the product (Patients' FAQs). A Historical note is included where appropriate and occasionally there are also Clinical note boxes that provide further information.

# ACKNOWLEDGMENTS

Each edition of *Herbs and Natural Supplements* is bigger than the last and has required even more effort to produce. This is certainly true of this, our fourth edition, which has been expanded to two volumes and is now also available as an eBook.

The increase in size is chiefly due to the enormous amount of new material we have uncovered and felt important enough to include in this completely revised edition. Between Medline, Science Direct and the Cochrane database, there are tens of thousands of peer-reviewed articles that are now available to help us uncover the potential of herbs and natural supplements.

Identifying, interpreting, collating and synthesizing this information is an important and challenging task. For this edition, we significantly expanded our contributor team and searched for people with a range of backgrounds, training and skills. Some contributors are research academics with an expertise in complementary medicine; others are university lecturers working at the interface with students, whereas others are clinicians that bring a real-world perspective to the task. As always, I believe the author team to be among the brightest and most talented technical CM writers in the country. Their dedication, tenacity and enthusiasm have been integral to this project and I am privileged to have them on the team.

On a personal note, undertaking such a major project as this book means many hours dedicated to working in the home office, away from family and friends. It also means mentally retreating from everyday life as thoughts about the book and the issues raised, permeate nearly everything.

I'd like to thank my husband Gary, who is my biggest support, greatest teacher and best friend. His understanding and patience are always given without a second thought and forever appreciated. My three daughters Sarah, Lori and Jaimie are wonderful, warm and intelligent people who have found a genuine interest in health and helping others. I am so proud and thank you for your understanding and support during my busy and distracted writing periods.

I'd also like to thank all my parents Shana and Fred Green, Judy Braun for their emotional and hands-on support; my late grandfather Leon Kustin and father-in-law Emil Braun, who continue to serve as reminders to me to have courage and persevere; and the rest of my wonderful extended family and friends who accept that I'm off the radar every now and again, working on another book.

I'd like to make a special mention of my late father, Magenesta, who passed away between editions. Without him I would not have finished my pharmacy degree or started my life long journey into natural medicine — you have been my mentor and guide from the beginning.

I'd like to thank associate editors Liza Oates, Rachel Arthur, Gina Fox, Evelin Tiralongo, Louise Zylan and Brad McEwan for helping to guide the newer contributors with their patience, experience and wisdom. I'd like to thank returning contributors Ondine Spitzer, Leah Hechtman, Emily Bradley, Trisha Dunning and Surinder Baines for their continued commitment and professionalism and Marc Cohen for your unwavering vision. We also have a large number of new contributors who have been important additions to the author team; without you, this book simply would not have been possible — thank you.

I'd like to thank the team at Elsevier, especially Neli Bryant, for her energy and co-ordination, and my inspiring work colleagues at The Alfred Hospital (especially Prof Frank Rosenfeldt), Monash University (esp. Prof Paul Komesaroff), National Institute of Complementary Medicine (esp Prof Alan Bensoussan) and most recently, Blackmores (esp Christine Holgate and Marcus Blackmore) and the wonderful Blackmores Institute.

Finally, thank you to all the health care professionals that have told me they use this book every day to guide their clinical practice. Knowing this helps make the difficult journey easier and is an important reminder of why our work is important, because the information within helps improve people's lives through you.

# ABOUT THE AUTHORS

## EDITORS

### **Lesley Braun, PhD, BPharm, DipAppSciNat**

Associate Professor of Integrative Medicine (Hon) National Institute of Complementary Medicine, University of Western Sydney, NSW, Senior Research Fellow (Hon), Monash/Alfred Psychiatric Research Centre, Melbourne, VIC, Australia

Senior Research Fellow (Hon), Monash/Alfred Psychiatric Research Centre, Vic, Australia

Dr Lesley Braun is a registered pharmacist and naturopath. She holds a PhD from RMIT University, Melbourne, in which she investigated the integration of complementary medicine into hospitals in Victoria. Dr Braun is an Adjunct Associate Professor of Integrative Medicine at the National Institute of Complementary Medicine (NICM) at the University of Western Sydney. NICM provides leadership and support for strategically directed research into complementary medicine and translation of evidence into clinical practice and relevant policy to benefit the health of all Australians.

Dr Braun serves on the Australian Therapeutic Goods Advisory Council, which oversees the implementation of TGA reforms and provides general strategic guidance to the TGA, advice on relationships and communication with stakeholders. She is also on the executive for the Complementary and Integrative Therapies interest group of the Clinical Oncology Society of Australia and is an advisory board member to the Australasian Integrative Medicine Association. As of 2014, she is also Director of Blackmore's Institute, the academic and professional arm of Blackmores, which entails engaging with a broad range of academics, government and industry bodies and overseeing a comprehensive academic and research program.

Since 1996 Lesley has authored numerous chapters for books and more than 100 articles, and since 2000 has written regular columns for the *Australian Journal of Pharmacy* and *Journal of Complementary Medicine*. She lectures to medical students at Monash University and to chiropractic students at RMIT University, and is regularly invited to present at national and international conferences about evidence-based complementary medicine, drug interactions, complementary medicine safety and her own clinical research.

Her role as the main author of *Herbs and Natural Supplements: an evidence-based guide* represents a

continuation of a life-long goal to integrate evidence-based complementary medicine into standard practice and improve patient outcomes safely and effectively.

### **Marc Cohen, MBBS(Hons), PhD, BMedSc (Hons), FAMAC, FICAE**

Professor of Health Sciences, School of Health Sciences, RMIT University, Melbourne, VIC, Australia

Professor Marc Cohen is one of Australia's pioneers of integrative and holistic medicine who has made significant impacts on education, research, clinical practice and policy. He is a medical doctor and Professor of Health Sciences at RMIT University, where he leads postgraduate wellness programs and supervises research into wellness and holistic health, including research on yoga, meditation, nutrition, herbal medicine, acupuncture, lifestyle and the health impact of pesticides, organic food and detoxification. Professor Cohen sits on the board of a number of national and international associations, including the Australasian Integrative Medicine Association, the Global Spa and Wellness Summit and the Australasian Spa and Wellness Association, as well as serving on the editorial boards of several international peer-reviewed journals. Professor Cohen has published more than 80 peer-reviewed journal articles and co-edited *Understanding the Global Spa Industry*, along with more than 10 other books on holistic approaches to health. He is a frequent speaker at many national and international conferences where he delivers inspiring, informative and uplifting presentations. His impact on the field has been recognised by four consecutive RMIT Media Star Awards, as well as the inaugural Award for Leadership and Collaboration from the National Institute of Complementary Medicine.

## ASSOCIATE EDITORS

### **Rachel Arthur, BHSc BNat(Hons)**

Rachel Arthur Nutrition

Rachel is a naturopath, lecturer, researcher and author. Graduating with a Bachelor of Health Science (Naturopathy) from the Southern School of Natural Therapies, Melbourne, she now lectures in clinical nutrition and naturopathic practice at a number of institutions, including Southern Cross University. In addition to this, Rachel is frequently asked to speak on nutrition by a variety of

organisations, including professional medical organisations across Australia and overseas. A contributing author for the previous editions, Rachel is also a regular contributor to a range of complementary medicine publications. In this edition, Rachel was involved with updating the Zinc monograph and was also an associate editor.

**Gina Fox, BHSc(Nat), GradCert (ReproMed)**

Gina is a clinician, writer, lecturer and speaker. She qualified as a naturopath in 2001 and has been specialising in pre-conception health, infertility, fertility and pregnancy since starting practice at Fertile Ground Health Group in Melbourne in 2003. Gina is an educator and lecturer and enjoys supervising student naturopaths at Endeavour College of Natural Health. She is also a meditation teacher and has co-written a Be Fertile series of guided relaxation CDs for women around conception, IVF support and pregnancy. Gina is currently undertaking a master degree in Reproductive Medicine with UNSW. In this edition, Gina has been involved in updating a number of monographs and was an associate editor.

**Bradley McEwen, PhD, MHSc(HumNutr), BHSc(CompMed), GCertHSc (HumNutr), AdvDip (Natur), DipBotMed, DipHom, DipNutr, Dip-SpMed, DipRMed**

PhD, MHLthSc (Hum. Nutr.), BHLthSc (CompMed), Grad. Cert. HlthSc (Hum. Nutr.), N.D. (Adv.), D.B.M., D.Hom., D.Nutr., D.S.M., D.R.M Lecturer, Clinic Supervisor, and Research and Curriculum Developer — Endeavour College of Natural Health

Dr Bradley McEwen is a naturopath, nutritionist, herbalist and educator. He has a PhD from the University of Sydney and a Master of Health Science (Human Nutrition) from Deakin University. His doctoral research investigated the effect of omega-3 on platelet function and coagulation in healthy subjects and cardiovascular patients.

Bradley has a passion for education and research. He has 15 years clinical experience and 10 years lecturing experience and currently lectures and supervises student clinic. In addition, he presents at seminars and conferences, both nationally and internationally. Bradley's research focus is on the effects of nutrition on chronic disease, particularly cardiovascular disease, omega-3 PUFA, and public health. He has a number of original research and review articles published in peer-reviewed international journals.

**Liza Oates, PhD, GCertECompMed, BHSc (Natr)**

Course co-ordinator Food as Medicine, and Wellness Practices & Perspectives, Postgraduate Wellness Program, RMIT University, Melbourne, Australia

Naturopathic Clinical Supervisor, Southern School of Natural Therapies and Endeavour College of Natural Health

Teaching Associate, Department of General Practice, Monash University

Dr Liza Oates is a naturopathic practitioner, educator and writer. Having initially graduated with a Bachelor of Health Science (Naturopathy) she later completed a Graduate Certificate in Evidence-based Complementary Medicine (University of Queensland and Southern Cross University), and a PhD (RMIT University). Her doctoral research investigated the health and wellness effects of organic diets and the findings have been presented at conferences in Australia, Poland, South Korea and the Czech Republic.

Liza is the course co-ordinator for Food as Medicine and Wellness Practices & Perspectives in the online Postgraduate Wellness program at RMIT University, and she supervises naturopathic student clinics. She has taught Nutrition, Complementary Medicine in Chronic Diseases and Health Enhancement to naturopathic and medical students.

Liza was a contributing author on the first three editions of *Herbs & Natural Supplements: an evidence-based guide*, and has published over 35 peer-reviewed journal articles in the complementary medicine field. Journal publications include *Australian Pharmacist*, *The Journal of Complementary Medicine*, *Journal of the Science of Food and Agriculture*, *Environmental Research*, *The International Journal of Environmental Research and Public Health* and *The Journal of Organic Systems*.

**Evelin Tiralongo, PhD, BPharm, GradCert (HigherEd)**

Associate Professor and Discipline Head in Complementary Medicine, School of Pharmacy, Griffith University, Gold Coast, QLD, Australia

Developer and Presenter, Short Course in Integrative Medicine, Griffith University School of Pharmacy

Associate Professor Evelin Tiralongo is a foundation member of Griffith University's Pharmacy School and is the discipline head for complementary medicine (CM) teaching and research at the School. She has an Honours degree in herbal medicine and a PhD in biochemistry. She gained extensive practical experience in integrative medicine as a registered pharmacist in German pharmacy practice, and has also completed her Australian registration as a pharmacist.

Her research focuses on CMs and natural products, and spans from laboratory to practice-based and clinical projects. As a chief investigator she has won over \$1.3 million in research funding and has co-authored 38 peer-reviewed publications and one patent, and designed online CM resources for *Pharmacology for Health Professionals* by Bryant et al.

She is a member of the NHMRC Homeopathy Advisory Committee, acts as a reviewer and editor for several internationally recognised CAM journals (eCAM) and has served on the scientific board of international conferences and forums (ICMAN5).

Evelin conducts continuous professional development seminars on CMs to pharmacists and other

healthcare professionals and is co-founder of the Short Course in Integrative Medicine. <http://www.integratedshortcourses.com/>

**Louise Zylan, PhD (candidate), MNutrMed, BHScNat**

Louise is the Head of Academic Studies for Natural and Nutritional Health and has over 25 years work experience in health and education. She ran a busy

private practice for 10 years, specialising in reproductive health.

Louise holds a Master degree in Nutritional Medicine and is currently undertaking a PhD in Public Health at Torrens University, where she is exploring the nutritional status of intellectually disabled adults in residential accommodation within Australia.

Naturopathic Practitioner, Lecturer, Endeavour College of Natural Health, Perth, WA, Australia

# PREFACE

Welcome to the fourth edition of *Herbs and Natural Supplements: an evidence based guide*. Due to the exponential growth in the peer-reviewed literature, we have had to expand our team of contributors significantly since the last edition. We have contributions from experts with a range of backgrounds such as nutrition and naturopathy, herbal medicine, pharmacy, dietetics and medicine and also a number of research active academics and university lecturers.

I started writing the first edition, together with Prof Marc Cohen, nearly 10 years ago, and it is very heartening to see the enormous growth in the evidence base that has occurred since that time. We now have far more information available in the peer-reviewed literature about key active components in herbal medicines, pharmacological activity in vivo and clinical trials. In particular, the complexity of herbal medicines has become more evident as nearly all have multiple mechanisms of action and we have well and truly moved beyond using solely traditional evidence to guide their use. Unfortunately, some authors of meta-analyses still continue to pool information from studies that have tested different plant parts and even species. This is like lumping apples and oranges together, and thereby compromises the usefulness of these reviews. However, overall reporting in herbal medicine studies has improved and where possible, we state the extract used, dose and administration form to help guide you in your practice.

The area of drug-herb interactions was of particular concern in the early-mid 2000s and there is now far more information about interactions that are clinically relevant. You will notice that we place most importance on drug interactions that have been demonstrated in vivo because in vitro testing has led us all astray in the past with false positives.

Probably the biggest growth area has been in nutritional science and research. In this edition, the fish oil, vitamin D and probiotic monographs in particular have expanded significantly. They are among the most popular supplements being bought in retail stores today. Fish oils are being intensively investigated for health conditions beyond

cardiovascular disease, and there is work being done in mental health, neurological diseases, neonates and children and even cancer. Unfortunately, some researchers still use olive oil as a placebo, which is unfortunate because this is not an inert substance and could be compromising results. Vitamin D is also being investigated for conditions unrelated to the musculoskeletal system, and population studies are indicating low vitamin D status is rife. Probiotics has been another area to explode with new information about potential effects beyond the gastrointestinal tract. The effect of the microbiome on multiple diseases is only starting to be understood and the role of pre- and probiotics in influencing it is slowly being uncovered. In contrast, there have been relatively fewer studies published on vitamins E and C than in the past.

Our team of contributors have systematically searched the main medical databases, using primary literature where possible, to capture, collate and synthesise the best and most relevant information for busy clinicians. We used Medline, Science Direct and the Cochrane database as a starting point to identify articles published since our last edition. This means having access to over 24 million peer-reviewed articles. Despite our best efforts, no doubt we will have missed something. This is due to the intense research activity underway and almost weekly publication of new information making it extremely difficult to keep up.

In this book, we report on positive, negative and inconclusive results and try to put forward theories as to why results are inconsistent. I think that in the future, we will better understand these differences. In particular, I wonder how much individual genetics is playing a role which we have not fully explored at this time.

Most adults in Western countries are using over-the-counter herbal and nutritional supplements, and informed advice from their healthcare practitioner is important and expected. I hope that this book will help expand your practice by unlocking the potential of natural medicines and safely guide your patients to use them appropriately.

# Adhatoda

**HISTORICAL NOTE** An important herb in Ayurvedic medicine for over 2000 years (Singh et al 2011), adhatoda is used traditionally in productive cough, asthma, haemoptysis and tuberculosis (Caldecott 2006). Adhatoda is a popular plant for digestion due to its extreme bitter taste (Caldecott 2006). The Sanskrit language term for adhatoda is *vasaka*, meaning a plant with characteristic unpleasant odour (Caldecott 2006, Pa & Mathew 2012). Adhatoda is an evergreen perennial shrub that grows all over the plains of India and Sri Lanka (Pole 2006).

## Clinical note

One of the alkaloids found in the herb (vasicine) has been chemically modified and is referred to as RLX (6,7,8,9,10,12-hexahydro-azepino-[2,1-b]-quinazoline-12-one) in the medical literature (Johri & Zutshi 2000). It has been shown in animal studies to inhibit antigen-induced mast cell degranulation and histamine release and to exert bronchodilator activity. It is the lead molecule for bromhexine and ambroxol (Gurib-Fakim 2006).

## COMMON NAMES

Adhatoda, Malabar nut tree, vasa, vasaka

## OTHER NAMES

*Adhatoda zeylanica*, *Justicia adhatoda*, arusha, bakash, *Justicia adhatoda-Folium*, vasaka, vasa, adusa, Baga-bahouk

## BOTANICAL NAME/FAMILY

*Adhatoda vasica* (family Acanthaceae)

## PLANT PARTS USED

Leaves, root, bark, flower

## CHEMICAL COMPONENTS

The leaves contain several different alkaloids, including vasicine, vasicinone, vasicinol, adhatodine, adhatonine, adhavaquinone, anisotine, peganine, 7-methoxyvasicinone, desmethoxyaniflorine, 3-hydroxyanisotine, vasnetine, betaine, steroids and alkanes (Claeson et al 2000, Kamal et al 2006, Mhaske & Argade 2006). The root also contains alkaloids (vasicinol, vasicinolone, vasicinone, adhatonine), a steroid (daucosterol), carbohydrates and alkanes (Claeson et al 2000).

## MAIN ACTIONS

Indigenous usage in India was as an antispasmodic, antiseptic and insecticide (Claeson et al 2000). Current application focuses on the herb's antispasmodic, oxytocic and cough-suppressant activities

(Gurib-Fakim 2006). It is an ingredient in the Rasayana preparation called chyavanprash, which is used widely as a health-promotive and disease-preventive tonic and is believed to be hepatoprotective and immunomodulating (Govindarajan et al 2007).

As with many Ayurvedic herbs, most investigation has been undertaken in India and locating original research from these sources is difficult.

## Antitussive effects

Results from animal studies show that *Adhatoda vasica* extract exerts considerable antitussive activity when administered orally and is comparable to codeine when cough is due to irritant stimuli (Dhuley 1999). The antitussive activity may be due to the action of vasicinone and vasicinol, which have activity in the cerebral medulla. In Ayurvedic medicine, adhatoda is prescribed in combination with *Curcuma longa*, *Zingiber officinale*, *Glycyrrhiza glabra*, *Terminalia chebula* and *Ocimum sanctum* to control cough and shortness of breath, especially for lung cancer patients (Balachandran & Govindarajan 2005).

## Anti-inflammatory

Vasicine, vasicinone, vasicine acetate, 2-acetyl benzyl amine and vasicinolone, the most bioactive constituents in adhatoda, showed strong anti-inflammatory activity in carrageenan-induced oedema in rats (Singh & Sharma 2013). Potent anti-inflammatory activity has also been demonstrated for the alkaloid fraction deoxyvasicinone, the naturally occurring quinazolinone alkaloid (Mhaske & Argade 2006). This has been shown to be equivalent to the anti-inflammatory effect of hydrocortisone in one study (Chakraborty & Brantner 2001).

## Bronchodilator and antiasthmatic activity

According to a 2002 review, both vasicine and vasicinone possess in vitro and in vivo bronchodilatory activity and inhibit allergen-induced bronchial obstruction in a manner comparable to that of sodium cromoglycate (Dorsch & Wagner 1991, Jindal et al 2002).

## OTHER ACTIONS

### Hepatoprotective and antioxidant activity

Traditionally adhatoda was used to treat liver disease: the juice of fresh leaves (5–10 g) was mixed with honey and orally ingested three times daily for 2–3 weeks (Kotoky & Das 2008). *A. vasica* leaf (50–100 mg/kg) was shown to protect against induced liver damage in rats (Bhattacharyya et al 2005); 100 mg/kg of *A. vasica* was comparable to the hepatoprotective ability of silymarin at 25 mg/kg. An earlier study showed that *A. vasica* (100–200 mg/kg) protected against carbon tetrachloride-induced liver damage in rats (Pandit et al 2004). The leaf extract significantly enhanced the protective enzymes superoxide dismutase and catalase in the liver: 200 mg/kg of *A. vasica* was shown to be comparable to 25 mg/kg of silymarin. In rats pretreated with aqueous extract of *Adhatoda vasica* an antioxidant effect against D-galactosamine-induced hepatic damage was shown (Jayakumar et al 2009). In vivo tests on mice also showed the extract is effective in inducing glutathione-S-transferase and DT-diaphorase in lungs and forestomach, and superoxide dismutase and catalase in kidneys (Singh et al 2000).

### Protection against radiation damage

*Adhatoda vasica* (800 mg/kg) protects haematopoietic stem cells against radiation damage by inhibiting glutathione deletion, reducing lipid peroxidation and increasing phosphatase activity in mice (Kumar et al 2005). Animals pretreated with oral doses of adhatoda showed an 81.25% survival rate at 30 days as compared to control animals, who could not survive past 25 days. In additional studies on mice, adhatoda exhibited highly significant increases in glutathione content and significant decrease in lipid peroxidation (Samarth et al 2008). A cyto-genomic analysis of 50% methanolic extract of adhatoda leaves on human peripheral lymphocytes showed radioprotective activity against therapeutically induced mutations, therefore demonstrating a potential as an adjuvant to cancer treatment (Sharma et al 2011).

### Enzyme induction

In vitro tests show that *A. vasica* acts as a bifunctional inducer, since it induces both phase I and phase II enzyme systems (Singh et al 2011). The clinical significance of this finding is unclear and remains to be tested.

### Abortifacient

One of the traditional uses of the herb is as an abortifacient and anti-fertility; however, inconsistent results from in vivo studies have made it difficult to determine whether adhatoda has significant abortifacient activity. One animal study investigating oral administration of leaf extracts showed 100% abortive rates at doses equivalent to 175 mg/kg of starting dry material (Nath et al 1992). Another study found

that an *A. vasica* extract had anti-implantation activity in 60–70% of test animals (Prakash et al 1985).

### Antispasmodic

The essential oil from the leaves exerts antispasmodic action, as demonstrated in an animal model of guinea pig tracheal chain (Claeson et al 2000).

### Nematocidal/anticestodal activity

Naga tribes in India have traditionally used adhatoda for curing intestinal worm infestations. In an experimental study *Adhatoda latibracteata* was shown to have high antiplasmodial activity (Lekana-Douki et al 2011). Animal studies indicate that crude aqueous root extracts of 3 g/kg body weight exhibit 37.4% reduction of mixed gastrointestinal nematode infestations in sheep, as a result of the alkaloid and glycoside content of adhatoda (Githiori et al 2006, Lateef et al 2003). In one animal study, adhatoda exhibited significant anticestodal efficacy, greater than that of praziquantel (Yadev & Tangpu 2008).

### Antidiabetic activity

Ethanol extract of *Justicia adhatoda* leaves and roots in doses of 50 and 100 mg/kg body weight, when administered to alloxan-induced diabetic rats showed reduction in blood glucose levels and at doses of 100 mg/kg body weight, hypoglycaemic activity was more pronounced than glibenclamide (Imran et al 2011).

### Other

Deoxyvasicinone, the naturally occurring quinazolinone alkaloid, exhibits antimicrobial and antidepressant activities (Mhaske & Argade 2006). Antimicrobial activity was specific to certain strains of penicillin- and ciprofloxacin-resistant *Neisseria gonorrhoeae* (Shokeen et al 2009). Vasicinone isolated from adhatoda showed in an in vitro study antimycobacterial and anticancer activities (Balachandran et al 2012). In an in vitro study, aqueous extract of adhatoda leaves showed antituberculosis activity against two multidrug-resistant isolates of *Mycobacterium tuberculosis*, DKU-156 and JAL-1236 (Gupta et al 2010).

## CLINICAL USE

Adhatoda has not been significantly investigated under clinical trial conditions, so evidence largely comes from traditional use; in vitro and in vivo studies providing preliminary support for its uses.

### Cough

The antitussive activity of adhatoda extract has been compared to that of codeine in two different models of coughing and in two different animal species (Dhuley 1999). When administered orally, *A. vasica* extract produced antitussive effects comparable to those of codeine against coughing induced by peripheral irritant stimuli. When coughing was induced by electrical stimulation of the tracheal mucosa, adhatoda extract was only one-quarter as active as codeine. Intravenous administration was far less effective in both cough models.

## IN COMBINATION

A double-blind, randomised, controlled trial of *Adhatoda vasica* in combination with *Echinacea purpurea* and *Eleutherococcus senticosus* was compared with an *Echinacea* and *Eleutherococcus* mixture and bromhexine (Narimanian et al 2005). Bromhexine is a semisynthetic derivative of the alkaloid vasicine found in *A. vasica* (Grange & Snell 1996) and is found in some pharmaceutical cough mixtures. Compared with the other two formulas, the *A. vasica* combination reduced the severity of cough, increased mucus discharge and reduced nasal congestion. Both herbal mixtures reduced the frequency of cough compared with bromhexine. Furthermore, Grange and Snell (1996) identified pH-dependent growth-inhibitory effects on *Mycobacterium tuberculosis*, which further supports its usage as a mucolytic.

## Asthma

Although *A. vasica* is used for asthma in combination with other herbs, clinical evidence is limited. Evidence of bronchodilator activity from in vitro and animal studies provides a theoretical basis for use in treating asthma.

One 12-week randomised, double-blind, placebo-controlled clinical trial was undertaken to assess the efficacy of an Ayurvedic herbal formula in asthmatic patients. While the formula contained 15 different herbs, almost half the total weight consisted of adhatoda. Active herbal treatment increased the efficacy of medication (salbutamol and theophylline) in bronchodilation, thus increasing forced expiratory volume in the first second. In addition, the herbal combination significantly improved other clinical parameters, resulting in reductions in dyspnoea, wheezing, expectoration, disability and respiratory rate when compared to a placebo (Murali et al 2006). Although these results are promising, the role of adhatoda as a stand-alone treatment remains unclear.

## OTHER USES

Adhatoda is traditionally used to treat cough, asthma, bronchitis and colds, but has also been used to treat fever, dysentery, diarrhoea, jaundice, tuberculosis and headache, to stimulate the birthing process and aid healing afterwards, and as an antispasmodic (Claeson et al 2000). It has also been used as an abortifacient in some Indian villages.

Leaves that have been warmed on the fire are applied topically in the treatment of joint pain, lumbar pain and sprains.

Use of the powder is reported as a poultice on rheumatic joints, a counterirritant for inflammatory swelling, a treatment for fresh wounds, and in urticaria and neuralgia (Dhuley 1999).

## DOSAGE RANGE

As clinical research is lacking, the following dosages come from Australian manufacturers' recommendations.

### Practice points/Patient counselling

- Adhatoda is an important Ayurvedic medicine used in the treatment of cough, asthma, bronchitis and colds.
- Traditional use further includes fever, dysentery, diarrhoea, jaundice, skin disorders, tuberculosis and headache.
- Preliminary evidence suggests that adhatoda may have bronchodilator activity and inhibit allergen-induced bronchoconstriction; however, clinical studies are unavailable to determine clinical significance.
- Antitussive effects comparable to those of codeine have also been reported in animal studies in which cough has been peripherally induced.
- Adhatoda has been used to stimulate the birthing process and aid healing afterwards, and may have abortifacient activity.
- Overall, little clinical evidence is available. Much of the available information is therefore speculative and based on in vitro and animal research and traditional use.

- Liquid extract tincture (1:2): 1–3 mL/day (Pole 2006).
- Dried herb/powdered leaf: 2.0–5.0 g/day (Caldecott 2006).

## ADVERSE REACTIONS

Insufficient reliable information is available.

## SIGNIFICANT INTERACTIONS

Controlled studies are not available, so interactions are based on evidence of activity and are largely theoretical and speculative.

## Codeine and other antitussive drugs

Theoretically, adhatoda may increase the antitussive effects of these drugs — beneficial interaction may be possible under professional supervision.

### CONTRAINDICATIONS AND PRECAUTIONS

Insufficient reliable information is available.

### PREGNANCY USE

Adhatoda is contraindicated in pregnancy, as the herb may have abortifacient activity. In Ayurvedic medicine it is considered safe postpartum (Pole 2006), and is used in combination with *Bacopa monniera* and 12 other herbal medicines in the treatment of vaginal discharge, pregnancy pain and pregnancy fever (Jadhav & Bhutani 2005).

## ! PATIENTS' FAQs

### What will this herb do for me?

Because *Adhatoda* has been investigated mainly in animal and test tube studies, its effects on humans are uncertain. Based on preliminary information and historical use, it may suppress cough and have some beneficial effects in asthma.

### When will it start to work?

This is uncertain because insufficient research data are available.

### Are there any safety issues?

Some research suggests that *Adhatoda* may stimulate uterine contractions, so it is not recommended in pregnancy.

# Albizia

**HISTORICAL NOTE** It is believed that albizia received its name because Filippo del Albizi, an 18th-century Florentine nobleman, introduced the species into cultivation ([The Plants Database 2004](#)). It has been used in Ayurvedic medicine for many years and is still a popular treatment for asthma, allergy and eczema.

## COMMON NAME

Albizia

## OTHER NAMES

Pit shirish shirisha

## BOTANICAL NAME/FAMILY

*Albizia lebbek* (family Fabaceae)

## PLANT PARTS USED

Leaves and stem bark

## CHEMICAL COMPONENTS

These are poorly understood, but albizia has been reported to contain alkaloids, steroids, terpenoids, coumarins, tannins, flavanoids, glycosides including anthraquinones, epicatechin, procyanidins, stigmastadienone, haemolytic proteins including lebeckalysin and saponins including albiziasaponins A, B and C ([Babu et al 2009](#), [Bobby et al 2012a](#), [Lam & Ng 2011](#)).

## MAIN ACTIONS

Albizia has not been significantly investigated in clinical studies; therefore, information is generally derived from in vitro and animal studies.

### Anti-inflammatory, antiarthritic

Albizia has demonstrated anti-inflammatory, analgesic and antiarthritic activity in several animal models ([Akilandeswari et al 2009](#), [Babu et al 2009](#), [Yadav et al 2010](#)). [Saha and Ahmed \(2009\)](#) suggest that albizia's anti-inflammatory and analgesic activity may be due to inhibition of cyclooxygenase activity and prostaglandin synthesis. [Pandey et al \(2010\)](#) suggest that albizia's antiarthritic activity may also be due to its antioxidant capacity, as they observed an increase in superoxide dismutase and catalase, and a decrease in lipid peroxidation in arthritic rats treated with albizia.

### Antibacterial

Albizia has demonstrated antibacterial activity against *Bacillus subtilis*, *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus vulgaris*, *Pseudomonas aeruginosa*, *Salmonella typhi* and *Staphylococcus aureus*, *Vibrio cholerae* and *Aeromonas hydrophila* in vitro ([Acharyya et al 2009](#), [Bobby et al 2012b](#), [Mahmood et al 2012](#)) in all but one study ([Seyyednejad et al 2010](#)).

### Antiprotozoal

Methanolic extracts of albizia demonstrated antitrypanosomal activity against *Trypanosoma cruzi* ([Al-Musayeib et al 2012](#)).

### Antiallergic

Both in vitro and in vivo tests have reported significant mast cell stabilisation effects similar to those of cromoglycate ([Johri et al 1985](#), [Tripathi et al 1979](#)). One study found that degranulation was inhibited by 62% ([Tripathi et al 1979](#)). The saponin fraction is believed to be the key group responsible for activity. An in vitro study compared the effects of albizia leaf, albizia stem bark and disodium cromoglycate on mast cell stabilisation. All three extracts were found to be equally potent ([Shashidhara et al 2008](#)). A more recent study confirmed dose-dependent mast cell stabilisation activity and inhibition of histamine release in mice with induced systemic anaphylaxis for the bark extract of albizia stem ([Venkatesh et al 2010](#)). Another study noted that albizia bark extract acted by suppressing histamine H<sub>1</sub> receptor (H<sub>1</sub>R), histidine decarboxylase (HDC), interleukin-4 (IL-4), IL-5 and IL-13 mRNA elevations in sensitised allergy model rats. It also decreased HDC activity and histamine content in the nasal mucosa, and significantly decreased the incidence of sneezing and nasal rubbing ([Nurul et al 2011](#)). In addition, albizia was found to prevent phorbol-12-myristate-13-acetate or histamine-induced increases in H<sub>1</sub>R mRNA in HeLa cells ([Nurul et al 2011](#)).

### Altering neurotransmitter activity

Albizia has an influence on  $\gamma$ -aminobutyric acid (GABA), serotonin and dopamine levels, according to in vivo studies ([Chintawar et al 2002](#), [Kasture et al 2000](#)). It appears that different fractions within the herb exert slightly different effects on neurotransmitters. In one study, a saponin-containing fraction from the extract of dried leaves of albizia was shown to decrease brain concentrations of GABA and dopamine, whereas serotonin levels increased. Another study that tested the methanolic fraction of an ethanolic extract of albizia leaves found that it raised brain levels of GABA and serotonin ([Kasture et al 2000](#)). Additionally, anticonvulsant activity has been demonstrated in vivo for this fraction.

### Memory enhancement

Saponins isolated from albizia have been shown to improve the memory retention ability of normal and

amnesic mice significantly, compared with their respective controls (Une et al 2001).

### Reduces male fertility

Three studies using animal models have demonstrated that albizia significantly reduces fertility in males (Gupta et al 2004, 2005, 2006).

Albizia saponins A, B and C (50 mg/kg) isolated from the stem bark have been shown to reduce the weight of the testis, epididymides, seminal vesicle and ventral prostate of male rats significantly (Gupta et al 2005). A significant reduction in sperm concentration was also noted and albizia reduced fertility by 100% after 60 days. A follow-up study administered oral doses of methanolic bark extract (100 mg/day) for 60 days (Gupta et al 2006). Testis, epididymides, seminal vesicle and ventral prostate weights along with sperm motility and density were all significantly decreased compared to controls, also resulting in a 100% drop in male fertility. The methanolic extract of albizia pods (50, 100 and 200 mg/kg) was also shown to decrease fertility significantly and arrest spermatogenesis in rats after 60 days (Gupta et al 2004).

### OTHER ACTIONS

Other actions seen in vitro and in vivo include antioxidant and antifungal actions, antispasmodic effect on smooth muscle, positive inotropy and an immunostimulant effect (Barua et al 2000, Bone 2001, Kasture et al 2000, Resmi et al 2006, Yadav et al 2011). Cholesterol-lowering activity has been demonstrated in vivo (Tripathi et al 1979).

Lebbeckalysin, a haemolytic protein isolated from albizia seeds, inhibited proliferation of breast cancer cells and hepatic cancer cells, and inhibited the growth of *Escherichia coli* and the fungus *Rhizoctonia solani* in vitro. However, it was also found to reduce the viability of murine splenocytes (Lam & Ng 2011).

### CLINICAL USE

Albizia has not been significantly investigated under clinical trial conditions, so evidence is mainly derived from traditional, in vitro and animal studies, providing preliminary support for its use.

### Allergy and asthma

Albizia is mainly used to treat allergic rhinitis, urticaria and asthma in clinical practice. In vitro and in vivo evidence of mast cell stabilisation provides a theoretical basis for its use in allergic conditions; however few clinical studies exist to confirm its significance. In a single-blind study 81 participants with asthma were given 50 mL of albizia stem bark decoction three times daily for 6 weeks. At 6 weeks, there was a significant increase in lung function and a decrease in total leucocyte count, eosinophil count and erythrocyte sedimentation rate. Of the 50 participants who completed the trial, 56% reported

symptom reduction of >75%, 38% reported symptom reduction of 50–75% and 6% reported symptom reduction of less than 50% (Kumar et al 2010).

### OTHER USES

Traditionally, a juice made from the leaves has been used internally to treat night blindness. The bark and seeds have been used to relieve diarrhoea and dysentery and treat haemorrhoids, most likely because of their astringent activity. The flowers have been used as an emollient to soothe eruptions, swellings, boils and carbuncles. In Ayurvedic medicine, albizia is used to treat bronchitis, asthma, allergy and inflammation.

### DOSAGE RANGE

#### Australian manufacturer recommendations

- Liquid extract (1:2): 3.5–8.5 mL/day or 25–60 mL/week.
- Dried herb: 3–6 g/day.
- Based on clinical trials:
  - Asthma: 50 mL of albizia stem bark decoction three times daily for 6 weeks (Kumar et al 2010).

### TOXICITY

This is unknown; however, research with the methanolic fraction of albizia extract has identified a median lethal dose of 150 mg/kg (Kasture et al 2000).

### ADVERSE REACTIONS

Insufficient reliable information available.

### SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

### Barbiturates

Additive effects are theoretically possible, as potentiation of pentobarbitone-induced sleep has been observed in vivo — use with caution.

### Antihistamines and mast cell-stabilising drugs

Additive effects are theoretically possible because both in vitro and in vivo tests have identified significant mast cell-stabilisation activity similar to that of cromoglycate — potentially beneficial interaction.

### Tricyclic and selective serotonin reuptake inhibitor antidepressant drugs

Increased risk of serotonin syndrome is theoretically possible, as albizia increases serotonin levels, according to in vivo studies — observe patient.

### ❓ CONTRAINDICATIONS AND PRECAUTIONS

Significant reductions in male fertility have been reported in tests using animal models; however, it is not known whether the effects also occur in humans. Until further research is conducted, caution is advised.

### 👤 PREGNANCY USE

Insufficient reliable information available. Based on animal studies indicating a significant effect on male fertility, males with low sperm counts or poor sperm motility should avoid this herb if attempting to father a child.

### Practice points/Patient counselling

- Albizia is a traditional Ayurvedic herb used to treat allergies, asthma, eczema and inflammation.
- Preliminary research has shown that it has significant mast cell-stabilisation activity comparable to cromoglycate, and has also identified memory enhancement activity and possible anticonvulsant effects.
- Preliminary human research suggests a possible role in asthma; however more research is required to clarify its role.
- Overall, little clinical evidence is available; therefore, much information is speculative and based on in vitro and animal research.

### ❗ PATIENTS' FAQs

#### What will this herb do for me?

Albizia is a traditional Ayurvedic medicine used to reduce allergic conditions, such as allergic rhinitis and urticaria. It is also used for atopic conditions, such as eczema and asthma, when indicated. Controlled trials have not been conducted, so it is uncertain whether it is effective.

#### When will it start to work?

This is uncertain because insufficient research data are available.

#### Are there any safety issues?

This is uncertain because insufficient research data are available. It is advised that people with asthma be monitored by a healthcare professional. Males with low sperm counts or poor sperm motility should avoid this herb if attempting to father a child.

# Aloe vera

**HISTORICAL NOTE** *Aloe vera* has been used since ancient times as a medicinal plant. In fact, evidence of use has been found on a Mesopotamian clay tablet dating back to 2100 BC (Atherton 1998). It has been used as a topical treatment for wounds, burns and other skin conditions and internally as a general tonic, anti-inflammatory agent, carminative, laxative, aphrodisiac and anthelmintic by the ancient Romans, Greeks, Arabs, Indians and Spaniards. According to legend, Alexander the Great captured an island in the Indian Ocean in order to access the *Aloe vera* for his wounded army. Today aloe is used to soothe skin complaints and treat burns, and is a common ingredient in many cosmetic products.

## OTHER NAMES

Aloes, Barbados aloe, Curacao aloe

## BOTANICAL NAME/FAMILY

*Aloe vera* (L.)/*Aloe barbadensis* (Mill.) (family Aloaceae)

## PLANT PARTS USED

The plant leaves are used, from which several different products are made; namely the exudate, gel, extract and juice. The exudate ('aloes' in older pharmacy texts) is a thick residue, yellow in colour and bitter in taste that comes from the latex that oozes out when the leaf is cut. The 'gel' refers to the clear gel or mucilage produced by the inner parenchymal cells in the central part of the leaf. Diluted aloe gel is commonly known as 'aloe vera extract' or 'aloe juice'.

## CHEMICAL COMPONENTS

*Aloe vera* extract, or diluted aloe gel, is made of mostly water (99%) and mono- and polysaccharides, the most important of which are the monosaccharide mannose-6-phosphate and the polysaccharide gluco-mannans, which are long-chain sugars containing glucose and mannose. Gluco-mannan has been named acemannan and is marketed as Carrisyn. A glycoprotein with antiallergic properties has also been isolated, and has been named alprogen. Recently, C-glucosyl chromone, an anti-inflammatory compound, has also been identified.

Aloe gel also contains lignans, saponins, salicylic acid, sterols and triterpenoids, vitamins A, C, E, B<sub>12</sub>, thiamine, niacin and folic acid, and the minerals sodium, calcium, potassium, manganese, magnesium, copper, chromium, zinc and iron (Shelton 1991, Yamaguchi et al 1993).

The fresh gel contains glutathione peroxidase, isozymes of superoxide dismutase and the proteolytic enzyme carboxypeptidase (Klein & Penneys 1988, Sabeh et al 1993). In vitro bioassays identified three malic acid-acylated carbohydrates from the gel, veracylglycan A, B and C, and determined that veracylglycan B exhibited potent anti-inflammatory and antiproliferative effects; veracylglycan C exhibited significant cell proliferative and anti-inflammatory

activities; and the third carbohydrate, veracylglycan A, was highly unstable and provided no biological effects. Of interest is that veracylglycan B and C proved to be highly competitive in their effects on cell proliferation (Esua & Rauwald 2006).

Ultimately, the types and levels of components present in aloe gel vary according to geographic origin, variety and processing method.

There are significant constituent differences between aloe vera gel, juice and total leaf extracts. The exudate (latex layer) contains the pharmacologically active anthraquinone glycosides aloin, aloemodin, barbaloin, emodin and aloetic acid (Choi & Chung 2003, Rodriguez-Fragoso et al 2008), while aloe vera gel contains no anthraquinones (Vogler & Ernst 1999). It must be noted that, due to these central differences, evidence for a particular preparation of aloe may not necessarily be translatable across all types of aloe vera preparations.

## MAIN ACTIONS

The active ingredients, whether acting alone or in concert, include glycoproteins, anthraquinones, polysaccharides, and low-molecular-weight species such as beta-sitosterol (Choi & Chung 2003).

### Assists in wound healing

Wound healing is associated with various mechanisms and constituents. Thromboxane inhibits wound healing and aloe has been shown to inhibit thromboxane in vitro (Zachary et al 1987). Enzymes in aloe have also been shown to break down damaged tissue, which can then be removed by phagocytosis (Bunyaphatsara et al 1996). A glycoprotein fraction was found to increase proliferation of human keratinocytes and increase the expression of receptors for epidermal growth factor and fibronectin in vitro (Choi et al 2001). The same research team then demonstrated that this glycoprotein enhanced wound healing by increasing cell proliferation in vivo. Beta-sitosterol appears to improve wound healing by stimulating angiogenesis and neovascularisation in vivo (Moon et al 1999). Aloe polysaccharides have been shown to ameliorate ultraviolet (UV)-induced immunosuppression (Strickland et al 1994).

In vitro and in vivo research generally shows that aloe vera application has beneficial effects in wound healing caused by thermal burns or frostbite. However few studies report on the levels of active constituents present in the test application or even the treatment regimen, making firm conclusions difficult. Not surprisingly, a 2012 Cochrane Review concluded that there is currently insufficient clinical trial evidence available to support the use of aloe vera topical agents or impregnated dressings as a treatment for acute and chronic wounds (Dat et al 2012). In future, better reporting of aloe vera preparations tested, their levels of active constituents and administration regimens, is necessary to better understand its effects.

### Tests in animal models

Several animal studies support the application of aloe gel to skin damaged by frostbite as a means of maintaining circulation and reducing the vasoconstrictive effects of thromboxane in the affected dermis (Heggens et al 1987, Klein & Penneys 1988, McCauley et al 1990, Miller & Koltai 1995). In combination with pentoxifylline, it will act synergistically to further increase tissue survival (Miller & Koltai 1995).

A study to test the effectiveness of topical application versus oral administration in rats with full-thickness wounds showed topical use of aloe gel to be slightly more effective than internal use. The collagen content in granulation tissue was measured to be 89% in the topical group compared with 83% in the oral group (Chithra et al 1998). Oral administration of lyophilised *A. vera* powder was also found to increase wound contraction in rats with acute radiation-delayed wound healing, which was associated with increased transforming growth factor- $\beta_1$  (TGF- $\beta_1$ ) and basic fibroblast growth factor (Atiba et al 2011).

Other studies have found that aloe gel not only increases collagen content, but also changes collagen composition, in addition to increasing collagen cross-linking, which in turn increases the breaking strength of scar tissue, making the seal stronger (Chithra et al 1998, Heggens et al 1996). Conversely, a study using a porcine model of partial-thickness burns found that the application of aloe vera did not improve the re-epithelialisation of the wound, the scar size or visual appearance of the scar compared to control (no intervention) (Cuttle et al 2008). The study used leaves of a mature, well-established plant which were skinned and enough of the inner pulp and gel was collected and applied directly to the wound to cover it.

Full-thickness hot-plate burns (3% total surface area) in test animals healed more quickly with the application of aloe gel compared to silver sulfadiazine (SSD) or salicylic acid cream (aspirin) (Rodriguez-Bigas et al 1988). Guinea pigs treated with aloe recovered in 30 days as compared to 50 days for control animals (dressing only) and wound bacterial counts were effectively decreased. *A. vera* was also found to promote healing and decrease inflammation

in second-degree burns in vivo (Somboonwong et al 2000). A significant reduction in vasodilation and postcapillary venular permeability was recorded on day 7 in the aloe group. At day 14 arteriolar diameter had returned to normal and the size of the wound was greatly reduced as compared to controls. More recently, a study found that treatment with aloe vera powdered gel (0.5%) 24 hours after a burn injury induced by hot water and then applied regularly over the next 25 days resulted in a significantly smaller wound size compared with SSD (Khorasani et al 2009). Additionally, a histological comparison showed aloe to increase re-epithelialisation in burn wounds significantly as compared with other cream-treated wounds which included SSD.

Aloe gel prevented delayed hypersensitivity of UV-irritated skin as well as contact hypersensitivity in animal models with allergic reactions (Strickland et al 1994). Acemannan gel (beta-(1,4)-acetylated mannan) has demonstrably improved radiation burns in mice. Best results were obtained when the gel was applied during the first week after injury (Roberts & Travis 1995).

### Use with pharmaceutical agents

Several topical pharmaceutical antimicrobial agents, such as SSD, inhibit wound contraction, thereby slowing the rate of wound healing. An experimental model was used to investigate whether co-administration of aloe could reverse this effect and improve the wound-healing rate (Muller et al 2003). Full-thickness excised wounds were treated with placebo (aqueous cream or saline), SSD cream 0.5%, 1% or 1% with *A. vera* three times daily for 14 days, then observed until healed. *A. vera* was found to reverse the delayed wound healing produced by SSD, resulting in the shortest wound half-life and healing time.

*A. vera* (100 and 300 mg/kg daily for 4 days) blocked the ability of hydrocortisone acetate to suppress wound healing by up to 100% (Davis et al 1994a). Growth factors in *A. vera* were thought to mask sterols and certain amino acids that prevent wound healing. Another study identified the sugar mannose-6-phosphate to be one of the chief constituents responsible for wound healing (Davis et al 1994b).

### Antioxidant

Studies have found that several compounds present in aloe gel protect tissues against oxidative damage caused by free radicals; however the clinical impact of this is yet to be determined (Singh et al 2000, 't Hart et al 1990, Wu et al 2006, Yagi et al 2002, Zhang et al 2006). This is achieved by direct antioxidant activity and indirect activity through stimulation of endogenous antioxidant systems. Two aloe dihydroisocoumarins have been identified and have demonstrated free radical scavenging properties (Zhang et al 2006, 2008).

Treatment with aloe gel extract decreased lipid peroxidation and hydroperoxides in diabetic rats to

near-normal levels (Rajasekaran et al 2005). The extract also significantly increased superoxide dismutase, catalase, glutathione peroxidase and glutathione-S-transferase in the liver and kidney. In another study, data obtained 3, 7 and 10 days after exposure to radiation showed that aloe gel significantly reduced oxidative damage in the liver, lungs and kidney tissues of irradiated rats (Saada et al 2003). The oral administration of aloe vera to rats prior to 8 Gy gamma radiation exposure decreased serum lipid peroxidation and increased the reduced glutathione level and vitamin C levels (Saini & Saini 2011). This correlated with higher percentage survival after 30 days compared to untreated controls (93.3% vs 20% respectively).

A study by Jain et al (2010) identified that *A. vera* 30% gel increased thiobarbituric acid reactive substance, superoxide dismutase and catalase levels back to baseline levels in a model of induced diabetes in rats.

Three-year-old aloe plants appear to have the highest amounts of flavonoids and polysaccharides and hence the best free radical scavenging capacity, as compared to 2- and 4-year-old plants (Hu et al 2003). Interestingly, the 3-year-old plant demonstrated antioxidant activity of 72.19%, compared to alpha-tocopherol at 65.20%.

### Immunostimulant

It has been suggested that aloe may have immunostimulating capabilities. Much of the available research has been performed on mice or in vitro and aloe shows antiviral, antitumour and non-specific immunostimulant activity. An experiment in 1980 demonstrated that mice given aloe extract 2 days before exposure to pathogens were protected against a variety of fungi and bacteria (Brossat et al 1981).

Later, the isolated compound acemannan (beta-(1,4)-acetylated mannan) was shown to increase the response of lymphocytes to antigens in vitro (Womble & Helderman 1988). In mice, acemannan stimulated cytokines, bringing about an immune attack on implanted sarcoma cells, leading to necrosis and regression of cancer cells (Peng et al 1991). A later trial investigated the effects of acemannan on mouse macrophages (Zhang & Tizard 1996). Acemannan stimulated macrophage cytokine production (interleukin-6 (IL-6) and tumour necrosis factor-alpha (TNF-alpha), nitric oxide release, surface molecule expression and cellular morphological changes. Similarly, a polysaccharide fraction isolated from *A. vera* promoted human keratinocytes to secrete TGF-alpha, TGF-beta<sub>1</sub>, IL-1beta, IL-6, IL-8 and TNF, and inhibited the release of nitric oxide as compared to control (Chen et al 2005). The immune-enhancing effects of acemannan may be due in part to the compound's ability to promote differentiation of immature dendritic cells (Lee et al 2001). These cells are crucial for the initiation of primary immune responses.

Multiple studies have highlighted the diverse immunomodulatory activities of aloe polysaccharides.

Some studies have identified that immunomodulatory activity varies with the size of the polysaccharide entity. It appears that aloe polysaccharides that are of smaller molecular weight (specifically between 5 and 400 kDa) have the greatest immunological effects, possibly because they are better absorbed than larger-molecular-weight entities (Im et al 2005).

Three purified polysaccharide fractions (PAC-I, PAC-II and PAC-III) from *A. vera* stimulated peritoneal macrophages, and splenic T and B cells, and increased the ability of these cells to secrete TNF-alpha, IL-1beta, interferon-gamma, IL-2 and IL-6 (Leung et al 2004). The compound with the highest mannose content, and therefore the highest molecular weight (PAC-I), demonstrated the most potential. This finding was again repeated by Liu et al (2006), whereby PAC-I exhibited potent stimulation of murine macrophages and produced tumoricidal properties of activated macrophages in vitro, thus providing evidence in support of its antitumour properties.

A 99% pure carbohydrate compound (purified acemannan) isolated from aloe demonstrated potent haematopoietic and haematological activity in myelosuppressed mice (Talmadge et al 2004).

Specific manufacturing methods can be applied to enhance the extracts. For example, 1 g of extract obtained from leaves subjected to cold and dark treatment contained 400 mg of neutral polysaccharide compared with 30 mg in leaves not specially treated (Shida et al 1985).

### Clinical note — Wound-healing models

Acute wound healing occurs in four stages that tend to overlap: haemostasis, inflammation, proliferation and remodelling. Underlying metabolic disturbances and/or disease may disrupt the regenerative process, causing delayed healing. Much investigation is conducted with in vitro assays based on cell culture models of the various phases of healing, which provide information about possible mechanisms of action. Experimental models using animals are undertaken to determine the reduction of wound size (usually in terms of area) and hence the rate of healing. Histological examination of granulation and epidermal tissues provides a concurrent analysis at the molecular level. Human models of wound healing provide an opportunity to observe a variety of healing disorders that are less predictable than their cell or animal-based counterparts. *Aloe vera* is one of the very few traditional wound-healing herbal medicines that has been subjected to a variety of cell culture-based, animal and human-based studies (Krishnan 2006).

### Anti-inflammatory

A number of in vitro and in vivo studies confirm the anti-inflammatory activity of *A. vera*.

The gel reduces oxidation of arachidonic acid, thereby reducing prostaglandin (PG) synthesis and inflammation (Davis et al 1987). It inhibits the production of PGE<sub>2</sub> by 30% and IL-8 by 20%, but has no effect on thromboxane B<sub>2</sub> production in vitro (Langmead et al 2004). Following burn injury in vivo, *A. vera* was also found to inhibit inflammation by reducing leucocyte adhesion and decreasing the proinflammatory cytokines TNF-alpha and IL-6 (Duansak et al 2003). Similarly, significant reductions in proinflammatory cytokines IL-1beta, IL-6 and TNF-alpha have been shown in in vitro models of monocyte-derived macrophages (Budai et al 2013) and human corneal cells (Woźniak and Paduch 2012).

An in vivo study of induced ulcerative colitis in rats found that dietary supplementation with aloe components aloin, aloesin and aloe gel resulted in significantly reduced plasma leukotriene B<sub>4</sub> and TNF-alpha concentrations, as well as colonic mucosal TNF-alpha and IL-1beta concentrations compared to controls (Park et al 2011). Similarly, IL-1beta, IL-6 and TNF-alpha were reduced following aloe vera treatment in a murine model of sepsis, which correlated with reduced bacterial count and increased survival (Yun et al 2009).

One study conducted on rats with croton oil-induced oedema reported a 47% reduction in swelling after the application of topical aloe gel (Davis et al 1989). Another study found aloe gel reduced vascularity and swelling by 50% in the inflamed synovial pouch in rats, along with a 48% reduction in the number of mast cells in the synovial fluid within the pouch. When aloe gel was applied topically there was also an increase in fibroblast cell numbers (Davis et al 1992). C-glucosyl chromone, isolated from aloe gel extracts, is chiefly responsible for the anti-inflammatory effect, with activity comparable to hydrocortisone in experimental models (Hutter et al 1996). A study of streptozotocin-induced diabetic mice further confirmed the anti-inflammatory activity of *A. vera* and identified the isolated constituent gibberellin as also effective (Davis & Maro 1989). Both compounds inhibited inflammation in a dose-dependent manner. A recent in vitro assessment using human immune cells displayed aloe's potential to reduce bacteria-induced proinflammatory cytokine production, specifically TNF-alpha and IL-1-beta, by peripheral blood leucocytes stimulated with *Shigella flexneri* or lipopolysaccharide (Habeeb et al 2007).

A number of studies have identified a possible role for aloe vera in the treatment of oral lichen planus (OLP), a chronic inflammation of the oral mucosal membranes. However, a 2011 Cochrane Review concluded that there was only weak evidence to support the use of *A. vera* to reduce pain and clinical signs of OLP compared to placebo (Thongprasom et al 2011).

### Laxative

The aloe latex contains anthraquinones, which have a stimulant laxative activity. Studies in rats have

shown that aloe latex increases intestinal water content, stimulates mucus secretion and induces intestinal peristalsis (Ishii et al 1994). However, aloe as a laxative is more irritating than other herbs (Reynolds & Dweck 1999) and long-term use can cause an electrolyte imbalance through depletion of potassium salts. Alternatives are recommended if long-term treatment is required.

### Antiulcer

The antiulcer activity of *A. vera* has been proposed to be due to anti-inflammatory, cytoprotective, healing and mucus stimulatory effects. According to an in vivo study, *A. vera* promotes gastric ulcer healing (Eamlannam et al 2006). In contrast to these results, in another study a stabilised fresh aloe gel preparation prolonged the effect of histamine-stimulated acid secretion but inhibited pepsin (Suvitayavat et al 2004).

### Hypoglycaemic

Glucosannan slows carbohydrate absorption and slows the postprandial insulin response by up to 50% (McCarty 2002).

*A. vera* leaf gel has been investigated as a possible hepatoprotective and kidney-protective agent in diabetes type 2 using animal models. In one study, the leaf gel and glibenclamide both decreased degenerative kidney changes, serum urea levels and creatinine levels, but only aloe further reduced kidney lipid peroxidation (Bolkent et al 2004). Can et al (2004) tested aloe pulp, aloe gel extract and glibenclamide, finding that all treatments decreased liver tissue damage compared to control animals. Aloe gel extract also increased glutathione levels and decreased non-enzymatic glycosylation, lipid peroxidation, serum alkaline phosphatase and alanine transaminase. In a mouse model of type 2 diabetes mellitus, administration of aloe gel to diabetic mice over 8 weeks resulted in lowered blood glucose levels, which correlated with a reduced insulin resistance (Kim et al 2009).

### Chemotherapeutic

Recent preclinical research has identified that aloemodin (an anthraquinone compound) present in the leaves of *A. vera* shows promising anticancer effects in human gastric carcinoma cell lines AGS and NCI-N87. Aloe-emodin induced cell death in a dose-dependent and time-dependent manner and caused the release of apoptosis-inducing factor and cytochrome c from mitochondria, followed by the activation of caspase-3, leading to nuclear shrinkage and apoptosis (AGS was more sensitive than NCI-N87 cells). In addition, casein kinase II activity was suppressed (time-dependent) and was accompanied by a reduced phosphorylation of Bid, a downstream substrate of casein kinase II and a proapoptotic molecule (Chen et al 2007).

Another study investigated the anticancer effect of aloe-emodin in T24 human bladder cancer cells and found that it induced apoptosis in T24 cells

mediated through the activation of p53, p21, Fas/APO-1, Bax and caspase-3 (Lin et al 2006).

In mouse B16 melanoma and human A375 melanoma cell lines, aloe-emodin reduced cell viability in a dose-dependent manner through mechanisms of terminal differentiation and caspase-dependent apoptosis respectively (Radovic et al 2012).

### Antimicrobial

*A. vera* is active against a wide variety of bacteria in vitro, such as *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Streptococcus pyogenes*, *Staphylococcus aureus* and *Escherichia coli* (Heck et al 1981, Shelton 1991). More recent research indicates antimicrobial activity against *Shigella flexneri*, methicillin-resistant *Staphylococcus aureus*, *Enterobacter cloacae* and *Enterococcus bovis* (Habeeb et al 2007).

### Antiviral

In vitro studies suggest that *Aloe vera* has antiviral activity due to its interference with DNA synthesis (Saoo et al 1996). The polysaccharide fractions of aloe gel inhibit the binding of benzopyrene to primary rat hepatocytes and thus prevent the formation of potentially cancer-initiating benzopyrene-DNA adducts in vitro. This was later confirmed by in vivo studies (Kim & Lee 1997). Moreover, in vitro experiments have shown the anthraquinones in aloe to be virucidal against herpes simplex virus types 1 and 2, vaccinia virus, parainfluenza virus and vesicular stomatitis virus (Anderson 2003).

Investigation with the acemannan component has identified antiviral activity, particularly against feline AIDS, HIV type 1, influenza virus, measles virus and herpes simplex (Kahlon et al 1991a, 1991b, Sydiskis et al 1991).

### Antifungal

An in vivo study using mice showed that the administration of processed *A. vera* gel reduced clearance of *Candida albicans* in both spleen and kidneys in a dose-dependent manner (Im et al 2010).

## CLINICAL USE

Although *A. vera* products are used for many indications, the chief use is treating skin conditions. Various test preparations have been used, including fresh aloe vera mucilage, aloe vera gel, powdered aloe vera and aloe vera used with various gauzes. Commercial aloe vera preparations vary considerably in their quality and polysaccharide content, such as acemannan, which is considered an important functional component. Ideally, aloe vera preparations should have adequate amounts of the polysaccharide acemannan (at least 10% w/w) (Bozzi et al 2007). Unfortunately, researchers do not appear to test their preparations for adequate levels of polysaccharides or report on the polysaccharide content of their aloe vera preparation, which makes it difficult to interpret study results or make meaningful comparisons.

## Skin conditions

Aloe is used in the treatment of wounds, burns, radiation burns, ulcers, frostbite, psoriasis and genital herpes, and is the only traditional wound-healing herbal medicine which has been subjected to a variety of cell culture-based, animal and human-based studies (Krishnan 2006). The healing properties may be attributed to antimicrobial, immunestimulating, anti-inflammatory and antithromboxane activities. Allantoin has also been shown to stimulate epithelialisation, and acemannan has been shown to stimulate macrophage production of IL-1 and TNF, which are associated with wound healing (Liptak 1997).

Most human studies have found that topical application of aloe vera gel increases wound-healing rate and effectively reduces microbial counts; however, there are some negative studies, most likely related to the fact that the composition of aloe vera gel varies, even within the same species. Chemical composition depends on source, climate, region and the processing method used (Choi & Chung 2003).

Dry-coated aloe vera gloves were tested by 30 women suffering from dry, cracked hands, with or without contact dermatitis due to occupational exposure, in an open contralateral comparison study (West & Zhu 2003). Women wore a glove on one hand for 8 hours daily for 30 days followed by a rest period for 30 days and then 10 more days of treatment. Results indicated that the aloe vera glove significantly reduced dry skin, irritation, wrinkling, dermatitis and redness and improved skin integrity. It would be interesting to see this study repeated using a standard non-aloe-fortified glove on the opposing hand.

The effects of aloe gel applied to skin following dermabrasion in humans are more controversial, with some patients experiencing severe adverse reactions, including burning sensations and dermatitis (Hunter & Frumkin 1991). One study found that topical aloe vera gel actually slowed healing after caesarean delivery (Schmidt & Greenspoon 1991).

## Burns

A systematic review of the efficacy of *A. vera* for healing of burns considered four controlled clinical trials involving 371 patients. Meta-analysis concluded that topical treatment with *A. vera* decreased healing time and was specifically more effective for first- and second-degree burns rather than third-degree burns. In particular, based on a meta-analysis using duration of wound healing as an outcome measure, the summary weighted-mean difference in healing time of the aloe vera group was 8.79 days shorter than those in the control group ( $P = 0.006$ ). It was noted that, due to variations in the aloe preparations and outcome measures used in the studies, more specific conclusions cannot be drawn (Maenthalsong et al 2007). The types of aloe vera preparations studied include fresh aloe vera mucilage, gauze impregnated with 85% gel, aloe vera cream and gauze with 1% aloe vera powder. Importantly, none of the studies

reported on the amount of key active constituents in their test preparations.

### Comparisons to silver sulfadiazine (SSD)

Several studies have compared aloe vera to SSD. The most recent study found that treatment with aloe vera cream twice daily in patients with second-degree burns on two different body sites ( $n = 30$ ) resulted in faster rates of re-epithelialisation ( $15.90 \pm 2.00$  vs  $18.73 \pm 2.65$  days) compared to SSD and were considered fully healed faster than SSD (16 days vs 19 days) (Khorasani et al 2009). An older study comparing SSD with *A. vera* mucilage or a combination of both found that the success rate in the aloe vera group and the SSD group was 95% and 83%, respectively in the treatment of first- or second-degree burns ( $n = 38$ ) (Thamlikitkul 1991).

### Psoriasis

A 2010 double-blind, randomised trial found that topically applied *A. vera* significantly improved psoriasis area and severity index [PASI] scores compared to 0.1% triamcinolone acetonide cream (Choonhakarn et al 2010). After 8 weeks of treatment, *A. vera* treatment resulted in a mean reduction in PASI of  $7.7 \pm 2.3$  compared to triamcinolone acetonide, which reduced PASI by  $6.6 \pm 2.1$  (95% confidence interval: 1.1 (-2.13, -0.16),  $P = 0.0237$ ).

A double-blind placebo-controlled study found topical aloe vera extract 0.5% in a hydrophilic cream to be beneficial in the treatment of psoriasis. Sixty patients aged 18–50 years with slight to moderate chronic psoriasis and PASI scores between 4.8 and 16.7 (mean 9.3) participated in the study, which was scheduled for 16 weeks with 12 months of follow-up. Patients were examined weekly and those showing a progressive reduction of lesions, desquamation followed by decreased erythema, infiltration and lowered PASI score were considered healed. By the end of the study, the *A. vera* extract cream had cured 83.3% of patients compared with the placebo cure rate of 6.6% ( $P < 0.001$ ). Psoriatic plaques decreased in 82.8% of patients versus only 7.7% in the placebo group ( $P < 0.001$ ). PASI scores decreased to a mean of 2.2 (Syed et al 1996a). In contrast, a randomised, double-blind, placebo-controlled trial found no significant benefits with a commercial aloe vera gel in 41 patients with stable plaque psoriasis (Paulsen et al 2005). Following a 2-week washout period patients applied either the aloe gel or the placebo twice daily for 1 month. Redness and desquamation decreased by 72.5% in the active treatment group as compared to 82.5% in the placebo group. It should be pointed out that 82.5% is an extremely high placebo responder rate. Fifty-five per cent of patients reported local side effects, mainly drying of the skin on test areas.

### Genital herpes

Two clinical studies have investigated the effects of *Aloe vera* 0.5% topical preparations in genital herpes, producing good results.

A double-blind, placebo-controlled study has demonstrated that *A. vera* extract 0.5% in a hydrophilic cream is more efficacious than placebo in the treatment of initial episodes of genital herpes in men ( $n = 60$ , aged 18–40 years). Each patient was provided with a 40 g tube containing placebo or active preparation, with instructions on self-application of the trial medication to their lesions three times daily for 5 consecutive days (maximum 15 topical applications per week). The treatment was well tolerated by all patients (Syed et al 1997).

The other study involving 120 subjects used a preparation containing 0.5% of whole aloe leaf extract in a hydrophilic castor and mineral oil cream base, which was applied three times daily for 5 days per week for 2 weeks. Treatment resulted in a shorter mean duration of healing compared with placebo. Aloe cream also increased the overall percentage of healed patients and there were no significant adverse reactions reported (Syed et al 1996b).

Another study involving 18 outpatients with moderate to deep second-degree burns ranging from 2 to 12% of total body surface area showed that a commercial aloe vera ointment was as effective as SSD in regard to protection against bacterial colonisation and healing time. More specifically, the mean healing time with aloe vera treatment was 13 days compared with 16.15 days for SSD (Heck et al 1981).

Results are less encouraging for sunburn protection and healing. A randomised double-blind trial in 20 healthy volunteers evaluated the effect of aloe vera cream for both prevention and treatment of sunburn (Puvabanditsin & Vongtongri 2005). The cream (70% aloe) was applied 30 minutes before, immediately after, or both before and after UV irradiation. The cream was then continually applied daily for 3 weeks. The results showed that the aloe vera cream did not protect against sunburn and was not an effective treatment.

### Frostbite

In combination with other treatments, topical *A. vera* significantly enhances healing and has a beneficial effect in frostbite. One clinical study compared the effects of topical aloe vera cream in combination with standard treatment, such as rapidly rewarming the affected areas, analgesics, antibiotics and debridement ( $n = 56$ ) with another group of 98 patients who did not receive *A. vera* treatment. Of those receiving *A. vera* in addition to usual treatment, 67% healed without tissue loss compared with 32.7% in the control group. Additionally, 7.1% of the total group of 56 required amputation compared with 32.7% in the control group. Although encouraging, this study is difficult to interpret because the groups were not well matched and combination therapies differed (Hegggers et al 1987).

### Radiation-induced dermatitis

There have been several studies which have focused on the effects of aloe on radiation-induced dermatitis. A 2005 review concluded that aloe gel was as

effective as mild steroid creams, such as 1% hydrocortisone, in reducing the severity of radiation burn, without the side effects associated with steroid creams (Maddocks-Jennings et al 2005).

In contrast, another review concluded that aloe was ineffective for the prevention or reduction of side effects to radiation therapy in cancer patients (Richardson et al 2005). That review analysed one past review, five published randomised controlled trials (RCTs) and two unpublished RCTs. It is important to note that various preparations, such as creams, juices, gels and fresh aloe, had been tested, which makes it difficult to assess the evidence.

More recently, a study with good methodology was conducted, involving 60 patients with chiefly breast, pelvic or head or neck cancers. Volunteers were asked to apply an aloe vera cream to half the irradiated area twice daily, continuing for 2 weeks after radiation treatment ended (Haddad et al 2013). Significant benefits were not apparent until the end of the third week of radiotherapy, when the mean grade of dermatitis was lower on the aloe-treated half, with a statistically significant difference for weeks 4 ( $P < 0.000$ ), 5 ( $P < 0.000$ ) and 6 ( $P = 0.006$ ) of radiotherapy, and weeks 2 ( $P = 0.003$ ) and 4 ( $P = 0.002$ ) afterwards. In particular, the effect was more evident in patients undergoing radiotherapy with larger treatment fields and higher doses of radiation. The aloe vera was in a lotion base consisting of lanolin oil, glyceryl stearate, diluted collagen, tocopherol, allantoin and paraben; however the concentration of aloe vera was not stated.

### Leg ulcers

A number of case reports tell of a positive effect on leg ulcers with topical use of aloe gel, including cases that did not respond to standard medical interventions (Zawahry et al 1973). Application of water-based aloe gel saline soaks, broad-spectrum antibiotics and antifungals allowed a wound, caused by necrotising fasciitis, to heal in 45 days in a 72-year-old woman. Aloe gel and saline-soaked sponges were also used to treat two large seroma cavities caused by deep-vein thrombosis in a 48-year-old man (Ardire 1997).

A small study of 6 patients with chronic leg ulcers found that the ingestion of 60 mL aloe juice daily in addition to applying aloe gel directly to the ulcer and surrounding area resulted in less exudate, odour and seepage through the bandaging (Atherton 1998).

### Acne

A double-blind RCT ( $n = 60$ ) found that the combination of *A. vera* gel and the topical retinoid tretinoin leaf gel significantly reduced the presence of inflammatory lesions after 8 weeks' treatment by 78.4% compared to a reduction of 41.1% in patients receiving tretinoin alone (Hajheydari et al 2014). Similarly, comedone scores were significantly reduced in the tretinoin and *A. vera* group compared to tretinoin alone, with respective reductions of 88.2% compared to 60.1%.

## Diabetes

### Glycaemic control

Three systemic reviews of herbal medicines for glycaemic control in diabetes found that *A. vera* can lower blood glucose levels in diabetic patients (Grover et al 2002, Vogler & Ernst 1999, Yeh et al 2003). A recent double-blind RCT which investigated the effects of an orally ingested aloe vera gel complex on 136 patients with prediabetes or early diabetes determined that the aloe complex reduced body weight, body fat mass and insulin resistance after 8 weeks (Choi et al 2013). The aloe vera capsule contained 147 mg/cap of aloe vera and aloesin powder (95% aloesin) 3 mg/cap, yeast chromone 125 mg/cap and excipients (soy bean oil, yellow beeswax and lecithin) 425 mg/cap taken at a dose of two capsules after breakfast and two after dinner.

In another trial aloe juice consisting of 80% gel or placebo was given in a trial of 40 patients who were recently diagnosed with type 1 diabetes in a dose of 1 tablespoon twice daily. From day 14 the blood sugar levels in the aloe group began to fall significantly compared with the control group and continued to drop steadily during the study period ( $P < 0.01$ ). Blood triglyceride levels were also substantially reduced but cholesterol levels remained the same (Yongchaiyudha et al 1996). A single-blind, placebo-controlled trial found that glibenclamide when combined with oral aloe gel was more effective in reducing blood sugar levels than glibenclamide alone in 72 patients with type 2 diabetes. Patients took 5 mg of glibenclamide twice daily and 1 tablespoon aloe gel. Fasting blood glucose levels dropped appreciably after just 2 weeks of treatment, and were still falling after 42 days (Bunyaphrapsara et al 1996).

## Cancer

There are some epidemiological studies suggesting that aloe may reduce the risk of certain cancers; however, further research is required to clarify its place in practice (Sakai et al 1989, Siegers et al 1993).

### Chemotherapy-induced oral and gastrointestinal mucositis

Earlier research reported that aloe gel may ameliorate chemotherapy-induced oral and gastrointestinal mucositis (Stargrove et al 2008); however, a 2011 Cochrane Review determined that, overall, there was currently insufficient evidence to support a role for aloe vera in the prevention of moderate to severe mucositis (Worthington et al 2011). Problems in determining the strength and quality of aloe vera preparations hamper interpretation of results.

### Oral submucous fibrosis

A double-blind, placebo-controlled, parallel-group RCT ( $n = 60$ ) identified that patients receiving adjuvant *Aloe vera* in addition to routine treatment (surgical or pharmacological) had significant improvement in most symptoms, including mouth

burning sensation and mouth opening, compared to treatment alone (Alam et al 2013). In patients receiving medicinal treatment, after 6 months those who had received *A. vera* returned a pain score of  $0.26 \pm 0.40$  on a 0–10 rating scale, whereas those without *A. vera* had a pain score of  $2.96 \pm 1.96$ .

## HIV

The acemannan component of *Aloe vera* has been used as adjunctive therapy to antiretroviral therapy in HIV infection. A preliminary clinical trial found that acemannan may enhance the activity of the anti-HIV drug AZT. A dose of 800 mg acemannan daily significantly increased circulating monocytes (macrophages) in 14 HIV patients. Aloe increased the number and activity of the monocytes (McDaniel et al 1990). Subsequently, a randomised, double-blind placebo-controlled study of 63 male subjects with advanced HIV, taking zidovudine and didanosine, investigated the effects of 400 mg of acemannan taken four times daily for 48 weeks. Results showed a decrease in CD4 cell numbers in the acemannan group compared with placebo (Montaner et al 1996).

## Gastrointestinal conditions

Oral *A. vera* is a popular treatment for a variety of gastrointestinal disorders. It has been shown to improve different parameters of gastrointestinal function in normal subjects, such as colonic bacterial activity, gastrointestinal pH, stool specific gravity and gastrointestinal motility (Bland 1986). Due to its anthraquinone content, the latex is used as a stimulant laxative.

Besides this indication, there is still a need for scientific validation to establish which gastrointestinal conditions are most receptive to treatment with aloe.

## Irritable bowel syndrome

There is conflicting evidence surrounding the use of *A. vera* in irritable bowel syndrome (IBS). An RCT ( $n = 58$ ) found that *A. vera* may be effective for patients with diarrhoea-predominant IBS (Davis et al 2006). In this study, both treatments were administered for 1 month with a follow-up period of 3 months. Within the first month, 35% of the patients receiving *A. vera* responded compared to 22% receiving placebo. Overall, diarrhoea-predominant IBS patients had a more statistically significant responder rate than placebo (43% vs 22%). Conversely, a multicentre, randomised, placebo-controlled, crossover study ( $n = 110$ ) found *A. vera* to be no better than placebo in improving any aspect of quality of life for IBS patients (Hutchings et al 2011).

## Ulcerative colitis

A double-blind, randomised, placebo-controlled trial evaluated the efficacy and safety of *A. vera* gel (100 mL twice daily for 4 weeks) in ulcerative colitis (Davis et al 2006). Aloe induced clinical remission in 30% of subjects compared to 7% for placebo and symptom improvement in 37%

compared to 7% for placebo. The Simple Clinical Colitis Activity Index and histological scores also decreased significantly for patients on the aloe treatment, but not for those receiving placebo.

## Practice points/Patient counselling

- Different parts of the *Aloe vera* plant are used therapeutically. The gel is used internally and topically and the latex is used internally. Differences in constituents between the different aloe extracts mean that evidence for a particular preparation may not be relevant for all aloe preparations.
- Some oral aloe preparations contain high sugar content to reduce bitterness, although this varies between brands. Be mindful of this if using aloe in diabetic patients.
- The gel may be beneficial in the treatment of skin conditions (wounds, burns, radiation burns, ulcers, frostbite, psoriasis and genital herpes). There is good scientific evidence for these indications.
- Traditionally, aloe latex is also used internally for gastrointestinal ulcers, dyspepsia and what is known today as IBS. Aloe is also used in conditions such as food allergies and disturbed bowel flora.
- Aloe may be a useful adjunct in the treatment of chronic poor immunity, HIV, cancer and chronic fatigue. There is preliminary scientific support for these indications.

## DOSAGE RANGE

- Aloe vera gel: fresh from a living plant or as stabilised juice 25 mL (4.5:1) up to four times daily.
  - Extracts standardised to acemannan: preparation containing up to 800 mg/day.
  - Topical application: gel, cream or ointment as needed.
  - 1.5–4.5 mL daily of 1:10 tincture of resin (latex).
- According to clinical trials:
- Type 1 diabetes: 1 tablespoon of aloe juice consisting of 80% gel taken twice daily.
  - Genital herpes: *Aloe vera* 0.5% topical applied three times a day.
- HIV and AZT use: 800 mg acemannan daily
- Pre-diabetes: 147 mg/capsule of aloe vera (in combination) taken as 2 capsules twice daily.
  - Psoriasis: aloe extract 0.5% cream applied three times daily.
  - Second degree burns: Aloe cream containing aloe vera gel powder 0.5% applied twice daily.
  - Ulcerative colitis: 100 mL twice daily for 4 weeks.

## ADVERSE REACTIONS

Although adverse reactions are rare, hypersensitivities and contact dermatitis to aloe have been reported (Morrow et al 1980, Nakamura & Kotajima 1984). Hypersensitivity manifested by generalised nummular eczematous and papular dermatitis, and presumably by contact urticaria, developed in a 47-year-old

man after 4 years of using oral and topical aloe. Patch tests for aloe were positive in this patient (Morrow et al 1980). Transient stinging and a mild itching sensation at oral lichen planus lesions have also been reported (Choonhakarn et al 2008).

### SIGNIFICANT INTERACTIONS

*A. vera* juice was found to inhibit both CYP3A4 and CYP2D6 by both CYP and non-CYP mechanisms (Djuv & Nilsen 2012). The estimated IC50 inhibition values were suggestive of no major interference in humans; however some degree of caution and acknowledgement should be exercised.

### Hypoglycaemic agents

Oral *A. vera* may have hypoglycaemic activity, therefore additive effects are theoretically possible — observe patients taking this combination.

### Digoxin

Excessive or long-term use of oral *A. vera* may result in lowered potassium levels, which can alter the mechanism of action of digoxin on the heart. Avoid combination.

### Laxatives

Additive effects are theoretically possible with oral aloe latex inducing griping pains. Use with caution.

### Topical cortisone preparations

In addition to its own anti-inflammatory effects, animal studies have shown that *A. vera* increases the absorption of hydrocortisone by hydrating the

stratum corneum, inhibits hydrocortisone's suppressive effects on wound healing and increases wound tensile strength — possible beneficial interaction (Davis et al 1994a).

### Vitamins C and E

Concurrent prescription of oral *A. vera* (both gel and latex) with vitamins C and E shows improved absorption and increased plasma life of vitamin concentration for both vitamins when taken together (Vinson et al 2005).

### Paclitaxel and doxorubicin

In vitro evidence suggests that aloe-emodin antagonises the cytotoxic effects on both paclitaxel and doxorubicin (Radovic et al 2012). While the clinical relevance of this remains unknown, caution should be observed in patients concurrently taking aloe with either of these chemotherapeutic agents.

### PREGNANCY USE

Strong laxatives such as aloe latex are not advised in pregnancy. Scientific evidence is unavailable to support conclusively the safe use of orally administered aloe.

### PATIENTS' FAQS

#### *What will this herb do for me?*

Aloe gel is traditionally used for burns, wounds and inflammatory skin disorders. There is good scientific evidence that aloe may be of benefit in these conditions; however, the chemical composition of *A. vera* products will vary depending on geographical and processing factors. Traditionally, aloe is also used internally for dyspepsia, gastrointestinal ulcers and IBS.

#### *When will it start to work?*

Aloe can have an immediate soothing effect on burns and inflammatory skin diseases. Improvement in wound healing can occur within several weeks, with the condition continuing to improve with use. Chronic conditions may require long-term use. Internal use of *A. vera* as a laxative can produce results within 12–24 hours.

#### *Are there any safety issues?*

Aloe gel is considered safe and non-toxic when used topically. Avoid chronic use of laxative preparations that contain highly irritant compounds, known as anthraquinone glycosides, in the latex.

### CONTRAINDICATIONS AND PRECAUTIONS

Strong laxatives such as aloe latex are contraindicated in children. Avoid in patients with known hypersensitivity to aloe or with nausea, vomiting or signs and symptoms of gastrointestinal obstruction. Avoid excessive use and long-term use (more than 2 weeks), as potassium losses may occur, which may alter cardiac electrophysiology.

Use with caution in people with thyrotoxicosis.

A case study of depression of thyroid hormones in a woman taking *A. vera* juice has been reported (Pigatto & Guzzi 2005). The patient consumed 10 mL daily for 11 months and laboratory testing showed reduced levels of thyroxine ( $T_4$ ) and triiodothyronine ( $T_3$ ). Levels returned to normal progressively after discontinuing the aloe juice and the patient achieved full clinical remission after 16 months. Reduced serum levels of the thyroid hormones  $T_3$  and  $T_4$  have been reported for *A. vera* in vivo (Kar et al 2002).

Caution is suggested with topical applications that contain *A. vera* as they may enhance sensitivity to ultraviolet light (Xia et al 2007).

# Alpha lipoic acid

**HISTORICAL NOTE** Lipoic acid was first identified in bacteria in 1937 (Lodge & Packer 1999). In 1951, its isolation and chemical structure characterisation by Reed saw lipoic acid tentatively classified as a vitamin (Wang et al 2011). It was subsequently found to be endogenously produced in humans from octanoic acid and the sulfur residue of cysteine. By the early 1950s, lipoic acid was understood as an essential cofactor in oxidative metabolism, involved in acyl-group transfer and as a mitochondrial coenzyme in the Krebs cycle (Patel & Packer 2008). Currently used as a medicine in the treatment of diabetic neuropathies in Europe, research has focused on its unique antioxidant properties and their application, mainly in diabetes management, but also in various neuropathologies, as well as in immune and inflammation modulation (Shay et al 2009).

## OTHER NAMES

Alpha lipoic acid (ALA), lipoic acid (LA), R-lipoic acid, S-lipoic acid, racemic lipoic acid, rhoctic acid, 6,8-thioctic acid, 1,2-dithiolane-3-valeric acid, dehydrolipoic acid (DHLA), 1,2-dithiolane-3-pentanoic acid.

## BACKGROUND AND RELEVANT PHARMACOKINETICS

### Chemical structure

ALA is a cyclic disulfide compound endogenously synthesised in the mitochondria from octanoic acid (caprylic acid) using cysteine as a source of sulfur. LA is manufactured in both R- and S-enantiomeric forms, but only the naturally produced R-form conjugates to lysine residues and attaches to a lipoyl protein carrier to act as an essential cofactor in physiological systems (Wang et al 2011); free LA is only present in very small amounts in the body (Patel & Packer 2008, Shay et al 2009), and is usually found in free form after therapeutic supplementation (Teichert et al 1998).

LA is insoluble in water, but soluble in organic solvents. At physiological pH, LA is anionic and in this form it is commonly called lipoate.

### Pharmacokinetics and bioavailability of LA

Most of the research for the bioavailability of ALA comes from studies using oral supplementation, usually made from manufactured racemic ALA.

Although not fully understood, the bioavailability of exogenous LA seems dependent on multiple carrier proteins. In vitro studies show that LA is absorbed through the cell membrane in a pH-dependent manner, through the monocarboxylate and Na<sup>+</sup>-dependent multivitamin transporter (Keith et al 2012, Shay et al 2009).

The gastrointestinal uptake of ALA is rapid but variable. A pharmacokinetic study by Teichert et al (1998) showed that humans absorb 20–40% of oral racemic ALA. Additionally, preferential uptake of the R-enantiomer has been established, as plasma concentrations were 40–60% more than those of the

L-enantiomer. However it is yet to be established if the S-form prevents polymerisation of ALA, thus increasing overall bioavailability (Breithaupt-Grogler et al 1999, Shay et al 2009).

Bioavailability fluctuates with concomitant absorption of food, suggesting nutrient interaction (Teichert et al 1998). Furthermore, it appears that the salt form has better bioavailability (Carlson et al 2007).

After rapid gastrointestinal uptake, ALA appears quickly in the plasma and generally peaks within 1 hour of administration and then declines rapidly, mainly via renal excretion (Harrison & McCormick 1974, Shay et al 2009). R-LA administered as a salt showed high plasma maximum concentrations and high area under the concentration versus time curve values (Carlson et al 2007). Ninety-eight per cent of radiolabelled LA is excreted within 24 hours (Schupke et al 2001).

Erythrocytes and a number of other cells take up ALA by glucose metabolism (GLUT 4), after which it reduces to DHLA, which is subsequently released in the extracellular environment (Packer & Cadenas 2010). However in adipocytes, it is poorly reduced and shows prooxidant activities (Cho et al 2003, Moini et al 2002a, 2002b, Packer & Cadenas 2010).

Supplemental LA has been shown to accumulate transiently in the liver, heart and skeletal muscles. Bioaccumulation in the brain has been debated (Chng et al 2009); however, in view of the large number of studies demonstrating a therapeutic effect on the brain, DHLA and other ALA metabolites should also be measured to establish their potential therapeutic benefits after oral ingestion of ALA (Shay et al 2009), as in vitro studies suggests that it is rapidly reduced to its DHLA form; catabolism of ALA, which occurs via  $\beta$ -oxidation, produces at least 12 major metabolites (Jones et al 2002).

## FOOD SOURCES

ALA is found in various natural sources in the form lipoyllysine, which is protein-bound ALA. While it is ubiquitous in most food and especially in organ

meats (liver, kidney) and spinach, with lesser amounts in broccoli floral buds, tomato, garden peas and Brussels sprouts, rice bran and yeast extract, it is only present in very low amounts and poorly bioavailable, thus it is not likely that it is consumed in appreciable amounts (Lodge & Packer 1999, Shay et al 2009, Sen & Packer 2000). Dietary supplements provide the main source of exogenous LA (Shay et al 2009).

### DEFICIENCY SIGNS AND SYMPTOMS

ALA is endogenously synthesised, primarily in the liver but also in other tissues. Animal studies have established that it is essential to life. To determine deficiency signs and symptoms, animal models of decreased ALA production have been studied.

No recommended daily intake has been established.

As an endogenous nutrient, little is known about the effects of genetic alteration that modify lipoic acid synthase (LIAS) expression and the reduction in endogenous LA production on disease pathogenesis. A rodent study in which the LIAS gene (homozygous mutation) has been switched off demonstrated that absence of LA is incompatible with life and ends in the early demise of all embryos in early implantation, presumably due to the inability of cells to produce oxidative metabolism. Supplementation of the mother did not alter the outcome (Yi & Maeda 2005). Interestingly, the intraperitoneal (IP) injection of ALA to diabetic pregnant rats did improve fetal and placental outcome, suggesting it can travel through the placenta (Al Ghaffi et al 2004).

Heterozygous mutation, impairing synthesis of ALA, showed an important decrease in erythrocyte glutathione levels and abnormal cellular antioxidant capacity (Yi & Maeda 2005).

Other animal models showed that LIAS deficiency resulted in overall cellular abnormality in antioxidant defence, increased inflammation and inflammatory cytokine expression, insulin resistance, mitochondrial dysfunction (Padmalayam et al 2009), and enhanced atherosclerosis formation, especially in males (Yi et al 2010). One case report of a newborn baby homozygous for LIAS deficiency manifested in mitochondrial encephalopathy with neonatal-onset epilepsy, muscular hypotonia, lactic acidosis and increased glycine in urine and plasma (Mayr et al 2011).

### MAIN ACTIONS

While de novo endogenous synthesis is considered sufficient for metabolic function, less is understood of ALA's role as an oral nutritional supplement. The growing body of evidence suggests it is bioavailable, safe in moderate doses and displays a range of metabolic and clinical effects (Shay et al 2009).

### Mitochondrial energy metabolism

De novo R-LA serves as an essential cofactor for the reduction of NAD to NADH in  $\alpha$ -keto acid

dehydrogenases (a multienzyme complex which includes pyruvate dehydrogenase) in the Krebs cycle, by catalysing the oxidative carboxylation of  $\alpha$ -keto acids (Booker 2004, Rüdiger et al 1972, Shay et al 2009).

### Antioxidant

Lipoate has the unique ability of being able to act as an antioxidant in fat and water-soluble tissues and also act as a 'metabolic antioxidant'. Enzymes in human cells accept it as a substrate for reduction. It is promptly taken up by cells and reduced to dihydrolipoate at the expense of cellular-reducing equivalents such as NADH and NADPH. As more of these reducing equivalents are used, the rate of cellular metabolism is sped up to cater for the enhanced demand (Sen & Packer 2000).

Both ALA (oxidised) and DHLA (reduced) act as a potent redox pair and scavenge a number of reactive oxygen species (ROS: hydroxyl radicals and hypochlorous acid). DHLA has been demonstrated to regenerate vitamin C and E in vitro (Bast & Haenen 2008, Biewenga et al 1997). R-LA feeding to rats has also been demonstrated to increase ascorbate levels in hepatocytes and cardiomyocytes subjected to normal aged-related loss (Lykkesfeldt et al 1999, Michels et al 2003, Suh et al 2001). Mechanisms of action appear indirect, by inducing the uptake from blood plasma, or promoting the synthesis of intracellular antioxidants via signal transduction (Shay et al 2009). DHLA increases intracellular glutathione by reducing cystine to cysteine (Han et al 1997, Suh et al 2001) and by enhancing cellular cysteine uptake (Suh et al 2004a).

Its role as an antioxidant and involvement in the broader antioxidant network underlie many of its observed actions in preclinical models.

### Glucose uptake and metabolism

Lipoate is known to promote the efficiency of glucose uptake by cultured skeletal muscle cells at a magnitude comparable to that of insulin and has also been shown to retain its ability to stimulate glucose uptake even where L6 myotubes were insulin-resistant (Sen & Packer 2000). In a rat model, Strepper et al (1997) demonstrated that a 10-day administration of R-LA improved significantly glucose uptake, decreased insulin resistance and increased glycogen synthesis and glucose oxidation compared to S-LA; it is important to note that GLUT 4 was slightly decreased by S-LA at doses of 30 mg/kg of body weight in the same study.

A SDZ rat study had demonstrated that 10 days' ALA treatment (30 mg/kg IP) enhanced muscle glucose metabolism and increased gastrocnemius GLUT 4 translocation (Khamaisi et al 1997). R-LA enhanced glucose uptake more rapidly and in larger amounts than S-LA or rac-LA (Estrada et al 1996). In the presence of insulin, ALA's effects were increased by 33% (Henriksen et al 1997). Similar results were observed in rat heart cells (Strödter et al 1995).

Estrada et al (1996) and Moini et al (2002b) demonstrated in vitro PI3K involvement. In vivo studies, while supporting the finding of GLUT4 upregulation, indicated a mechanism independent of PI3K as well (Henriksen et al 1997, Packer & Cadenas 2010). It is important to note a great disparity in in vitro and in vivo study dosage administration, which could explain this difference.

### Endothelial function

A number of clinical studies have demonstrated that treatment with ALA significantly improves endothelial function, increases nitric oxide (NO) synthesis and prevents loss in endothelial NO synthase phosphorylation, thus restoring vasodilation in diabetic and impaired-glycaemia patients. Although mechanisms are yet to be explained, it is thought to be acting through the PI3K/Akt signalling pathway (Heinisch et al 2010, Heitzer et al 2001, Sena et al 2008, Sola et al 2005, Xiang et al 2011).

### Hypotensive

Oral ALA supplementation tested in a number of hypertensive rat models was shown to normalise systolic blood pressure and aortic superoxide production (Vasdev et al 2000a, 2000b, 2003, 2005). In addition to improving endothelial NO synthesis, ALA is thought to reduce sulphhydryl group denaturation of  $Ca^{2+}$  channels in vascular smooth muscles through the regeneration of reduced glutathione and by inhibition of renal and vascular overproduction of endothelin-1, an endothelial vasoconstrictor (Takaoka et al 2001). In vivo research further suggests that long-term treatment with ALA improves baroreflex sensitivity in rats with renovascular hypertension (Queiroz et al 2012).

ALA also appears to prevent the development of glucocorticoid-induced hypertension according to in vivo research, an effect not mediated by mitochondrial superoxide reduction (Ong et al 2013).

### Anti-inflammatory

Numerous preclinical studies have demonstrated that LA affects several important inflammatory pathways in vivo, such as inducing a significant increase in cyclic adenosine monophosphate (cAMP) concentration and affecting the cAMP/protein kinase A signalling cascade (Salinthoné et al 2010). These effects have also been demonstrated in humans.

In particular, LA, in either racemic or individual S- or R-forms, but not DHLA, is able to stimulate cAMP production in natural killer and T cells (Salinthoné et al 2011, Schillace et al 2007), thus having an effect on inflammation, immunomodulation and autoimmunity.

It appears that LA stimulates cAMP production by activating G-protein coupled receptors, such as adenosine, likely to be responsible for the anti-inflammatory action of LA; curiously, LA also activated histamine, but not  $\beta$ -adrenergic receptors.

The histamine activation pathway findings have an implication in the safety of long-term intake of LA and warrant further studies, especially in the development of allergies and cancers (Salinthoné et al 2011).

LA, but not DHLA, downregulates CD4<sup>+</sup> expression in a concentration-dependent manner, potentially inhibiting T-cell activation to antigens, especially in the central nervous system environment, showing potential benefits in the management of multiple sclerosis (MS), and autoimmune pathologies (Marracci et al 2006).

In a small clinical study, ALA demonstrated an effect on exercise-induced inflammatory response in physically active males. Twenty minutes after a 90-minute exercise trial, ALA intake increased serum interleukin-6 (IL-6) and IL-10 (anti-inflammatory cytokines) and decreased IL-1 $\beta$  (proinflammatory). It also improved muscle regeneration (Zembron-Lacny et al 2013). In MS patients ( $n = 20$ ), LA was shown to stimulate cAMP by 43%, reduce IL-6 and IL-17 (cytokines involved in MS pathogenesis) and inhibit T-cell proliferation by 90% and activation by 40%, demonstrating anti-inflammatory effects (Salinthoné et al 2010).

### Neuroprotective

ALA demonstrates neuroprotective effects in various test models. This is accomplished via several different mechanisms. As a result, ALA has a potential role in a number of neurodegenerative disorders, including diabetic neuropathies, Alzheimer's dementia, burning-mouth syndrome, amyotrophic lateral sclerosis, seizures, brain injuries and MS (Yamada et al 2011).

Peroxyntirite involvement has been demonstrated in the pathogenesis of various neurodegenerative diseases through DNA strand break; an in vitro study by Jia et al (2009) demonstrated the inhibition of peroxyntirite-mediated DNA damage by ALA, suggesting it may be partly responsible for the neuroprotective action. ALA's ability to promote the expression of antioxidative genes via the PI3K/Akt pathway that upregulates glutathione has also been demonstrated in SH-SY5Y brain cells in vitro (Yamada et al 2011).

In a cryo-injured rat brain model, ALA was shown to stimulate the synthesis of glutathione, decrease cell death, promote angiogenesis and decrease glial cell scar formation (Rocamonde et al 2012). ALA also appears to reduce monocyte migration across the blood-brain barrier effectively, protect its integrity and inhibit cerebral inflammation in a dose-dependent manner (Schreibelt et al 2006).

A number of experimental models demonstrate protective mechanisms in cerebral ischaemic-reperfusion injury when subjects are pretreated before occlusion (Connell et al 2011, Richard et al 2011). ALA was also shown to significantly prevent neuronal oxidative stress induced by a number a pharmacological drugs and environmental poisons in animal models: haloperidol (Perera et al 2011),

L-dopa (Abdin & Sarhan 2011), cyanide-induced seizures (Abdel-Zaher et al 2011), dimethoate, glyphosate and zineb (Astiz et al 2012) and morphine-induced tolerance and dependence (Abdel-Zaher et al 2011).

### Hepatoprotective

Hepatoprotective activity has been demonstrated in different animal studies, indicating a potential role in chronic liver disease and damage.

A hepatoprotective effect was observed after ALA treatment in lipid peroxidation-induced liver injury, and thioacetamide-induced fibrosis. Treatment with ALA resulted in a decrease in serum aspartate transaminase (AST) and alanine transaminase (ALT), decrease in lipid peroxidation, maintenance of antioxidant capacity, and reduction in histomorphological damage to hepatocytes (Kaya-Dagistanli et al 2013, Ning-Ping et al 2011).

Protection from paracetamol- and methotrexate-induced mitochondrial toxicity was demonstrated in rodent experimental models, again with maintenance of antioxidant capacity, inhibition of oxidative stress and protection of hepatocyte morphology (Abdel-Zaher et al 2008, Tabassum et al 2010).

### Antiatherosclerotic

Animal models of LA synthase deficiency in apolipoprotein E-deficient animals show they have an increased propensity to develop atherosclerotic plaque, especially male subjects (Yi et al 2010, 2012b). In animal models fed high-fat, hypercholesterolaemic diets, ALA was shown to attenuate and decrease plaque formation, decrease inflammation, decrease T-cell content in plaque, decrease vascular smooth-muscle proliferation and improve lipid profile (Lee et al 2012, Xu et al 2012, Ying et al 2010).

### Cardioprotective

Pretreatment of rats with LA reduced infarct size and preserved cardiac function in a study of myocardial ischaemia-reperfusion injury (Deng et al 2013).

## OTHER ACTIONS

### Metal chelation

ALA chelates transition metals by forming stable complexes with  $Mn^{2+}$ ,  $Cu^{2+}$  and  $Zn^{2+}$  (Sigel et al 1978). DHLA, but not ALA, significantly inhibited ascorbate oxidation by Fe(III) and Cu(II) in a concentration-dependent manner through chelation, without removing copper or iron from the active sites of enzymes or altering the activity of copper- and iron-dependent enzymes (Suh et al 2004b).

While administration of ALA in lead-poisoned animal models or in vitro cellular models demonstrated a reduction in lead oxidation of the brain (Pande & Flora 2002), the kidney (Sivaprasad et al 2004), erythrocytes (Caylak et al 2008) and ovarian

tissue (Gurer et al 1999), especially in combination with dimercaptosuccinic acid (DMSA, a pharmacological molecule commonly used as an antidote to heavy metal poisoning), it showed no chelation properties in decreasing the lead burden. Other studies showed a similar effect, alone or with DMSA, in cadmium-induced oxidation of rat heart, brain, testis and liver (Sumathi et al 1996), in arsenic-induced oxidation of rat brain (Shila et al 2005) and in in vitro human glial cells (Cheng et al 2007).

### Signal transduction

ALA is involved in the reduction and oxidation of the thiol/disulfide bonds in transcription factors, and as such has been demonstrated to modulate cell signalling via NF- $\kappa$ B, AMPK and PI3K/Akt signalling (Packer & Cadenas 2010).

### Cataract protection

ALA inhibited the development and progression of naphthalene and proton-induced cataract in healthy and diabetic rats (Chen et al 2010, Davis et al 2010, Kojima et al 2007). It also showed the ability to penetrate the human aqueous after topical application, showing a potential use of LA's antioxidant capacity in ophthalmology (Cagini et al 2010).

### Cancer

#### Prevention

ALA has exhibited antimutagenic and anticlastogenic activities in tumorigenic animal and human cell models, including breast, melanoma, ovarian epithelial and colon cancers, through the inhibition of inflammatory mediators, the inhibition of NF- $\kappa$ B activity and DNA fragmentation and inhibition of metastasis (Goraca et al 2011).

#### Treatment

Four cases of pancreatic cancer patients undergoing a long-term treatment of 300–600 mg intravenous (IV) ALA twice a week, oral naltrexone (4.5 g/day) in addition to dietary modification, selenium (200 mcg bd) and silymarin (300 mg qd) were reported to have improved survival outcomes. These results warrant further investigation given the general poor prognosis of pancreatic cancer patients (Berkson et al 2009).

ALA also demonstrated neuroprotection from chemotherapy side effects (paclitaxel, cisplatin, frataxin and methotrexate) in human cell models of cancer and in vivo animal models (Dadhania et al 2010, Melli et al 2009, Tabassum et al 2010). Current clinical trials are underway.

### Neuromodulation

LA improved the status of dopamine, serotonin and adrenaline in rodent's aged brain (Arivazhagan & Panneerselvan 2002).

### Radioprotection

Report of a Russian open trial of the treatment of children exposed to radiation from the Chernobyl

disaster is often stated as the basis of the radioprotective effects of ALA.

A small number of recent published *in vitro* and *in vivo* studies seem to support the potential role of ALA in radioprotection. These studies report protection of cerebellar structure and cognitive function in  $\gamma$ -irradiated rodents (Manda et al 2008), increased protection in cell membrane and DNA stability, as well as increased survival time in lethally radiated mice (Ramachandran & Nair 2011) and maintenance of haemoglobin integrity and rheology in irradiated blood bags for transfusion (Desouky et al 2011).

## CLINICAL USE

Most clinical research has been conducted in diabetic populations and people with disease states where an antioxidant, neuroprotective and/or anti-inflammatory mechanism of action may have benefits.

### Diabetes

Oral and injectable forms of LA have been investigated in diabetes as a means of enhancing insulin sensitivity and either preventing or treating chronic complications which occur years after the onset of disease, such as polyneuropathy, nephropathy and retinopathy. Many of these complications are the result of an overabundance of ROS produced by the mitochondrial transport chain as a result of a sustained hyperglycaemic state.

ALA was approved in Germany several years ago in the treatment of diabetic neuropathy and as a dietary supplement for patients affected by diabetic retinopathy (Nebbio et al 2013). It is covered by medical insurance (Mijnhout et al 2012).

### Insulin resistance

Increase in insulin sensitivity is primarily achieved through diet, exercise, weight loss and improvement of lean:fat body mass ratio and, lastly, pharmacological intervention if glycaemic control cannot be achieved and maintained.

Several clinical trials have investigated the effect of parenterally-administered LA to diabetic subjects. A study by Jacob et al (cited in Evans & Goldfine 2000) showed insulin-mediated metabolic clearance rates (MCR) of glucose improved by at least 30% in subjects with type 2 diabetes (well controlled with diet alone or with glibenclamide) at doses of 500 mg ALA/500 mL NaCl/day infusion for 10 days. A second study by the same group (Jacob et al 1996), using a dose of 1000 mg ALA/500 mL NaCl for 10 days, reported improvement in glucose infusion rates of 47%, MCR by 55% and insulin sensitivity by 57%. No effects were observed on fasting glucose and insulin levels.

More recently, a study by Zhang et al (2011) investigated 22 obese subjects with impaired glucose tolerance (IGT) (obese-IGT), 13 of whom underwent 2-week ALA treatment, 600 mg intravenously once daily. This short-term treatment significantly

improved insulin sensitivity and plasma lipid profile. More specifically, the insulin sensitivity index was impressively enhanced by 41% and significant reductions were seen for plasma levels of free fatty acids, triglyceride, total cholesterol, low-density lipoprotein cholesterol, small dense lipoprotein cholesterol, oxidised lipoprotein cholesterol, and very-low-density lipoprotein cholesterol ( $P < 0.01$ ). At the same time, both plasma oxidative products (malondialdehyde, 8-iso-prostaglandin) and inflammatory markers (tumour necrosis factor- $\alpha$ , IL-6) were remarkably decreased ( $P < 0.01$ ), while adiponectin was increased ( $P < 0.01$ ) (Zhang et al 2011).

Oral ALA supplementation has also been investigated in several studies and produced inconsistent results regarding effects on insulin sensitivity (de Oliveira et al 2011, Jacob et al 1999, Yan et al 2013).

Four weeks' treatment with oral ALA was found to improve insulin sensitivity in patients with type 2 diabetes according to this early randomised, placebo-controlled study involving 74 volunteers with type 2 diabetes (Jacob et al 1999). Patients were randomised to either placebo or active treatment in various doses of 600 mg once daily, twice daily (1200 mg) or three times daily (1800 mg); however no dose effect was observed. In contrast, no change in insulin sensitivity was reported in this double-blind randomised controlled trial (RCT) of 102 patients with type 2 diabetes which compared 4 months of treatment with 600 mg/day LA ( $n = 26$ ); 800 mg/day  $\alpha$ -tocopherol ( $n = 25$ ); 800 mg/day  $\alpha$ -tocopherol + 600 mg/day LA ( $n = 25$ ) and placebo ( $n = 26$ ). In this study, no treatment arm resulted in a significant change to the lipid profile or insulin sensitivity of patients (de Oliveira et al 2011).

Yan et al (2013) performed a double-blinded, randomised, cross-over trial involving 103 patients without cardiovascular disease, hypertension, diabetes or any other inflammatory diseases, to investigate whether oral ALA administration lowers the risk of cardiovascular disease by decreasing the level of oxidative stress markers or improving insulin sensitivity (Homeostatic Model Assessment of Insulin Resistance [HOMA-IR] levels, a method used to assess insulin resistance and beta-cell function). Treatment with oral ALA (1200 mg/day) over 8 weeks produced no significant difference in HOMA or oxidative biomarkers between the two groups. Interestingly, at this treatment dose, ALA was associated with significantly lower body mass index (BMI), weight and waist circumference after 8 weeks. There were no significant differences in the incidence of side effects between ALA and placebo.

Overall, it appears that oral supplementation of ALA may not be as effective as intravenous intake, possibly due to the short plasma half-life and limitations on maximal plasma levels achieved with oral dose forms (Evans & Goldfine 2000, Yan et al 2013). Enteric coating, sustained-release forms, timing of administration and form of LA used are also considerations that may influence future results.

### Diabetic polyneuropathy

Diabetic polyneuropathy represents a considerable morbidity of long-term uncontrolled diabetes and occurs in about one-third of people. Symptoms of pain have been reported to occur in 13–34% of patients with diabetes, with the risk of painful neuropathic symptoms considerably higher in type 2 diabetes than in type 1 diabetes (Boulton et al 2013). Persistent hyperglycaemia leading to increased synthesis of ROS in the mitochondria and subsequent oxidative damage to endothelium and neuronal cells are part of the aetiology.

The use of ALA as a treatment for diabetic neuropathy has been studied since the 1950s, with numerous clinical trials of variable quality published (McIllduff & Rutkove 2011). In the last decade, several meta-analyses have been published, with results most consistent for injectable forms of ALA (300–600 mg daily) as a method of reducing symptoms; however the use of high oral doses (600–1200 mg/day) also appears to provide symptomatic relief and, possibly, slow disease progression.

An early meta-analysis from 2004 which analysed four RCTs concluded that 3 weeks of parenterally administered ALA (600 mg/day) provided a significant decrease in pain scores (Ziegler et al 2004). A similar conclusion was reached in a meta-analysis by McIllduff and Rutkove (2011), which included the ALADIN, SYDNEY, ORPIL, SYDNEY II and ALADIN III trials ( $n = 1160$ ; level 2b evidence). Once again, authors reported that parenterally-administered ALA was associated with a clinically meaningful improvement on symptom scores compared to placebo, at IV doses of 600 mg/day for at least 3 weeks. Oral supplementation also produced a significant improvement in symptoms and impairment at doses of 600 mg, 1200 mg and 1800 mg/day over periods ranging from 3 weeks to 2 years. Side effects were described as dose-dependent, as an oral dose of 600 mg/day over 2 years was well tolerated; however the higher dose of 1200 mg/day was associated with an increase in side effects (nausea, vomiting and vertigo). This was particularly notable in the ALADIN study, whereby rates of adverse events were 32.6% for ALA 1200 mg/day, 18.2% for ALA 600 mg/day, 13.6% for ALA 100 mg/day and 20.7% for placebo. It is important to note that some of the studies selected did not exclude diet control, hypoglycaemic medication, insulin or recent antioxidant use, or the inclusion of some type 1 diabetes patients, which may have influenced the results.

In 2012, a new meta-analysis evaluated four level 1b RCTs ( $n = 653$ ) with combined results for both oral and IV effects of LA for symptomatic control of neuropathies (pain, burning, paraesthesiae, numbness). All studies reported a reduction in total symptom scores; however, equivocal results were reported in trials using oral dose forms (Mijnhout et al 2012). Another 2012 meta-analysis, this time evaluating intravenous treatment only, concluded

that treatment with 300–600 mg daily for 2–4 weeks was safe, and improved both nerve conduction velocity and neuropathic symptoms (Han et al 2012).

The NATHAN study, not reported in earlier meta-analyses, was a large multicentre, double-blind, RCT that evaluated the efficacy of oral ALA (600 mg/day) taken over 4 years by volunteers with mild to moderate diabetic distal symmetric sensorimotor polyneuropathy. The primary end point was a composite score (Neuropathy Impairment Score–Lower Limbs [NIS-LL] and seven neurophysiological tests), which was not significantly different for ALA compared to placebo after 4 years. However, change from baseline was significantly better with ALA than placebo for NIS ( $P = 0.028$ ), NIS-LL ( $P = 0.05$ ) and NIS-LL muscular weakness subscore ( $P = 0.045$ ). Importantly, more patients showed a clinically meaningful improvement and fewer showed progression of NIS ( $P = 0.013$ ) and NIS-LL ( $P = 0.025$ ) with ALA than with placebo. Treatment was well tolerated, although the rates of serious adverse events were higher on ALA (38.1%) than on placebo (28.0%).

The most recent meta-analysis (Xu et al 2013) considered results from a larger cohort of 1106 patients with diabetic neuropathy in a series of 15 China-based trials, which demonstrated significant efficacy of a combined therapy of LA (300–600 mg IV) and methylcobalamin (500–1000 mg IV or intramuscularly) once a day for 2–4 weeks. The combination was shown to be more effective than monotherapy of LA or methylcobalamin. However, the authors recognised methodological quality issues and the small size sample, emphasising the need for larger, well-designed, multicentre RCTs.

### Diabetic nephropathy

Administration of LA reduces diabetic nephropathy in animal models through mitochondrial protection, glomerular histological changes and decrease in ROS generation (Wang et al 2013, Yi et al 2011). Protection of  $\beta$  cells, decrease in cholesterol levels, decrease in albuminuria, serum urea and creatinine, and amelioration of proteinuria have also been noted in these models (Obrosova et al 2003, Wang et al 2013, Winiarska et al 2008, Yi et al 2011). A rodent model of LIAS deficiency was shown to accelerate the development of nephropathy and treatment with ALA improved kidney metabolic regulation and antioxidant capacity (Yi et al 2012a).

In a small clinical study, oral ALA administration (600 mg/day) to diabetic patients (type 1 diabetes  $n = 20$ ; type 2 diabetes  $n = 15$ ) over a period of 18 months has shown a significant decrease in thrombomodulin and unchanged urea/creatinine ratio compared to a control group, demonstrating a slowing of kidney damage (Morcos et al 2001). Larger and better-designed studies are needed to confirm these findings.

## Diabetic retinopathy

ALA is used as a dietary supplement to slow down the progression of diabetic retinopathy. ALA prevents microvascular damage and preserves pericyte coverage of retinal capillaries in addition to improving insulin sensitivity, thereby providing a theoretical basis for its use (Nebbioso et al 2013).

### IN COMBINATION

One randomised study of 32 diabetic volunteers with pre-retinopathy and good metabolic control found that oral treatment with ALA at 400 mg/day (in association with genistein and vitamins) resulted in an increase in plasma antioxidant capacity after 30 days and significant increases in the electrophysiological response, as measured by electroretinography, suggesting a protective effect on retinal cells by strengthening the plasma antioxidant barrier (Nebbioso et al 2012).

In contrast, a randomised study examining the effects of ALA on macular oedema in patients with type 2 diabetes found an oral dose of 600 mg daily taken over 2 years did not produce a significant improvement in blood levels of glycated haemoglobin, visual acuity or any reduction in retinal thickness compared to placebo (Haritoglou et al 2011). Further clinical research is required, ideally with larger doses taken in divided daily doses. Alternatively, a combination of substances with antioxidant effects, such as the one used in the study by Nebbioso et al (2012), might have more promise.

## Age-related macular degeneration (AMD)

A randomised study of 62 patients (50–75 years old) with early and intermediate dry form of AMD showed that treatment with ALA produced a significant increase in serum superoxide dismutase activity, suggesting that ALA may have a possible preventive effect in the development of AMD through an antioxidant mechanism (Sun et al 2012).

## Peripheral neuropathic pain (sciatic nerve pain)

A double-blind RCT compared acetyl-L-carnitine (ALC: 1180 mg/day) to ALA (600 mg/day) over a 60-day treatment period in 64 consecutive patients (mean age 61 years; range 29–85 years) with acute backache and moderate sciatica associated with a herniated disc (Memeo & Loiero 2008). Treatment with ALA produced significantly greater mean improvement than ALC from baseline for NIS-LL, Neuropathy Symptoms and Change in the Lower Limbs and Total Symptom Score scores ( $P < 0.05$  for all comparisons). Additionally, a significant reduction in analgesic requirements was reported for more patients taking ALA than ALC (71.0% vs 45.5%, respectively;  $P < 0.05$ ).

## Cardiac autonomic neuropathy and platelet reactivity

Cardiac neuropathy and platelet reactivity are complications in diabetes which increase the risk of cardiovascular events (Mollo et al 2012). One in vitro study investigating the mechanisms of LA's

antiplatelet activity found it significantly inhibited platelet aggregation in a dose-dependent manner and suggested the mechanisms were linked to an increase in cAMP formation, followed by thromboxane  $A_2$  inhibition,  $Ca^{2+}$  mobilisation and protein kinase C activation (Lai et al 2010).

One small clinical study looked at platelet reactivity in type 1 diabetes patients ( $n = 56$ ) who were randomly assigned a 600 mg oral LA dose daily or a placebo for 5 weeks and found LA significantly reduced platelet activation. Mechanisms remain unclear, as markers of oxidative stress (8-iso-prostaglandin  $F_{2\alpha}$ ) and inflammation (C-reactive protein) were unchanged (Mollo et al 2012).

In the Deutsche Kardiale Autonome Neuropathie (DEKAN), ALA supplementation (oral ALA, 800 mg daily for 4 months) in 73 type 2 diabetic patients showed modest improvement in heart rate variability, a validated tool in the assessment of cardiac neuropathy (Coleman et al 2001).

## HIV/AIDS

Supplementation with ALA (300 mg three times daily) may positively impact patients with HIV and AIDS by restoring blood total glutathione level and improving functional reactivity of lymphocytes to T-cell mitogens, according to a placebo-controlled RCT (Jariwalla et al 2008). The mean blood total glutathione level in ALA-supplemented subjects was significantly elevated and the lymphocyte proliferation response was significantly enhanced or stabilised after 6 months compared to progressive decline in the placebo group (ALA vs placebo:  $P < 0.001$  with phytohaemagglutinin;  $P = 0.02$  with anti-CD3 monoclonal antibody). A positive correlation was seen between blood total glutathione level and lymphocyte response to anti-CD3 stimulation. There was no change in CD4 count over 6 months.

One study showed that antioxidant supplementation (with ALA + *N*-acetyl cysteine) may have a protective role on mitochondrial function, with limited effects on the reversal of clinical lipodystrophic abnormalities in HIV-1-infected patients (Milazzo et al 2010).

## Multiple sclerosis

MS is a chronic inflammatory disease of the central nervous system, characterised mainly as an autoimmune neurodegenerative disorder. Excessive oxidative stress or a loss of the antioxidant/oxidant balance may contribute to its development or be a consequence of disease (Ferreira et al 2013). Additionally, transmigration of activated immune cells across the blood-brain barrier plays a significant role in MS pathogenesis as it leads to the development of new inflammatory lesions in MS. As such, it is not surprising that ALA has been investigated as a potential treatment in this disease.

ALA has been proven to be an effective treatment in the management of MS in experimental autoimmune encephalomyelitis (EAE) rats, the accepted model for MS. In these models, ALA was

shown to decrease the migration of encephalitogenic T cells to the spinal cord through the inhibition of intercellular adhesion molecule 1 and vascular cell adhesion molecule-1. In vitro, ALA has been shown to activate cAMP-activated protein kinase A (an enzyme involved in immunomodulation and neuroprotection); this pathway is believed to be central in the pathogenesis of MS (Chaudhari et al 2006, Marracci et al 2002, Morini et al 2004, Salinthoné et al 2010, Schreibelt et al 2006). Oral ALA supplementation (1200 mg/day) taken by MS volunteers resulted in increased cAMP levels in peripheral blood mononuclear cells 4 hours after ingestion and, on average, cAMP levels in 20 subjects were 43% higher than baseline (Salinthoné et al 2010).

A small, double-blind, placebo-controlled, dose-finding trial ( $n = 37$ ) found a significant dose relationship between ALA plasma levels and inhibition of metalloprotein 9 and intracellular adhesion molecules also involved in MS pathogenesis. Effects were noted after 2 weeks at doses of oral 1200 mg/day and were significantly better than a 600 mg/day dose; however, there was a significant individual variability in ALA peak serum — potentially an effect of the administration of ALA with food in this study (Yadav et al 2005). A more recent double-blind randomised controlled study testing the effect of oral ALA (1200 mg/day) in 52 MS patients (relapsing-remitting) over 12 weeks showed a significant increase in total antioxidant capacity ( $P = 0.004$ ) compared to placebo but no change in malondialdehyde levels or the activities of superoxide dismutase or glutathione peroxidase (Khalili et al 2014).

MS is a common aetiology of optic neuritis and is often a presenting sign. A small animal study ( $n = 14$ ) demonstrated protection against axonal loss and degeneration with ALA (100 mg/kg) reducing CD4<sup>+</sup> and CD11b<sup>+</sup> T cell, inflammation and demyelination in an EAE mice model (Chaudhari et al 2011).

A study by Yadav et al (2010) compared the pharmacokinetics of a 1200 mg single dose of three different formulations of racemic LA in 24 MS patients (formula A: 1200 mg tablet, excipients unknown; formula B: 300 mg gelatine capsule, cellulose and ascorbyl palmitate and silica; formula C: 600 mg capsule, pine cellulose and ascorbyl acid) against three different doses in rats (20 mg, 50 mg, 100 mg). The MS patients taking the capsule formulas B and C achieved  $C_{max}$  and area under the concentration curve (AUC) equivalent to subcutaneous 50 mg/kg in mice, the therapeutic dose in experimental MS mice models. As a result, the authors suggest 1200 mg as a therapeutic dose for further clinical trials. The tablet formulation showed the lowest AUC and clearance, and widest patient intervariability. The authors recognised that the postprandial administration, chosen to decrease potential gastric side effects, rather than the manufacturer-recommended fasting intake, may have influenced the pharmacokinetics of the tablet.

A placebo-controlled study is currently underway in the United States to determine whether oral ALA 1200 mg/day can slow the progression of MS over time.

### Weight loss

According to a randomised, double-blind study involving 360 obese participants (BMI  $\geq 30$  kg/m<sup>2</sup> or 27–30 kg/m<sup>2</sup> plus hypertension, diabetes mellitus or hypercholesterolaemia), active treatment with 1800 mg/day of racemic ALA over 20 weeks led to significantly more weight loss than placebo. Weight loss was significantly greater with 1800 mg/day of ALA compared to placebo from week 4. Additionally, there was a significant difference between the groups with regard to percentage of subjects who achieved a  $\geq 5\%$  reduction in baseline body weight (21.6% vs 10.0%,  $P < 0.01$ ). No significant changes were observed in triglyceride concentrations and triglyceride/high-density lipoprotein cholesterol ratios. The significant difference in weight loss was also reported for the group with BMI 27–30 kg/m<sup>2</sup> plus additional risk factors. Subjects with diabetes receiving 1800 mg/day ALA showed a mean 0.38% reduction from baseline in haemoglobin A<sub>1c</sub> level ( $P < 0.05$ ) but there was no change in blood pressure or fasting plasma glucose and cholesterol concentrations. Mild and transient urticaria and itching were experienced in ALA groups; however, overall incidence of side effects was similar to the placebo group (Koh et al 2011).

Oral ALA (1200 mg/day) was associated with significantly lower BMI, weight and waist circumference after 8 weeks in another double-blinded, randomised trial, conducted by Yan et al (2013), involving 103 patients without cardiovascular disease, hypertension, diabetes or any other inflammatory disease. There were no significant differences in incidence of side effects between ALA treatment and placebo.

### Weight loss in schizophrenia

A case series of a 12-week ALA trial in 5 schizophrenia patients treated with atypical antipsychotic drugs found that treatment resulted in a mean weight loss of 3.16 kg ( $P = 0.043$ ) and, on average, BMI showed a significant reduction ( $P = 0.028$ ) over the 12 weeks (Kim et al 2008). No change was seen to the Brief Psychiatric Rating Scale and the Montgomery-Asberg Depression Rating Scale.

A small open study was more recently published, whereby ALA (1200 mg/day) taken for 10 weeks by 12 non-diabetic schizophrenic patients produced a significant weight loss during the intervention ( $-2.2$  kg  $\pm$  2.5 kg). Treatment with ALA was well tolerated and particularly effective for individuals taking strongly antihistaminic antipsychotics ( $-2.9$  kg  $\pm$  2.6 kg vs  $-0.5$  kg  $\pm$  1.0 kg) (Ratiff et al 2013).

### Migraine prophylaxis

An RCT using ALA in migraine prophylaxis was steered by the Belgian Headache Society and

included five Belgian centres, which recruited 54 migraineurs (43 migraine without aura, 11 with aura; mean age  $38 \pm 8$  years; 7 males) (Magis et al 2007). ALA (600 mg/day) was taken for 3 months and was found to reduce migraine attack frequency compared to placebo ( $P = 0.06$ ). Within-group analyses showed a significant reduction of attack frequency ( $P = 0.005$ ), headache days ( $P = 0.009$ ) and headache severity ( $P = 0.03$ ) in patients treated with ALA whereas these outcome measures remained unchanged in the placebo group. The treatment was well tolerated with no adverse effects reported.

Before any firm conclusion can be drawn, a larger clinical trial is now necessary.

## OTHER USES

### Alzheimer's disease (AD)

ALA, with its proven antioxidant, anti-inflammatory, neuroprotective, metal-chelating and glycaemic regulation activities, is showing potential in the treatment of AD and worthy of further investigation.

AD is characterised by neurofibrillary tangles and amyloid plaques leading to neuronal loss. Its pathophysiology is thought to involve progressive cholinergic deficit, a chronic inflammatory oxidative process leading to mitochondrial dysfunction. Recent preliminary studies are showing insulin abnormality and resistance in AD patients, including impaired cerebral glucose metabolism, leading to neuron toxicity (Maczureck et al 2008).

The first indication that ALA may be beneficial in AD and related dementias came from a serendipitous case of a 74-year-old woman with signs of cognitive impairment and diabetic polyneuropathy treated with an anticholinesterase inhibitor drug and 600 mg LA daily for her neuropathy. Since 1997, when treatment first began, several tests have been performed which show no substantial decline in cognitive function and neurological tests show unusually slow progress of her cognitive impairment (Maczureck et al 2008).

Since then, studies in rodents have shown a protective effect of cognitive deficits (Wang & Chen 2007) and chronic feeding of ALA in conjunction with *N*-acetyl cysteine showed improvement in cognition in aged subjects (Farr et al 2003).

A small open pilot trial ( $n = 9$ ) of patients with AD were given 600 mg oral ALA daily, 30 minutes before breakfast in conjunction with standard treatment of acetylcholinesterase inhibitors over a period of 371 days. The treatment provided stabilisation in cognition compared to pretreatment decline in cognition. The size of this pilot study increased to 48 patients for up to 48 months, providing similar results. The need for well-designed RCTs is warranted to confirm these findings (Maczureck et al 2008).

### Polycystic ovary syndrome (PCOS)

Although generally associated with high BMI, about 20% of women presenting with PCOS are of normal

weight. Some studies have suggested that insulin resistance in PCOS is a result of genetic predisposition to a defective insulin-signalling pathway (and resulting compensatory hyperinsulinaemia), rather than dependent on BMI. In normoinsulinaemic lean PCOS women, the use of insulin-reducing and sensitising drugs was shown to improve free testosterone and androstenedione serum values, suggesting insulin-related hyperandrogenism (Baptiste et al 2010); improving this resistance has been recognised as essential to improve metabolic and reproductive outcomes (Marshall & Dunaif 2012).

A pilot trial administering controlled-release lipoic acid 600 mg twice daily to 6 non-obese PCOS patients with no other comorbidity, including insulin resistance, and ingesting an isocaloric diet showed improvement in their insulin sensitivity, a decrease in their triglyceride and increase in low-density lipoprotein molecular size (Masharani et al 2010).

### Hepatoprotection

A small trial ( $n = 24$ ) of patients undergoing liver resection showed decreased serum AST and ALT (used in combination in the diagnosis of liver damage) and histomorphological damage to hepatocytes when 600 mg of IV ALA was administered 15 minutes before resection compared to the group administered IV NaCl (Dünschede et al 2006).

ALA (300 mg/day) has been investigated in alcoholic liver disease in a 6-month RCT ( $n = 40$ ), which found that only those participants abstaining from alcohol showed significant improvement in AST and gamma-glutamyl transaminase (which is raised in chronic alcohol toxicity) values and histological biopsy with use (Marshall et al 1982). These results are problematic as the number of abstainers was not even in both groups, and the dose used was low. Hepatoprotective effects have been shown in animal studies in recent studies (Kaya-Dagistanli et al 2013, Foo et al 2011).

### Hypertension

A cross-over double-blind study tested whether adding oral ALA to the angiotensin-converting enzyme inhibitor quinapril would potentiate regulation of blood pressure, endothelial function and proteinuria in obese diabetic patients with stage 1 hypertension. Patients were randomised to receive either quinapril (40 mg/day) alone or quinapril (40 mg/day) and LA (600 mg/day) for 6 weeks. Biomarkers of obesity and endothelial-dependent flow-mediated dilation were improved in the group of combination quinapril and ALA (Khan et al 2010). Another study noted a reduction in blood pressure, proteinuria and endothelial function (Rahman et al 2012).

### Kwashiorkor

A small longitudinal clinical pilot study comparing the standard World Health Organization treatment

protocol to one of three groups supplemented with reduced glutathione, LA or *N*-acetyl cysteine to a healthy control group showed that reduced glutathione and LA both positively increased recovery and survival, and correlated with erythrocyte glutathione concentration — a predictive value of survival (Becker et al 2005).

### Burning-mouth syndrome

Three small clinical trials showed significant results in decreasing symptoms of burning-mouth syndrome with dosages of 600 mg daily for 1–2 months. However, the placebo groups in these studies also reported high levels, although non-significant, of symptomatic improvements, especially in the double-blind trial, compared to the open-label trials (Zakrzewska et al 2009); Crow and Gonzalez (2013) report three subsequent studies with similar dosage in which LA does not yield statistical significance over placebo, possibly due to the large variation in pain response in both groups.

### Carpal tunnel syndrome — in combination

A study compared the efficacy of LA (600 mg/day) in combination with  $\gamma$ -linolenic acid 360 mg/day to a vitamin B complex (B6 150 mg; B1 100 mg; B12 500 mcg/1 daily) for 90 days in 112 subjects with moderate to severe carpal tunnel syndrome. The LA/ $\gamma$ -linolenic group scored significant improvement in symptoms, confirmed by electromyography, compared to the B vitamin group (Di Geronimo et al 2009).

### Erectile dysfunction

With the classical causes of erectile dysfunction including diabetes mellitus, hypertension, obesity, hyperlipidaemia and cardiovascular conditions, and the pathophysiological mechanisms understood to involve oxidative stress, especially due to advanced glycosylated end products, and alteration of vascular and endothelial function through dysregulation of NO synthase (Shamloul & Ghanem 2012), a theoretical basis exists for the use of LA for this condition.

An animal study also demonstrated that the neurotomy associated with prostatectomy resulted in a loss of NO synthase-containing nerve fibres and in significant oxidative stress; treatment with LA (65 mg/kg/day IP) showed improvement in cavernous tissue regeneration (Alan et al 2010). No clinical trials are available at this time.

### Wound healing

Human trials show that hyperbaric oxygen therapy increases IL-6 and ROS production. In a small double-blind randomised study, supplementation with LA (600 mg/day) in patients undergoing hyperbaric oxygen therapy for various conditions, with the inclusion criterion of leg ulcers older than 30 days, showed an 80% reduction or remission of

the lesions at 40 days of treatment compared to the placebo group (Alleva et al 2005).

### Glaucoma

Glaucoma is a progressive neurodegenerative condition in which the retinal ganglia and optic nerve are damaged due to increased intraocular pressure, leading to loss of vision. ALA has demonstrated a protective effect on retinal neurons in vitro and in animal models (Koriyama et al 2013). A small Russian study reported an improvement in visual function after 4 weeks of treatment with 150 mg/day of ALA in patients with glaucoma (Cotlier & Weinreb 2008).

### Photoageing of skin

The low molecular weight of ALA, combined with its solubility characteristics, suggests the possibility of LA being absorbed by the skin and having pharmacological activities. Swift penetration through the epidermis has been demonstrated in a hairless mouse model and, after 4 hours, distribution to the dermis and subcutaneous tissue underneath. This was further explored in a 12-week RCT ( $n = 33$ ) with a 5% ALA cream, which was applied twice daily to half the face and placebo cream to the other. Self-assessment, clinician assessment, standardised photography and laser profilometry before and after the period of treatment were used to evaluate effects. The ALA-enriched cream significantly improved profilometry in photoageing of facial skin.

According to photographic evaluations, ALA cream was shown to improve the appearance of fine lines ( $P < 0.031$ ), decrease pigmentation ( $P < 0.007$ ), decrease under-eye bags and puffiness ( $P < 0.09$ ) and decrease pore size ( $P < 0.08$ ). The clinical evaluation also reported a significant improvement in fine lines ( $P = 0.01$ ). Additionally, self-assessment showed that 78% of subjects claimed the active side showed improvement, compared to 31% who claimed the placebo treatment was better ( $P < 0.002$ ).

### *Amanita* spp. mushroom poisoning

The use of thioctic acid in *Amanita* spp. has been a treatment of choice in Europe since the 1960s, often alongside silymarin or silibin. Intravenous doses of 300 mg/24 h with 10% glucose in saline for up to 6 days have been used (Becker et al 1976). However, usage of ALA remains controversial, with some reports of inefficacy (Enjalbert et al 2002, Tong et al 2007), mostly because of the inability to carry out blinded RCTs in mushroom poisoning ethically (Klein et al 1989). ALA is not currently used as an *Amanita* spp. antidote in Australia (Roberts et al 2013).

### DOSAGE RANGE

As LA absorption decreases with food intake, it is recommended that LA be ingested 30–60 minutes

before meals or 120 minutes after; however, side effects are more likely on an empty stomach (Gleiter et al 1996, McIllduff & Rutkove 2011, Shay et al 2009).

According to clinical studies, oral doses for ALA are:

- Diabetes and peripheral neuropathies: 600–1200 mg/day.
- Cardiac autonomic neuropathy in type 2 diabetes patients: 800 mg/day.
- MS: 1200 mg/day.
- AD: 600 mg/day in conjunction with *N*-acetyl cysteine.
- PCOS: 600 mg twice daily.
- Hypertension: 600 mg/day.
- Burning-mouth syndrome: 200–600 mg/day — efficacy uncertain.
- Carpal tunnel syndrome: 600 mg/day.
- Wound healing: 300 mg twice daily.
- Weight loss: 1800 mg/day.
- Migraine prevention: 600 mg/day.
- Sciatic nerve pain: 600 mg/day.
- Glaucoma: 150 mg/day.

Safety and dosage have not been studied in children.

## TOXICITY

The maximum tolerated dose of ALA in human subjects has not been well defined; however, based on the observation that the oral lethal dose (LD<sub>50</sub>) for rats and mice is 1130 and 502 mg/kg, respectively, it is assumed that human beings can tolerate several grams of ALA daily. The IP LD<sub>50</sub> is 200 and 160 mg/kg for rats and mice, respectively (Biewenga et al 1997).

## ADVERSE REACTIONS

Clinical trials testing oral ALA, at concentrations as high as 1800 mg/day for 6 months and as high as 1200 mg/day for 2 years, have not identified any serious adverse effects. Similarly, a clinical trial of obese volunteers found a daily dose of 1200 mg/day or 1800 mg/day over 20 weeks was well tolerated, with the most common side effects reported as itchiness and urticaria, although the overall incidence of side effects was no different from the placebo group (Koh et al 2011).

Overall, the most common side effects of oral supplementation tend to appear when used at doses of 1200 mg and above and include nausea, vomiting, rashes, tingling and itching sensations and headaches.

Topically, ALA has been used safely for up to 12 weeks at 5% concentration. Side effects can include mild rash and local irritation, stinging and burning sensations.

Intravenously, ALA has been used at doses of 600 mg and 1200 mg daily, with side effects reported at 1200 mg. Local irritations have been reported at the injection site.

A case was reported of a 63-year-old man with multiple pathologies and taking multiple medications who was administered 600 mg/day of LA to treat diabetic neuropathy. He developed low-grade fever, nausea and fatigue and elevated serum transaminase. Discontinuation resulted in elimination of symptoms and return to normal of liver enzymes. A second attempt at treatment led to the return of symptoms and abnormal transaminase. The report investigated other potential aetiologies of liver injuries. While the authors recognise the case as unique and ALA as generally safe, they recommended liver enzyme monitoring in conjunction with ALA treatment (Ridruejo et al 2011). However the case report does not examine potential LA contamination or a drug-LA interaction as a potential aetiology for the liver enzyme abnormalities.

## SIGNIFICANT INTERACTIONS

When controlled studies are not available, interactions are based on evidence of pharmacological activity, case reports and other evidence and are largely theoretical.

### Copper

ALA is a metal chelator and binds to copper in vivo — separate doses by 3 h.

### Manganese

ALA is a metal chelator and binds to manganese in vivo — separate doses by 3 h.

### Zinc

ALA is a metal chelator and binds to zinc in vivo — separate doses by 3 h.

### Hypoglycaemic agents

Theoretically, concomitant use may affect glucose control and require medication dosage changes — observe.

### Vitamin E, vitamin C, coenzyme Q10 and glutathione

ALA reconstitutes these antioxidants from their oxidised form to their unoxidised form as part of the antioxidant cycle in humans — beneficial interaction.

### Warfarin

ALA reduces platelet reactivity in vitro (Lai et al 2010). It is uncertain whether the effect is clinically significant — observe patients taking these agents together.

### Levothyroxine

Uncertain interaction exists. When co-administered, ALA may suppress the conversion of thyroxine to triiodothyronine — decrease total cholesterol, triglycerides, albumin and total protein (Segermann et al 1991).

**? CONTRAINDICATIONS AND PRECAUTIONS**

Age is believed to affect bioavailability markedly, with older age associated with reduced bioavailability of oral supplements (Keith et al 2012).

Insulin autoimmune syndrome is a condition that develops in individuals not previously injected with pharmacological insulin; it appears to be drug-induced in about 50% of cases, especially drugs from the sulphhydryl group. In East Asians, especially Japanese, and Native Americans, there is a high expression of a human leucocyte antigen genotype that confers susceptibility to this syndrome. A number of cases have been reported in Japan after intake of ALA. Anti-insulin antibody

titres reduce after ALA discontinuation (Ishida et al 2007). The case of an Italian Caucasian woman was also reported in 2011 (Bresciani et al 2011).

ALA supplementation in pigeons and mice has caused fatal toxicity in thiamine-deficient subjects (20 mg/kg, a high dose). A theoretical basis exists for caution in prescribing LA to alcoholics, Wernicke-Korsakoff patients and other thiamine-depleting conditions. ALA does not, however, deplete thiamine in healthy or deficient individuals (Gal & Razevska 1960).

**! PREGNANCY USE**

A study of diabetic rats injected intraperitoneally with ALA improved survival of their embryos, showing that is likely that ALA can cross the placenta. It also showed a decreased rate of neural tube defects (Al Ghaffi et al 2004).

While ALA appears essential to fetal rat formation as an essential mitochondrial enzyme (Yi & Maeda 2005), no clinical trials of supplementation exist in human pregnancy or lactation.

**Practice points/Patient counselling**

- ALA is endogenously synthesised in the human body and is essential for cellular metabolism. It acts as an antioxidant, regenerates vitamins C and E and glutathione in the body, chelates metal ions and repairs oxidised proteins.
- ALA can be safely used in supplementary form at doses under 1200 mg for up to 2 years for a wide range of diseases.
- Meta-analysis supports its use in type 2 diabetes and diabetic neuropathy.
- There is preliminary clinical evidence suggesting a role in PCOS, MS, AD, hypertension, carpal tunnel syndrome, wound healing and glaucoma, although further research is required. Effects are uncertain in burning-mouth syndrome.
- Supplemental forms are often manufactured in a racemic form, but some trials show a greater efficacy with L-enantiomer.

**! PATIENTS' FAQs****What will this nutrient do for me?**

LA supplementation is used in type 2 diabetes, diabetic neuropathy, hypertension, carpal tunnel syndrome, PCOS, MS and AD. ALA confers antioxidant and neuroprotective effects as well as improving glycaemia.

**When will it start to work?**

It depends on the dose and indication for use.

**Are there any safety issues?**

LA should be used with caution in people of East Asian and Native American origin; thiamine deficiency and alcoholics; patients with cancer, high homocysteine, liver impairment, thyroid disorders; people treated for diabetes or glycaemic impairment. There are also several drug interactions that should be considered before use.

## Andrographis

**HISTORICAL NOTE** Andrographis has long been used in traditional medicine systems in numerous countries. It has been included in the pharmacopoeias of India, Korea and China, possibly because it grows abundantly in India, Pakistan and various parts of Southeast Asia. In traditional Chinese medicine, andrographis is considered a 'cold' herb and is used to rid the body of heat, as in fevers and acute infections, and to dispel toxins from the body. In Ayurvedic medicine it is used as a bitter tonic, to stimulate digestion and as a treatment for a wide range of conditions such as diabetes and hepatitis. It is still a common household remedy and found in more than half the combination tonics used to treat liver conditions in India. In recent years, andrographis has gained popularity in Western countries as a treatment for upper respiratory tract infections and influenza.

### COMMON NAMES

Andrographis, chirayata, chiretta, green chiretta, Indian echinacea, kalmegh, king of bitters

### BOTANICAL NAME/FAMILY

*Andrographis paniculata* (family Acanthaceae)

## PLANT PARTS USED

Leaves, aerial parts

## CHEMICAL COMPONENTS

The main active constituent group is considered to be the bitter diterpenoid lactones known as andrographolides. This group includes andrographolide (AP1), 14-deoxy-11,12-didehydroandrographolide (AP3) and neoandrographolide (AP4) (Lim et al 2012). Other constituents found in the plant roots include flavonoids, diterpenoids, phenylpropanoids, oleanolic acid, beta-sitosterol and beta-daucosterol (Xu & Wang 2011). Constituents identified in the aerial parts include flavonoids, alkanes, ketones, aldehydes, lactones, diterpene glucosides, driterpenoids and diterpene dimers (Akbar 2011).

Clinical studies show that andrographis is well absorbed, with peak plasma concentrations reached after 1.5–2 hours and a half-life of 6.6 hours (Panossian et al 2000).

## MAIN ACTIONS

The mechanism of action of andrographis has not been significantly investigated in clinical studies, so results from in vitro and animal tests provide most of the evidence for this herbal medicine.

## Immunomodulation

A number of immunomodulatory actions have been identified with andrographis and its derivatives (Jayakumar et al 2013). One of the main constituents responsible for the immunostimulant activity is andrographolide, which has an effect on the stimulation and proliferation of immunocompetent cells and the production of key cytokines and immune markers in vitro (Panossian et al 2002).

In vitro and in vivo research demonstrates that andrographolide has the ability to interfere with T-cell proliferation, cytokine release and maturation of dendritic cells, as well as to substantially decrease the antibody response in delayed-type hypersensitivity (Iruetagoiena et al 2005). Additionally, andrographolide demonstrated a capacity to inhibit T-cell and antibody responses in experimental autoimmune encephalomyelitis in mice, and to protect against myelin sheath damage (Iruetagoiena et al 2005).

Andrographolide has been demonstrated to inhibit production of interleukin-12 (IL-12) and tumour necrosis factor-alpha (TNF-alpha) in lipopolysaccharide-stimulated mice macrophages, which appeared to relate to suppression of the ERK1/2 signalling pathway (Qin et al 2006). It has also been found to decrease interferon-gamma (IFN-gamma) and IL-2 production and therefore display an immunosuppressive effect. As a result, Burgos et al (2005) concluded that andrographis may be useful for autoimmune disease, especially where high levels of IFN-gamma are present, for example in multiple sclerosis and rheumatoid arthritis. Interestingly, andrographolide exerted antigrowth

and proapoptotic effects in a study utilising rheumatoid arthritis fibroblast-like synoviocytes (Yan et al 2012).

Immunostimulatory activity of andrographolide in phytohaemagglutinin-stimulated human peripheral blood lymphocytes has been reported with laboratory studies (Kumar et al 2004).

Other pharmacologically active constituents are also present, as demonstrated by a study that found that the immunostimulant activity of the whole extract is greater than that of the isolated andrographolide constituent alone. Investigation with a combination of the whole extract and *Eleutherococcus senticosus* in the formula Kan Jang demonstrated a more profound effect (Panossian et al 2002).

## Anticancer activity

In vivo and in vitro experiments have demonstrated the possible benefits of andrographolide and its derivatives on various cancer cells via multiple mechanisms. According to a recent review, Lim et al (2012) identified anticancer mechanisms, including inhibition of Janus tyrosine kinases–signal transducers, inhibition of activators of phosphatidylinositol 3-kinase, transcription and NF-κB signalling pathways, suppression of growth factors, cyclins, cyclin-dependent kinases, heat shock protein 90 and metalloproteins. Andrographolide has also been shown to induce tumour-suppressor proteins p53 and p21, leading to inhibition of cancer cell proliferation, survival, metastasis and angiogenesis (Lim et al 2012). Andrographolide increases apoptosis of prostate cancer cells and human leukaemic cells and increases cell cycle arrest (Cheung et al 2005, Geethangili et al 2008, Kim et al 2005, Zhao et al 2008, Zhou et al 2006). It also inhibits the proliferation of human cancer cells and increases IL-2 induction in human peripheral blood lymphocytes in vitro (Kumar et al 2004, Rajagopal et al 2003). A cytotoxic effect of andrographolide on HepG1 human hepatoma cells was observed in a laboratory study which was attributed primarily to the induction of cell cycle arrest via alteration of cellular redox status (Li et al 2007).

In vivo results show that andrographolide increases IL-2, IFN-gamma and T-cell activity (Sheeja et al 2007). In certain circumstances, andrographolide has been found to decrease IFN-gamma and IL-2 and may have an immunosuppressive effect (see Immunomodulation, above).

Andrographis and andrographolide may also inhibit angiogenesis and cancer cell adhesion (Jiang et al 2007, Sheeja et al 2007). Antiangiogenesis and chemotherapeutic potential of andrographolide have been shown in a lung tumour mouse model. In this study, andrographolide significantly reduced expression of hVEGF-A165 compared with a control group and also decreased tumour formation (Tung et al 2013).

Halogenated di-spiropyrolizidino oxindole derivatives of andrographolide were more cytotoxic than andrographolide in some cancer cells,

according to a recent study conducted in human cancer cell lines. One of the derivatives (CY2) induced death of a number of different types of cancer cells, involving cell rounding, nuclear fragmentation and an increase in percentage of apoptotic cells, cell cycle arrest at G1 phase, reactive oxygen species (ROS) generation and involvement of the ROS-dependent mitochondrial pathway (Dey et al 2013).

### Antimicrobial

Aqueous extract of *Andrographis paniculata* has demonstrated antibacterial and antifungal activity in vitro. In various laboratory studies, activity was shown against *Bacillus subtilis*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Staphylococcus aureus* and *Candida albicans* (Singha et al 2003, Voravuthikunchai & Limsuwan 2006). An ethanolic extract of *A. paniculata* demonstrated potent inhibitory activity against both Gram-positive and Gram-negative bacteria according to an in vitro study (Mishra et al 2009).

The andrographolides from andrographis have displayed antiviral activity against herpes simplex virus type 1 in vitro (Wiert et al 2005). Inhibitory activity against the dengue virus serotype 1 has also been demonstrated in a laboratory study using a methanolic extract of andrographis (Tang et al 2012).

### Cardiovascular effects

Several in vivo studies have suggested a potential role for andrographis in cardiovascular disease. Antihypertensive effects have been demonstrated in animal models, which appear to be related to relaxation of vascular smooth muscle and a decrease in heart rate (Jayakumar et al 2013, Yoopan et al 2007). According to a recent review, early animal studies have shown that andrographis may reduce restenosis after angioplasty and may prevent myocardial reperfusion injury (Jayakumar et al 2013). In a study using rat hearts, a dichloromethane extract of andrographis significantly reduced coronary perfusion pressure by up to  $24.5 \pm 3.0$  mmHg at a 3 mg dose and heart rate was also significantly decreased at this dose (Awang et al 2012). Andrographis has demonstrated hypolipidaemic action in an experimental rat model: a significant reduction ( $P < 0.05$ ) in triglycerides, low-density lipoprotein cholesterol and blood glucose levels was observed after administration of a purified andrographolide extract (Nugroho et al 2012).

### Hypoglycaemic

Andrographis has demonstrated significant hypoglycaemic activity in vitro and in various diabetic animal models.

In vitro tests reveal that andrographis has a strong dose-dependent action on insulin production in vitro (Wibudi et al 2008) and inhibits alpha-glucosidase (Subramanian et al 2008) and increases glucose uptake via the phospholipase C/protein

kinase C pathway (Hsu et al 2004), all of which may contribute to the hypoglycaemic effect.

Hypoglycaemic and lipid lowering have also been observed in vivo in a model of type 2 diabetes. Administration of either andrographis or andrographolide extracts for 5 days significantly reduced preprandial and postprandial blood glucose levels in a dose-dependent manner. The effect was similar to that observed for metformin (90 mg/kg body weight) (Nugroho et al 2012). Similarly, oral administration of aqueous extract of andrographis to streptozotocin-induced diabetic rats resulted in a significant decrease in blood glucose levels at a dose of 400 mg/kg. This was accompanied by an antioxidant effect with an increase in superoxide dismutase and catalase activity (Dandu & Inamdar 2009). One in vivo study in alloxan-induced diabetic rats demonstrated significantly reduced blood glucose levels as compared to placebo (Reyes et al 2006). The authors commented that andrographis may restore impaired oestrous cycle in this model. A previous animal trial concluded that andrographolide (1.5 mg/kg) lowers plasma glucose by enhancing glucose utilisation in diabetic rats (Yu et al 2003).

### Hepatoprotective

Hepatoprotective activity of andrographis has been identified in vitro and in vivo using various toxic liver insults and is mainly attributed to the andrographolide constituent. A significant dose-dependent protective action has been shown against paracetamol-induced hepatotoxicity in rats. Experimental rat models have also identified a protective action for andrographis and its constituents against liver toxicity induced by galactosamine, carbon tetrachloride and tertbutylhydroperoxide. Several mechanisms have been identified (Ghosh et al 2011, Jayakumar et al 2013). Pretreatment of mice for 7 days with andrographolide and another andrographis metabolite, arabinogalactan proteins, produced a protective effect against ethanol-induced toxicity to liver and kidney tissue. In this study, at doses of 500 mg/kg body weight andrographolide and 125 mg/kg body weight arabinogalactan proteins respectively, the results were comparable to that seen with silymarin 500 mg/kg body weight. Silymarin is an established hepatoprotective agent and was used as a comparator substance in this animal study (Singha et al 2007).

### Antipyretic and anti-inflammatory

Antipyretic activity with andrographis has been demonstrated in animal models (Mandal et al 2001, Suebsasana et al 2009).

Anti-inflammatory activity has also been observed in vitro and in vivo with andrographis, which is primarily associated with andrographolide (Jayakumar et al 2013).

Andrographolide has been shown to reduce production of cytokines, chemokines, adhesion molecules, nitric oxide and lipid mediators (Lim et al 2012) as well as IL-1beta, IL-6, prostaglandin E<sub>2</sub> and thromboxane B<sub>2</sub>, and the allergic mediator

leukotriene B<sub>4</sub> (Chandrasekaran et al 2010). A decreased induction of nitric oxide synthetase and cyclooxygenase-2 has been observed in laboratory studies, probably via inhibition of the NF-κB signaling pathway (Lee et al 2011, Lim et al 2012).

*A. paniculata* extract completely inhibited inflammation induced by carageenan in mice, compared to controls (Sheeja et al 2006). In vitro data from the same study showed that andrographis inhibited superoxide (32%), hydroxyl radicals (80%), lipid peroxidation (80%) and nitric oxide (42.8%). These antioxidant mechanisms are likely to contribute to the herb's anti-inflammatory effect.

### Antiplatelet activity

Research has demonstrated that andrographis inhibits platelet-activating factor (PAF)-induced human platelet aggregation and also appears to confer additional antiplatelet activity, for which several mechanisms may be involved (Jayakumar et al 2013, Lu et al 2011, 2012, Thisoda et al 2006). A number of compounds appear to be involved in these actions. Thisoda et al (2006) identified andrographolide (AP1) and 14-deoxy-11,12 didehydroandrographolide (AP3) as key antiplatelet constituents. More recently, an additional four flavonoids were isolated that inhibit thrombin and PAF-induced platelet aggregation (Wu et al 2008).

### OTHER ACTIONS

#### Anti-HIV activity

Andrographolide derivatives have been shown to possess anti-HIV activity in vitro. Inhibition of gp120-mediated cell fusion of HL2/3 cells with TZM-bl cells was observed. There is potential for future research in this area (Uttekar et al 2012).

#### Snake antivenom activity

Andrographis ethanolic extracts have been shown to exhibit neutralising effects on cobra venom. Andrographis was shown to prolong survival time in an animal study, but did not prevent death (Premendran et al 2011).

### CLINICAL USE

Andrographis is most commonly used for its effects on immune function and inflammation, such as the treatment and prevention of upper respiratory tract infections (URTIs), while use in non-infective conditions such as ulcerative colitis and rheumatoid arthritis has also been investigated.

#### Upper respiratory tract infections and the common cold

*A. paniculata* has become popular as a treatment for URTIs. It is most often used in combination with other herbal medicines, in particular Siberian ginseng and sometimes echinacea. The fixed combination known as Kan Jang contains a standardised extract from *Andrographis paniculata* SHA-10 and *Eleutherococcus senticosus* and has been used

for more than 20 years in Scandinavia as a herbal medicinal product in uncomplicated URTI (Gabrielian et al 2002). Clinical studies confirm that treatment with andrographis either by itself or in combination with Siberian ginseng (as in Kan Jang) is beneficial in cases of uncomplicated acute URTIs, providing some symptom relief within several days; however maximal effects appear by day 5.

Clinical evidence indicates that treatment with andrographis reduces the severity of cough, expectoration, nasal discharge, headache, fever, sore throat, malaise/fatigue, sinus pain and sleep disturbances. The dose of andrographis used in various studies has differed, but the majority have used a dose standardised to 60 mg andrographolide/day (Coon & Ernst 2004, Kligler et al 2006, Poolsup et al 2004, Saxena 2010).

A systematic review (Kligler et al 2006) of seven clinical trials ( $n = 879$ ) concluded that evidence for the effectiveness of andrographis in the treatment of URTI is encouraging. At the time, the authors also made the comment that most of the studies have been done in conjunction with a major manufacturer of the product and further independent testing was required (Kligler et al 2006). Similar positive conclusions were drawn in two earlier systematic reviews. Coon and Ernst (2004) conducted a review that included seven double-blind randomised controlled trials (RCTs) and concluded that, collectively, the data suggest that andrographis is superior to placebo in alleviating symptoms of uncomplicated URTI, and has only mild, infrequent adverse effects. In five of the seven trials, the daily dose was equivalent to 60 mg of andrographolide, which was administered for 3–8 days. Another review of four RCTs confirmed that *A. paniculata*, either by itself or in combination with *E. senticosus* (Kan Jang), is effective for the treatment of uncomplicated acute URTI (Poolsup et al 2004).

More recently, the efficacy of a standardised extract of andrographis (KalmCold) was confirmed in a multicentre, double-blind RCT involving 223 adults with uncomplicated URTIs (Saxena 2010). Treatment with KalmCold (100 mg andrographis/capsule, standardised to 31.3% andrographolide), taken twice daily for a period of 5 days, resulted in a significant decrease in symptoms by day 5 compared to the placebo group for cough, expectoration, nasal discharge, headache, fever, sore throat, malaise/fatigue and sleep disturbances ( $P \leq 0.05$ ); however no improvement in the symptom of earache was observed in either group. The overall efficacy of andrographis 200 mg/day (equivalent to approximately 60 mg andrographolide/day) as KalmCold was 2.1 times higher than placebo in reducing symptoms of URTIs (Saxena 2010).

Andrographis (as Kan Jang) may also reduce the incidence of the common cold according to the available evidence. A double-blind RCT of 107 healthy school children found that treatment with Kan Jan tablets (100 mg standardised to 5.6 mg

andrographolide/tablet) taken twice daily for 5 days a week for a period of 3 months reduced the risk of developing a cold by approximately 50% after 2 months when compared to placebo. In the third month, the percentage occurrence of the common cold was 30% in the andrographis-treated group, compared to an occurrence of 62% in the placebo group. This represented a 2.1 times lower risk of the common cold in the group taking Kan Jang ( $P < 0.05$ ) (Caceres et al 1997).

### Comparisons between andrographis and echinacea in the treatment of the common cold in children

One study has compared andrographis to echinacea. However this was in the form of Kan Jang which also included Siberian ginseng, making a direct comparison difficult. An RCT involving 133 children with uncomplicated common cold compared the effectiveness of Kan Jang to Immunal (containing *Echinacea purpurea* [L.] extract), when both were used as adjuncts to standard treatment (Spasov et al 2004). The children were randomised to one of three groups. Group 1 received Kan Jang (2 tablets three times daily for 10 days) plus standard care; group 2 received Immunal (10 drops three times daily for 10 days) plus standard care; and group 3 received standard care only, including gargles and paracetamol as required. Adjuvant treatment with Kan Jang was shown to be significantly more effective than adjuvant treatment with Immunal or standard treatment alone. The group taking Kan Jang experienced less severe symptoms, in particular nasal congestion and volume of nasal secretion. Recovery time was also faster in the Kan Jang group than in the Immunal group as well as there being less need for additional standard treatment. Additionally, Kan Jang treatment was well tolerated and no side effects or adverse reactions were reported.

### Pharyngotonsillitis

A clinical benefit of andrographis in the treatment of pharyngotonsillitis was reported in one early RCT involving 152 volunteers (Thamlikitkul et al 1991). Symptoms of sore throat and fever were reduced at a dose of 6 g/day of a non-standardised andrographis preparation after 3 days. No subsequent research appears to have been conducted for this indication to confirm these results.

### Ulcerative colitis

Two RCTs have found benefits for andrographis treatment in mild to moderate ulcerative colitis.

The efficacy of *Andrographis paniculata* (HMPL-004) in the treatment of mild to moderate ulcerative colitis was assessed in a double-blind RCT ( $n = 224$ ) (Sandborn et al 2013). Two different strengths of andrographis (1200 mg, or 1800 mg per day) were compared to placebo over 8 weeks. By the end of the treatment period, a clinical response was achieved in 60% of patients receiving andrographis 1800 mg/day ( $P = 0.02$ ), compared to 45% taking

the 1200 mg dose and 40% of those taking placebo ( $P = 0.6$  andrographis 1200 mg vs placebo) (Sandborn et al 2013). Therefore, only the higher strength was significantly superior to placebo whereas the lower dose of andrographis was not effective. Interestingly, the lower dose of andrographis 1200 mg (HMPL-004) daily was as effective as slow-release mesalazine (4500 mg/day) after 8 weeks in another multicentre RCT involving 120 patients with mild to moderate ulcerative colitis (Tang et al 2011).

### Rheumatoid arthritis

Anti-inflammatory and immunomodulating effects have been observed in laboratory and animal studies providing the basis of investigation into the effects of andrographis in rheumatoid arthritis. To date, only one clinical study has been published, producing promising results.

Treatment with andrographis tablets (standardised to 30 mg andrographolide/tablet) three times a day for 14 weeks significantly reduced joint tenderness, number of swollen or tender joints and total grade of swollen or tender joints compared to placebo in a double-blind RCT involving 60 patients with active rheumatoid arthritis (Burgos et al 2009). A reduction in rheumatoid factor IgA and C4 was also observed. Of note, participants were not permitted to take non-steroidal anti-inflammatory drugs during the study and paracetamol was only used in cases of severe pain. Joint pain intensity decreased in the andrographis treatment group compared to the placebo group, but the difference was not statistically significant (Burgos et al 2009).

### OTHER USES

#### Familial Mediterranean fever — in combination

A standardised fixed combination (ImmunoGuard) of *Andrographis paniculata*, *Eleutherococcus senticosus*, *Schisandra chinensis* and *Glycyrrhiza glabra* was shown to be effective for the treatment of familial Mediterranean fever (FMF) in children (3–15 years), according to a small double-blind, randomised, placebo-controlled study (Amaryan et al 2003).

The herbal combination treatment significantly reduced the frequency, severity and duration of attacks compared to placebo. The treatment formulation included andrographis 50 mg/tablet (equivalent to 4 mg standardised andrographolide), which was given as four tablets three times a day for 1 month (Amaryan et al 2003). This herbal combination product, ImmunoGuard, has been shown to raise serum nitric oxide levels in FMF patients during attack-free periods and to have a normalising effect on blood levels of both nitric oxide and IL-6 during FMF attack periods (Panossian et al 2003).

#### HIV infection

A phase I clinical trial involving non-medicated HIV-positive patients and healthy controls found

that oral andrographolides taken for 6 weeks at increasing doses produced no significant benefits and a high incidence of adverse effects, causing the trial to be stopped prematurely (Calabrese et al 2000). A recent in vitro study concluded that andrographolide derivatives may still hold promise as a potential agent in the prevention of HIV (Uttekar et al 2012).

### Cancer (in combination)

An integrative treatment approach was investigated in 20 patients with various end-stage cancers. The patients were given a daily combination of six different immunoactive nutraceutical products plus *Andrographis paniculata* (500 mg twice daily) for 6 months. After 6 months, 16 of the 20 patients were still alive, with a statistically significant increase in both natural killer function and TNF-alpha levels. Haemoglobin, haematocrit and glutathione levels were all greatly increased (See et al 2002). Although these results are interesting, it is difficult to examine the direct effect of *A. paniculata*, as so many other nutritional supplements were given concurrently.

### Spermatogenesis

Early studies with andrographis have reported anti-fertility effects in animal models at high doses (Jayakumar et al 2013). The only clinical studies investigating this further have used the herbal combination Kan Jang which contains andrographis and Siberian ginseng, making it difficult to ascertain the effect of andrographis alone.

A phase I clinical study investigated the effects of three different strengths of Kan Jang (combination of *Andrographis paniculata* and *Eleutherococcus senticosus*) on spermatogenesis and fertility in 14 healthy men aged between 18 and 35 years (Mkrtchyan et al 2005). The men were randomised into one of five groups to receive one of the following: (1) Kan Jang equivalent to 60 mg andrographolide; (2) Kan Jang equivalent to 120 mg andrographolide; (3) Kan Jang equivalent to 180 mg andrographolide; (4) a ginseng mixture; or (5) a valerian extract. The study confirmed no significant negative effects of Kan Jang on male sperm or fertility even at doses corresponding to three times the standard daily dose and only a positive trend towards the number of active spermatozooids in the whole ejaculate (Mkrtchyan et al 2005).

### Traditional uses

The herb is traditionally given as a restorative and tonic in convalescence and used as a choleric to stimulate bile production and flow, which improves appetite and digestion. It is often used in combination with aromatic herbs, such as peppermint, for stronger digestive effects and to prevent gastrointestinal discomfort at higher doses. It has also been used in traditional cultures for protection against snake bites, to treat fever, dysentery, cholera, gonorrhoea, diabetes, influenza and dyspepsia.

### DOSAGE RANGE

The majority of clinical trials have been conducted using products standardised to the andrographolide fraction.

### Upper respiratory tract infection

- Symptomatic treatment: 100 mg twice daily of a standardised andrographis extract providing 60 mg andrographolide per day — maximal effects by day 5.
- Prevention: Kan Jang 200 mg (equivalent to standardised extract of 11.2 mg/day of andrographolide) taken daily for 2 months has been used to prevent incidence of the common cold.
- Ulcerative colitis (mild to moderate): 1200–1800 mg/daily of andrographis (HMPL-004) — maximal effects reported by week 8.
- Rheumatoid arthritis: andrographis tablets (standardised to 30 mg andrographolide/tablet) taken three times daily for at least 3 months.

### Toxicity

Animal tests suggest low toxicity (Mills & Bone 2000). Dose-related toxicity leading to termination of a study occurred at doses of 5–10 mg/kg/day of andrographolide (Calabrese et al 2000). This dose was 6–12 times higher than the standard dosage range used in all other studies.

### ADVERSE REACTIONS

Generally well tolerated with adverse effects infrequent and mild at usual recommended doses. Unpleasant chest sensation, headache, fatigue, urticaria, gastrointestinal discomfort, nausea, vomiting and metallic taste have been reported at high doses (Coon & Ernst 2004).

### SIGNIFICANT INTERACTIONS

No specific drug–herb interactions have been reported, therefore interactions are theoretical and based on evidence of pharmacological activity with uncertain clinical significance.

### Anticoagulants

Increased risk of bruising and bleeding is theoretically possible, because andrographolide and other constituents in andrographis inhibit PAF-induced platelet aggregation. However andrographis used together with warfarin did not produce any significant effects on the pharmacokinetics of warfarin, and had even less effect on its pharmacodynamics in vivo (Hovhannisyan et al 2006). Caution should still be exercised until further research is available.

### Antiplatelet drugs

Additive effects are theoretically possible, as andrographis has been shown to inhibit platelet aggregation in animal and laboratory research — patients should be observed for increased bruising or bleeding.

### Barbiturates

Additive effects are theoretically possible, according to an animal study (Mandal et al 2001).

### Hypoglycaemic agents

A hypoglycaemic effect has been observed in animal studies (Nugroho et al 2012, Wibudi et al 2008). Additive effects are theoretically possible.

### Cytochrome p450 enzyme metabolism

Andrographolide was shown to induce the CYP1A1 enzyme pathway in laboratory studies; however, the clinical significance of this is unknown (Chatuphonprasert et al 2011, Jaruchotikamol et al 2007). Another in vitro study has demonstrated an inhibitive effect of andrographis extract and andrographolide on CYP3A and 2C9 pathways (Pekthong et al 2008). Further research is required before clinical relevance can be determined.

### Immunosuppressants

Immunomodulatory activity has been observed with andrographis in vitro and in vivo (Jayakumar et al 2013). Clinical significance of use in combination with immunosuppressive drugs is not clear, but caution is advised.

### CONTRAINDICATIONS AND PRECAUTIONS

Inhibition of platelet aggregation has been observed in vitro (Thisoda et al 2006). While it is uncertain whether the effect is clinically relevant, it is advised to suspend use 1 week prior to high-risk surgery, such as neurosurgery, where a small bleed can have serious consequences.

Doses equivalent to or higher than 5 mg/kg/day of the constituent andrographolide should be avoided due to a risk of significant adverse effects (Calabrese et al 2000).

### PREGNANCY USE

There is insufficient reliable evidence available to determine safety.

### PATIENTS' FAQs

#### *What will this herb do for me?*

Human studies confirm that it is effective in reducing symptoms of the common cold and uncomplicated URTIs. New research also suggests it can reduce symptoms in ulcerative colitis and possibly rheumatoid arthritis. It reduces the risk of developing the common cold when taken with Siberian ginseng for at least 2 months.

#### *When will it start to work?*

During an acute infection, effects may be seen within 3–4 days of starting the correct dose and maximal symptom-relieving effects are seen by day

5. Used together with Siberian ginseng, it can reduce the risk of developing a cold when used for at least 2 months. Symptom relief in ulcerative colitis develops within 8 weeks and a minimum of 3 months is required to achieve benefits in rheumatoid arthritis.

#### *Are there any safety issues?*

Andrographis is not recommended in pregnancy or lactation. This herb is well tolerated but may interact with certain medications.

### Practice points/Patient counselling

- Several clinical studies suggest that andrographis, both as a stand-alone treatment and in combination with Siberian ginseng, is a useful symptomatic treatment in cases of common cold and uncomplicated URTIs, with significant symptom relief experienced after 3 days' use.
- It may also reduce the risk of the common cold when used daily for several months.
- New clinical research shows it can reduce symptoms in mild to moderate ulcerative colitis within 8 weeks and may also improve symptoms in rheumatoid arthritis when taken for at least 3 months.
- Preclinical experiments suggest that andrographis may be useful in cases of hepatotoxicity (paracetamol, alcohol), to reduce myocardial reperfusion injury, improve blood glucose management in diabetes, and in hypertension.
- Traditionally, the herb is used to increase bile production and relieve symptoms of dyspepsia and flatulence, loss of appetite and general debility.
- Because of the extreme bitterness of the herb, solid-dose forms may be better tolerated than liquid preparations.

## Astragalus

**HISTORICAL NOTE** Astragalus was first recorded in *Shen Nong's Materia Medica* about two thousand years ago and was believed to stimulate immune function and have antioxidant effects and other benefits in the treatment of viral infections and cardiovascular disease (Zhang et al 2007). The roots of astragalus are still considered among the most important and popular Chinese herbs for invigorating vital energy, health promotion and strengthening Qi. Western herbalists began using astragalus in the 1800s in various tonics and the gummy sap (tragacanth) is still used as an emulsifier, food thickener and antidiarrhoeal agent. Today, Western herbalists use astragalus as an immunomodulating agent, adaptogen and in the management of cardiovascular disease.

### **Clinical note — Polysaccharides and immunity**

Plant polysaccharides are known for their ability to enhance host defence responses. Several types of immunomodulators have been identified, most recently botanically sourced polysaccharides isolated from mushrooms, algae, lichens and higher plants. These polysaccharides tend to have a broad spectrum of therapeutic properties and relatively low toxicity. One of the primary mechanisms responsible for immunomodulation involves non-specific induction of the immune system, which is thought to occur via macrophage stimulation and modulation of the complement system. According to one report, polysaccharides isolated from 35 plant species among 20 different families have been shown to increase macrophage cytotoxic activity against tumour cells and microorganisms, activate phagocytic activity, increase reactive oxygen species and nitric oxide production, and enhance secretion of cytokines and chemokines, such as tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1 $\beta$  (IL-1 $\beta$ ), IL-6, IL-8, IL-12, interferon- $\gamma$  (IFN- $\gamma$ ) and IFN- $\beta$ 2 (Schepetkin & Quinn 2006). These effects have a major influence on the body's ability to respond rapidly and potently to a diverse array of pathogens, giving the polysaccharides wide clinical application.

### **COMMON NAME**

Astragalus

### **OTHER NAMES**

Astragali, beg kei, bei qi, hwanggi, huang-qi, milk vetch, goat's horn, green dragon, Mongolian milk, ogi, Syrian tragacanth

### **BOTANICAL NAME/FAMILY**

*Astragalus membranaceus* (family Fabaceae)

### **PLANT PART USED**

Root

### **CHEMICAL COMPONENTS**

Astragalus is a chemically complex herb and contains over 60 components, including beta-sitosterol, glycosides (astragalosides I–VII, soyasaponin, daucosterin), polysaccharides (astroglucans A–C), saponins such as cycloastragenol, astragalosides, isoflavones and other flavonoids, plant acid, choline, betaine, rumatakenin, formonetin, amino acids (including gamma-aminobutyric acid), monomeric lectin and various microelements (Duke 2003, Li & Wang 2005, Mills & Bone 2000, Yan et al 2010).

### **MAIN ACTIONS**

Evidence about mechanisms of action is mainly derived from in vitro and animal studies.

### **Immune modulation**

Studies using various experimental models indicate that astragalus and its saponins, polysaccharides and flavonoids have immune-modulating activity by

stimulating macrophage activity and enhancing B- and T-cell activity (Chu et al 1988, Jin et al 1994, Kuo et al 2009, Lonkova 2010, Shen et al 2008, Sugiura et al 1993, Sun et al 2008). Astragalus enhances lymphocyte blastogenesis in vitro (Sun et al 1983). Immunostimulant effects have also been observed in the presence of immunosuppressive therapy in vivo (Jin et al 1999).

Although usually administered in the oral form, research has also been undertaken with injectable forms. A study conducted with both normal and immunosuppressed mice found that astragalus administration increased antibody responses and T-helper cell activity (Zhao et al 1990). A flavonoid identified in the stem and leaves of astragalus is believed to be one of the main constituents responsible for immune modulation (Jiao et al 1999) and, more recently, several studies have identified that astragalus polysaccharide also exerts significant biological effects, including increasing cellular and humoral immune responses in vivo (Guo et al 2004).

Other in vitro and animal studies reveal that astragalus polysaccharides increase beneficial gut flora and decrease harmful gut bacteria, suggesting beneficial immune effects within the gastrointestinal tract (Guo et al 2003).

A 2009 animal model observed a switch to Th-1-dominant immune regulation along with increased exercise tolerance in chronic fatigue rats (Kuo et al 2009), which suggests potential benefit for the use of astragalus in postviral syndrome and chronic fatigue.

### Hypotensive and positive inotrope

Several constituents from *Astragalus* spp. have demonstrated effects on heart contractility, heart rate and blood pressure. In particular, 3-nitropropionic acid has been shown to decrease blood pressure and induce bradycardia when administered as an intravenous (IV) preparation in normotensive rats or renal hypertensive dogs (Castillo et al 1993). Another compound, astragaloside IV, demonstrated positive inotropic activity in patients with congestive heart failure (Luo et al 1995).

Recent research indicates that astragalus improves endothelial function by increasing the bioavailability of nitric oxide and decreasing reactive oxygen species production (Zhang et al 2007).

### Antioxidant

In vivo studies have found that astragalus raises superoxide dismutase activity in the brain and liver, thus demonstrating an indirect antioxidant activity (Jin et al 1999). The constituent astragaloside IV (20 and 40 mg/kg) prevented the formation of cerebral infarction after induced focal ischaemia in an animal model, most likely due to its antioxidant and anti-inflammatory actions (Luo et al 2004). Recent in vitro experiments with astragalus polysaccharides also suggest they are potent free radical scavengers of hydroxyl radicals as well as hydrogen peroxide (Niu 2011).

### Anticarcinogenic effects

Both in vitro and animal studies indicate that astragalus may have a role as adjunctive therapy in the treatment of some cancers. In vivo studies have shown that astragalus extract exerts anticarcinogenic effects in carcinogen-treated mice, mediated through activation of cytotoxic activity and the production of cytokines (Kurashige et al 1999). An extract of the root (90 and 180 mg/kg) prevented the development of preneoplastic lesions and delayed hepatic cancer in chemically-induced hepatocarcinogenesis in a rat model (Cui et al 2003). The saponin, astragaloside IV, can increase the fibrinolytic potential of cultured human umbilical vein endothelial cells by downregulating the expression of plasminogen activator inhibitor type 1 (Zhang et al 1997).

Another constituent (astragalin) increased the secretion of TNF-alpha and TNF-beta (Zhao & Kong 1993). More recent research attributes some of the antiproliferative effects of astragalus to lectins which inhibit the growth of tumour cells and induce apoptosis (L Huang et al 2012).

An animal study using a combination of *Astragalus membranaceus* and *Ligustrum lucidum* demonstrated antitumour effects by augmenting phagocyte and lymphokine-activated killer cell activities (Lau et al 1994). Via gene suppression, the saponin, astragaloside II, exerted antitumour effects, in both in vivo and in vitro experimental models on multi-drug-resistant hepatocellular carcinoma cell lines (C Huang et al 2012).

### Hypoglycaemic

There is a growing body of experimental evidence demonstrating activities of relevance in insulin resistance and its comorbidities.

A meta-analysis of nine in vivo studies on rats published from 2005 to 2007 found that astragalus significantly lowers fasting blood glucose levels (Zhang et al 2009). In vivo and in vitro experimentation of polysaccharides of astragalus corroborates these findings and hypothesises that this effect is achieved via downregulation of gene expression and gene splicing for enzymes that regulate insulin signalling at a subcellular level (Mao et al 2009). These findings are significant within the context of emerging models of pathological understanding of non-insulin-dependent diabetes, which suggest that stress created at a subcellular level by hyperglycaemia perpetuates dysregulated insulin signalling and sensitivity.

Other rodent models demonstrate lowered blood glucose, and preservation of pancreatic beta cells when compared with controls (C Li et al 2011); improved insulin sensitivity in skeletal muscle (Liu 2010, Zou et al 2009); and restoration of defective hypoglycaemia (Zou et al 2010) with astragalus treatment.

In a diabetic hamster model with concomitant cardiomyopathy, astragalus polysaccharides reduced serum glucose, glycosylated serum protein and myocardial enzymes and lipid levels increased genetic expression for GLUT-4 transporters, suggesting that

astragalus may have a significant role in diabetes and comorbid cardiomyopathy (W Chen et al 2012).

### Hepatoprotective actions

Astragalus has hepatoprotective qualities against paracetamol, carbon tetrachloride and D-galactosamine poisoning (Zhang et al 1990). Increases in liver glutathione levels observed as a result of the herbal treatment may be partly responsible. Studies have identified the constituent betaine as an important contributor to this activity.

### Renal protective

Alone and in combination, astragalus demonstrated reno-protective effects in animal models by reducing proteinuria and by protecting the microstructure of the kidney architecture (Li & Zhang 2009, Song et al 2009, Wojcikowski et al 2009).

### Neuroprotective

A decoction of astragalus produced neuroprotective effects in rats with experimentally induced cerebral ischaemia, and memory enhancement has been observed in vivo (Jin et al 1999).

## OTHER ACTIONS

Astragalus is also thought to have adaptogenic activity. It has shown weak oestrogenic activity in vitro when compared with other Chinese herbs and controls (17-beta-oestradiol). This could partially explain its traditional use in menopause.

### Traditional action

Of note is a recent in vivo study (in rats) exploring the basis for meridian tropism theory in traditional Chinese medicine (TCM), the premise of which is that particular principles in plants have an affinity for specific tissues, organs and meridians, thus influencing the therapeutic application of herbal medicines in TCM. The results produced by Chang et al (2012) confirmed that astragaloside IV was mainly distributed to the liver, kidney, lung, spleen and heart, which reflects the traditional use of astragalus and may provide experimental validity for the application of meridian tropism.

### Hypocholesterolaemic

A specific astragalus polysaccharide, extracted from *Astragalus membranaceus*, possessed hydroxyl radicals and hydrogen peroxide scavenging activities, and showed a chelating effect on ferrous ions in vitro (Niu 2011). This suggests that astragalus may have a cholesterol-lowering effect and reduces the risk of cardiovascular diseases.

### Digestive effects

Astragalus strengthens the movement and muscle tone of the small intestine (especially the jejunum) in animal tests, which may account for its clinical application in a variety of common digestive symptoms (Yang 1993).

### Improved sperm motility

An aqueous extract of *Astragalus membranaceus* was tested in vitro and found to have a significant stimulatory effect on sperm motility (Hong et al 1992). Astragalus has shown a significant effect on human sperm motility in vitro when compared with controls (Liu et al 2004).

### Cytochrome 1A2 inhibition

An experimental model found astragaloside IV inhibited the activity of the cytochrome enzyme CYP1A2 in a rat model, suggesting that astragalus may affect the pharmacokinetics of co-administered medicines and that caution should be exercised, especially in medicines with a narrow therapeutic window (Zhang et al 2013).

## CLINICAL USE

Astragalus is a popular Chinese herbal medicine and has been the subject of many clinical trials, mainly published in foreign-language peer-reviewed journals. To provide a more complete description of the evidence available, secondary sources have been used when necessary. As a reflection of clinical practice, astragalus is sometimes tested in combination with other herbal medicines, and also administered by injection in some countries. In these instances the preparation or route of administration is stated in this review.

### Viral infection

Owing to its immunomodulatory actions, astragalus is widely used for preventing and treating various viral infections. A popular use is as a preventive treatment against common colds and influenza. To date, scientific evidence is scant to confirm effectiveness, although one review stated that astragalus has been tested in clinical trials in China, reducing the incidence and shortening the duration of the common cold (Murray 1995).

A 2013 systematic review found that astragalus reduced the incidence of upper respiratory tract infections in children with nephrotic syndrome, a very common complication in this patient group (Zhou et al 2013).

### Viral myocarditis

The effect of astragalus on heart function has been the subject of several investigations and, most recently, a Cochrane systematic review, which analysed studies of Chinese herbs used in viral myocarditis. It concluded that astragalus significantly improves cardiac function, arrhythmia and creatinine kinase levels (Liu et al 2012). The review assessed data from 20 randomised controlled trials (RCTs) that used a variety of single preparations of astragalus as well as combination therapy across a range of dosage forms from decoction to injection. Where possible, comparable studies were included in a meta-analysis which revealed that astragalus injection had a significant positive effect on patients

with abnormal electrocardiograms, especially the S-T segment. The authors concluded that the studies which met the inclusion criteria for the review were overall of poor quality in terms of design, reporting and methodology.

### Cardiovascular disease

#### Congestive heart failure

Some of the clinical signs and symptoms recognised as indicators for this medicine by TCM practitioners suggest that the herb may be useful for congestive heart failure. Recent positive results obtained in clinical studies have reinforced this possibility.

Two clinical trials investigated continuous IV administration of astragalus. One study, involving 19 patients, found that after 2 weeks' continuous administration of astragaloside IV, major symptoms were alleviated in 15 patients. Treatment produced a positive inotropic effect and improved left ventricular modelling and ejection function (Luo et al 1995). The second study, involving 38 patients with congestive heart failure who were administered astragalus 24 g IV for 2 weeks, found that 13.6% had significantly shortened ventricular late potentials (Shi et al 1991).

#### IN COMBINATION

Huang-qi, a traditional Chinese medicine combination of astragalus root, licorice root and zizyphus fruit, has historically and prolifically been used and studied for the treatment of congestive heart failure. However a systematic review of 62 RCTs and quasi-RCT human trials found that, while the results seem promising for Huang-qi injections, the overall methodological quality of the studies was poorly described (Fu et al 2011).

#### Angina pectoris

Two clinical studies have suggested that astragalus may be an effective treatment for angina pectoris. One study used Doppler echocardiography to study the action of astragalus on left ventricular function in 20 patients with angina pectoris. Treatment resulted in increased cardiac output after 2 weeks, but no improvement in left ventricular diastolic function (Lei et al 1994). One Chinese study reported 92 patients with ischaemic heart disease who were successfully treated with astragalus as measured by electrocardiogram readings. Results obtained with the herb were considered superior to those obtained with nifedipine (Li et al 1995).

#### Stroke

*Astragalus membranaceus* has an established history of use in China to assist recovery after stroke. Several clinical trials have been undertaken in China to explore the mechanism of action and to measure the effect; however they have not met the standards of the International Conference on Harmonization and Good Clinical Practice guidelines, and they used positive controls (C Chen et al 2012). A more robust trial with a sample size of 68 subjects has

demonstrated that, when stroke patients are administered astragalus within 24 hours of the stroke, their functional independent outcome measures, such as dressing, eating and bladder control, were significantly improved when compared to controls at 4 and 12 weeks after the event. The researchers speculate that this may be due to the anti-inflammatory and antioxidant actions of astragalus, therefore reducing oedema (C Chen et al 2012). However inflammatory biomarkers such as erythrocyte sedimentation rate and C-reactive protein were not consistently measured after 7 days.

#### Cancer

Astragalus is used in cancer patients to enhance the effectiveness of chemotherapy and reduce associated side effects. It is additionally used to enhance immune function.

Few details are available of clinical studies looking at the potential for astragalus to alter patient survival outcomes, as most information has been published in non-English journals. However, two clinical studies are worth mentioning: they suggest that intravenously administered astragalus may have potential benefit as adjunctive therapy when given with chemotherapy. In one randomised study of 120 cancer patients receiving chemotherapy, IV astragalus extract was administered daily (20 mL in 250 mL normal saline), and tumour growth was slowed compared to controls (Duan & Wang 2002). Four treatment cycles were administered lasting 21 days each. Unfortunately, no further details are available about this study.

Another randomised study investigated IV astragalus in 60 patients with advanced non-small-cell lung cancer (Zou & Liu 2003). This time 2–3 treatment cycles were given of 21–18 days each. The mean remission rate was 5.4 months in the herbal-treated group vs 3.3 months in the untreated group, and the 1-year survival rate was 46.75% with herbal treatment vs 30.0% without. All differences were considered statistically significant. Once again, further details are not available in English.

#### Colorectal cancer

According to a 2005 Cochrane systematic review, astragalus may be a useful adjunct to chemotherapy in colorectal cancer as it reduces treatment side effects. The review assessed various Chinese herbal medicines taken in combination with chemotherapy for colorectal cancer for their ability to reduce common side effects of chemotherapy, such as nausea, vomiting, sore mouth, diarrhoea, hepatotoxicity, myelosuppression and immunosuppression (Taixiang et al 2005). Four trials were analysed: adjunctive treatment with astragalus was compared with chemotherapy alone in three trials, and with two other Chinese herbal treatments in the fourth trial. Overall, herbal treatment resulted in a significant reduction in the proportion of patients who experienced nausea and vomiting when decoctions of Huang-qi (astragalus) compounds were given in

addition to chemotherapy. There was also a decrease in the rate of leucopenia (white blood cell count  $< 3 \times 10^9/L$ ) and increased proportions of T-lymphocyte subsets: CD3, CD4 and CD8 with no significant effects on immunoglobulins G, A or M. The authors concluded that astragalus may stimulate immunocompetent cells and decrease chemotherapy side effects; however a definitive conclusion could not be made because of the studies' methodological limitations. Additionally, no evidence of harm was identified with use of the Chinese herbal treatment in these studies.

#### Prostate cancer (in combination)

Although no human studies could be located, encouraging results were obtained from an in vitro study investigating the effects of a proprietary product known as Equiguard on prostate cancer cells. It is prepared according to TCM principles and contains standardised extracts of nine herbs: herb *Epimedium brevicornum maxim* (stem and leaves), *Radix Morindae officinalis* (root), *Fructus rosae laevigatae* Michx (fruit), *Rubus chingii* Hu (fruit), *Schisandra chinensis* (Turz.) Baill (fruit), *Ligustrum lucidum* Ait (fruit), *Cuscuta chinensis* Lam (seed), *Psoralea corylifolia* L. (fruit) and *Astragalus membranaceus* (root). It is used in TCM to restore Qi in the urogenital region. The product was shown to significantly reduce cancer cell growth, induce apoptosis, suppress expression of the androgen receptor and lower intracellular and secreted prostate-specific antigen (Hsieh et al 2002).

#### Chronic kidney disease

Astragalus is one of the most commonly prescribed Chinese herbs in chronic kidney disease. Pharmacological studies have confirmed that different constituents in the herb have effects which could be valuable in chronic kidney disease such as antioxidant, diuretic and anti-inflammatory effects, and studies in rat models indicate that astragalus decreases glomerular hyperperfusion and improves kidney function (Li & Wang 2005).

A meta-analysis of 14 RCTs involving 524 Chinese patients with primary nephrotic syndrome showed that treatment with astragalus for 1–3 months could increase the therapeutic effect of prednisone and immunosuppressants (reported in Li & Wang 2005). Herbal treatment decreased proteinuria and increased levels of total cholesterol and albumin. Although further details are unavailable, these results are encouraging.

A 2011 meta-analysis measuring the clinical effect of astragalus injection in diabetic nephropathy corroborated these results (M Li et al 2011). The pooled results from 25 clinical studies that included 945 patients and 859 control subjects demonstrated that astragalus injection, when compared with controls, provided greater renal protection and systemic improvement by reducing serum urea nitrogen, serum creatinine, urine protein and urine microalbumin; and increasing serum albumin in patients

with diabetic nephropathy compared with controls (Okuda et al 2012).

A Cochrane systematic review compared the efficacy of pharmaceutical treatments and TCM for preventing infections in nephrotic syndrome in adults (Wu et al 2012). While the authors concluded that huang-qi granules (astragalus) may have positive effects on the prevention of infection in children with nephrotic syndrome, the methodological quality of all studies was poor, and there was no compelling evidence on the effectiveness of the intervention.

The efficacy of astragalus injection for hypertensive-induced renal damage was examined by systematic review of five RCTs comparing astragalus to placebo and antihypertensives (Sun et al 2012). Although the individual studies were considered to have poor methodological quality, the pooled data indicate that astragalus has protective effects for this patient group.

#### Glucose regulation

In a randomised trial of pregnant women with gestational diabetes ( $n = 84$ ), the treatment group, who received insulin plus astragalus, had better outcomes for malondialdehyde, superoxide dismutase, renal function and blood lipids compared to the control group who received insulin alone (Liang et al 2009).

#### Adaptogenic tonic – traditional use

Within traditional Chinese herbal medicine, astragalus is used to invigorate and tonify Qi and the blood, as an adaptogen, for severe blood loss, fatigue, anorexia, organ prolapse, chronic diarrhoea, shortness of breath, sweating and to enhance recuperation (Mills & Bone 2000).

#### **Clinical note — The concept of an adaptogen is foreign to Western medicine but often used in traditional medicine**

The term 'adaptogen' was first coined by N. Lazarev in the Soviet Union in the mid 20th century, although the concept has been used for centuries in traditional herbal systems. Adaptogens are considered natural bioregulators that increase the ability of the organism to adapt to environmental factors and to avoid damage from such factors. Herbal medicines with adaptogenic activity are used when extremes of physical or emotional activity are present, environmental influences are severe or allostatic load has developed over time. The aim of treatment is to improve the patient's endurance and ability to deal with these changes in a healthy way, and for abnormal parameters to shift towards normal. The best-known example of a plant adaptogen is ginseng (*Panax ginseng*), but others are also well established, such as *Schisandra chinensis*, *Eleutherococcus senticosus* (Siberian ginseng), *Astragalus membranaceus* and *Withania somnifera* (see Siberian ginseng and Glossary).

### **Cholesterol reduction (in combination with other herbs)**

A randomised, double-blind clinical trial compared the effects of a traditional Chinese herbal medicine combination known as jian yan ling (which includes astragalus as a main ingredient) to a placebo in 128 hyperlipidaemic patients. After 3 months' treatment it was found that total cholesterol, triglyceride, apo-proteins and lipoprotein-a levels were significantly reduced in the treatment group compared with placebo.

### **Asthma (in combination with other herbs and minerals)**

A herbal combination of *Astragalus membranaceus*, *Codonopsis pilulosa* and *Glycyrrhiza uralensis* was investigated in an open study for effects on airway responsiveness. Twenty-eight patients with asthma were treated with the herbal combination for 6 weeks, after which values for forced vital capacity, forced expiratory volume and peak expiratory flow were all higher than at baseline (Wang et al 1998).

In a 6-week randomised, double-blinded placebo-controlled trial of a proprietary preparation of astragalus and zinc, the intensity of rhinorrhoea was significantly improved in seasonal allergic rhinitis in 48 patients (Matkovic 2010).

### **Memory deficits (in combination with other herbs)**

In TCM, invigorating Qi and warming Yang are believed to have a beneficial therapeutic effect on some brain diseases, such as senile dementia. Some studies have been conducted to determine the outcome of following this ancient principle.

### **DOSAGE RANGE**

- Dried root: 2–30 g/day.
- Liquid extract (1:2) or solid-dose equivalent: 4.5–8.5 mL/day.
- Decoction: 8–12 g divided into two doses daily on an empty stomach.

### **TOXICITY**

Animal studies have shown that the herb has a wide safety margin.

### **ADVERSE REACTIONS**

None known.

### **SIGNIFICANT INTERACTIONS**

Interactions are theoretical and based on the herb's pharmacodynamic effects; therefore clinical significance is unclear and remains to be confirmed. There is some evidence that a component in astragalus inhibits CYP 1A2 in vivo but no human studies have tested whether the effect is clinically significant for astragalus extract. Meanwhile, clinicians should supervise patients taking drugs with a narrow therapeutic index chiefly metabolised by CYP1A2 to avoid drug interactions.

### **Aciclovir**

Possibly enhances antiviral activity against herpes simplex type 1 (Stargrove et al 2008) — adjunctive use may be beneficial.

### **Immunosuppressant medication**

Reduced drug activity is theoretically possible, as immunostimulant activity has been demonstrated — use caution.

### **Positive inotropic drugs**

Additive effects are theoretically possible with intravenous administration of astragalus, based on positive inotropic activity identified in clinical studies. The clinical significance of these findings for oral dose forms is unknown — observe patients using high-dose astragalus preparations.

### **Cyclophosphamide**

Adjunctive treatment with astragalus may have beneficial effects in regard to improving patient wellbeing and reducing adverse effects associated with treatment, such as nausea and vomiting — only use combination under professional supervision.

### **Practice points/Patient counselling**

- Astragalus is widely used as an immunostimulant medicine to reduce the incidence of the common cold and influenza and is sometimes used to improve immune responses to other viral infections, such as herpes simplex type 1.
- It is also used to enhance recuperation and reduce fatigue, and reduce the side effects of chemotherapy while improving immune function.
- Astragalus is a commonly prescribed Chinese herb in chronic kidney disease.
- According to TCM practice it is widely used to invigorate and tonify Qi and the blood, and as an important adaptogen.
- Some evidence suggests it enhances digestion, improves heart function in viral myocarditis, lowers cholesterol and fasting blood sugar and has hepatoprotective activity.
- Under the TCM system, astragalus is not used during periods of acute infection.
- In clinical practice it is often used in combination with other herbs, such as *Bupleurum chinense*, *Scutellaria baicalensis* and *Codonopsis pilulosa*. As such, most clinical trials have tested combination formulas.
- Astragalus injections are protective against chronic kidney conditions such as diabetic nephropathy and renal hypertension.
- Astragalus may improve the contractility of the heart muscle and prolong the S-T segment in patients with viral myocarditis.
- Astragalus root by oral and nasopharyngeal administration improves functional outcomes in stroke patients, when administered within 24 h of the stroke.

## ⚠️ CONTRAINDICATIONS AND PRECAUTIONS

According to the principles of TCM, astragalus should not be used during the acute stages of an infection.

## 👶 PREGNANCY USE

Safety is unknown, although no evidence of fetal damage has been reported in animal studies (Mills & Bone 2005). There were no reported safety concerns in the trial by Liang et al (2009) of pregnant women with gestational diabetes.

## ❗ PATIENTS' FAQs

### What will this herb do for me?

Astragalus appears to have numerous biological effects, such as digestive and immune system modulation, as a hypoglycaemic agent and cardiac tonic. Research suggests that it may have a role to play in recovery from viral infection, in chronic kidney disease and as an adjunct to chemotherapy treatment for cancer.

### When will it start working?

This will depend on the indication and dose; some studies have shown that effects can begin within 2 weeks.

### Are there any safety issues?

Overall the herb appears to be safe, although it has the potential to interact with some medicines. Professional supervision is advised for people receiving chemotherapy and considering using this herb.

## Baical skullcap

**HISTORICAL NOTE** Baical skullcap is a herb used in Chinese medicine to clear 'heat and dry dampness'. Diseases with heat are associated with symptoms such as fever, irritability, thirst, cough and expectoration of thick, yellow sputum. Damp diseases may be associated with diarrhoea, a feeling of heaviness of the chest and painful urination (Bensky & Gamble 1986). From a modern perspective this suggests that baical may be useful for infection and inflammation of the respiratory, digestive and urinary systems. The experimental investigations described in this monograph demonstrate that baical skullcap's constituents have antibacterial, antiviral, anti-inflammatory, hepatoprotective, anxiolytic, hypocholesterolaemic, neuroprotective and antimetastatic actions.

### OTHER NAMES

Baical skullcap, Chinese skullcap, huang qin (Mandarin), ogon (Japanese), scute

### BOTANICAL NAME/FAMILY

*Scutellaria baicalensis* Georgi (family Lamiaceae)

### PLANT PART USED

#### Root

In a notification for definition of pharmaceuticals from the Food Safety Bureau, Ministry of Health, Labour and Welfare of Japan, the roots of *Scutellaria*

*baicalensis* were classified as raw materials used as pharmaceuticals (Makino et al 2008).

While it is typically and traditionally the root of *S. baicalensis* that is used therapeutically, experimentation is also being conducted on the aerial parts (Luo et al 2009).

### CHEMICAL COMPONENTS

Baical skullcap contains resin, tannins, numerous flavonoids and their glycosides. Makino et al (2008) maintain that the flavone content in the root stock is significantly greater than that found in the aerial parts.

Baical also contains melatonin. It has been shown that dietary melatonin contributes directly to the circulating level of the hormone. The clinical effects of plant-derived melatonin remain to be investigated (Hardeland & Poeggeler 2003). Baicalin itself is poorly absorbed from the gut, but is hydrolysed to its aglycone, baicalein, by intestinal bacteria and then restored to its original form from the absorbed baicalein in the body (Akao et al 2000).

### MAIN ACTIONS

The actions of baical skullcap, some of its individual constituents and combination formulations have been studied in various models.

#### Anti-inflammatory

The anti-inflammatory activity of baical skullcap has been well documented by in vitro and in vivo studies. The main constituents responsible are baicalein and wogonin (Chang et al 2001, Chi et al 2001, Chung et al 1995, Huang et al 2006, Krakauer et al 2001, Li et al 2000a, Park et al 2001, Wakabayashi 1999). Li and Lin (2011) identified six major biologically active flavones existing in the form of aglycones (baicalein, wogonin, oroxylin-A) and glycosides (baicalin, wogonoside, oroxylin A-7-glucuronide).

In an in vitro model, Yoon et al (2009) demonstrated that a water extract of baical skullcap exerted broad anti-inflammatory effects. It significantly inhibited the activation of macrophages by lipopolysaccharides (derived from Gram-negative bacteria cell walls), the production of nitric oxide, interleukin (IL)-3, IL-6, IL-10, IL-2p40 and IL-17, interferon-inducible protein-10, keratinocyte-derived chemokine and vascular endothelial growth factor.

These results are corroborated in a mouse model where baical skullcap was a potent inhibitor of multiple inflammatory markers and mediators, including inducible nitric oxide synthase (iNOS), cyclooxygenase-2 (COX-2), prostaglandin E<sub>2</sub> (PGE<sub>2</sub>), IL-1 $\beta$ , IL-2, IL-6, IL-12 and tumour necrosis factor- $\alpha$  expression (Kim et al 2009).

In a study using mice, baicalein 50 mg/kg has been shown to ameliorate the inflammatory symptoms of induced colitis, including body weight loss, blood haemoglobin content, rectal bleeding and other histological and biochemical parameters (Hong

et al 2002). Pretreatment with wogonin also significantly reduced ethanol-induced gastric damage in vivo (Park et al 2004) and reduced immunoglobulin E (IgE), IL-4, IL-5 and IL-10 secretion in a colitis-induced mouse model (Lim 2004). The methanolic extract of the baical skullcap root and its flavonoids wogonin, baicalein and baicalin have been shown to inhibit lipopolysaccharide-induced inflammation of the gingivae (gums) in vivo. The three flavonoids exerted an anti-inflammatory effect similar to prednisolone. In addition, the flavonoids exerted a moderate inhibition (33–36%) of collagenolytic activity, comparable to the 40% inhibition by tetracycline. Meanwhile, the cellular activity of fibroblasts was augmented remarkably (40%) by baicalein and slightly by baicalin and wogonin. Consistent with the cellular activation, the flavonoids enhanced the synthesis of both collagen and total protein in fibroblasts in vitro (Chung et al 1995).

The anti-inflammatory mechanisms are varied and summarised below.

#### Chemokine binding

In vivo and in vitro data suggest that *Scutellaria baicalensis* may prove to be a useful anti-inflammatory agent through its downregulation of the expression of various inflammatory mediators by limiting the biological function of chemokines (Jung et al 2012).

Excessive release of proinflammatory cytokines mediates the toxic effect of superantigenic staphylococcal exotoxins. In vitro data suggest that baicalin may be therapeutically useful for mitigating the pathogenic effects of staphylococcal exotoxins by inhibiting the signalling pathways activated by superantigens (Krakauer et al 2001).

Baicalin inhibited the binding of a number of chemokines to human leucocytes or cells expressing specific chemokine receptors, with an associated reduced capacity of the chemokines to induce cell migration. Based on these results, it is possible that the anti-inflammatory mechanism of baicalin is to bind a variety of chemokines and limit their biological function (Bao et al 2000, Li et al 2000a).

Four major flavonoids from baical skullcap have been shown in vitro to suppress eotaxin. Eotaxin is an eosinophil-specific chemokine associated with the recruitment of eosinophils to sites of allergic inflammation. Eotaxin is produced by IL-4 plus tumour necrosis factor (TNF)- $\alpha$ -stimulated human fibroblasts. This may explain why it has been used traditionally in the treatment of bronchial asthma (Nakajima et al 2001). In a rat model, baicalin inhibited induced eosinophilia and associated airway restriction by lowering IL-4 and IL-17A levels (Ma et al 2014).

#### COX-2 inhibition

Wogonin is a direct COX-2 inhibitor. Wogonin inhibits both iNOS and COX-2 induction (Chen et al 2001, 2008, Chi et al 2001, Wakabayashi & Yasui 2000). Wogonin has been shown to inhibit inducible PGE<sub>2</sub> production in macrophages by

inhibiting COX-2 (Wakabayashi & Yasui 2000). Additionally baicalein, but not baicalin, has been shown to inhibit COX-2 expression in lipopolysaccharide-induced RAW 264.7 cells (a murine leukaemic macrophage-like cell line) (Woo et al 2006). Both compounds also suppressed iNOS protein expression, iNOS mRNA expression and NO production in a dose-dependent manner.

Wogonin may be beneficial for COX-2-related skin disorders. When applied topically to the dorsal skin of mice, it inhibited COX-2 expression and PGE<sub>2</sub> production (Byoung et al 2001, Chi et al 2003, Park et al 2001).

### Lipoxygenase inhibition

The inhibition of the 5-lipoxygenase pathway of arachidonic acid metabolism may be one of the mechanisms of baicalein's anti-inflammatory activity, according to an in vivo study (Butenko et al 1993).

### Antioxidant activity

The anti-inflammatory activity of baicalein may be associated with inhibition of leucocyte adhesion by the scavenging of reactive oxygen intermediates (Shen et al 2003).

### Nuclear factor-kappa B (NF-κB) inhibition

Baicalin has been shown to inhibit NF-κB in vitro (Cheng et al 2007, Hsieh et al 2007, Kim et al 2006, Wang et al 2006), and microglial cells treated with wogonin indicated that the anti-inflammatory activity is exerted at least in part by suppressing microglial cell motility via inhibition of NF-κB activity (Piao et al 2008).

### Antifibrotic

A methanolic extract of baical skullcap has been shown to inhibit fibrosis and lipid peroxidation induced by bile duct ligation or carbon tetrachloride in rat liver. Bile duct ligation in rodents is an experimental model for extrahepatic cholestasis caused by, for example, cholelithiasis (gallstones). Liver fibrosis was assessed by histological observation and by measuring levels of liver hydroxyproline, lipid peroxidation based on malondialdehyde production and serum enzyme activities. Treatment with baical skullcap significantly reduced the levels of liver hydroxyproline and malondialdehyde, with improved histological findings (Nan et al 2002).

In a 12-week study hypertensive rats treated with baicalein (flavone) had decreased heart to body weight ratio (a measure of left ventricular hypertrophy), decreased systolic blood pressure, decreased intraventricular thickness and a reduced expression of collagen and 12-lipoxygenase in cardiac tissue (antifibrotic), with the effect being more pronounced at the higher dose of 200 mg/kg/day (Kong 2011).

In an in vitro model, an ethanolic extract of baical skullcap (of unknown concentration) reduced markers associated with liver fibrogenesis such as

collagen content and smooth-muscle actin, and also induced apoptosis of hepatic stellate cells, which are known to be implicated in the pathogenesis of liver fibrosis (Pan 2011).

### Hepatoprotective

Baicalein, baicalin and wogonin have been shown to have hepatoprotective effects in vivo. The flavonoids decrease the toxicity produced by a variety of chemicals. Significant protective effects were seen by comparing the serum levels of aspartate transaminase (AST) and alanine aminotransferase (ALT) and by histopathological examination (Lin & Shieh 1996). Two different dried root preparations of baical skullcap (1% of total feed) were added to the diet of animals that were subsequently exposed to aflatoxin-B<sub>1</sub> (de Boer et al 2005). Mix A contained 3.13 mcg/g baicalin, 1.5 mcg/g baicalein, 0.021 mcg/g wogonin and 65.3 nmol/g melatonin compared to 0.94 mcg/g baicalin, 0.41 mcg/g baicalein, 0.003 mcg/g wogonin and 1176 nmol/g melatonin in mix B. The addition of mix A and B reduced hepatic damage by approximately 60% and 77%, respectively. The feed mixtures also increased the expression of the gene for glutathione-S-transferase A<sub>3</sub> by 2.5–3.0-fold. Interestingly, the mix with the lower concentration of flavonoids was the more protective. The authors explain this by stating that it was probably due to the much higher (18-fold) amount of melatonin which has been shown to enhance aflatoxin detoxification pathways in animals.

Baicalein, baicalin and wogonin have also been shown to inhibit haemin-nitrite-H<sub>2</sub>O<sub>2</sub>-induced liver injury in a dose-dependent manner by inhibiting oxidation and nitration (Zhao et al 2006). In other in vitro and in vivo studies baicalin reduced *tert*-butyl hydroperoxide hepatic damage, attenuated glutathione depletion, ALT and AST levels and reduced oxidative stress (Huang et al 2005). Additionally, further histopathological examination showed a significant reduction in the incidence of hepatic lesions and swelling. More recently it was found that baicalein significantly elevated the serum level of TNF-α and IL-6 in mice, in the early phase after liver injury was induced by carbon tetrachloride, suggesting that it may have a part to play in liver regeneration (Huang et al 2011).

### IN COMBINATION

The combination Sho-saiko-to (a Japanese herbal supplement containing baical skullcap, also known as Minor Bupleurum Combination, and Xiao Chai Hu Tang in Mandarin) has been shown to inhibit chemical hepatocarcinogenesis in animals, act as a biological response modifier and suppress the proliferation of hepatoma cells by inducing apoptosis and arresting the cell cycle. These effects may be due to baicalin, baicalein and saikosaponins (from *Bupleurum falcatum*), which have the ability to inhibit cell proliferation (Shimizu 2000). Further testing is required to determine the role of baical skullcap in achieving these effects.

## Antioxidant

Several studies have shown that baical skullcap constituents exert antioxidant activity in vitro and in vivo. Flavones produced a concentration-dependent protection of liposome membrane against ultraviolet-induced oxidation. The ability to scavenge free radicals and protect against the effects of lipid peroxidation (in this case, caused by sunlight irradiation) may in part account for the herb's underlying mechanism of action (Gabrielska et al 1997).

Fourteen flavonoids and flavone glycosides demonstrate good free radical-scavenging properties in vitro (Gao et al 1999, Lin & Shieh 1996). Baicalin has been found to have the most potent antioxidant effect (Bochorakova et al 2003).

Baicalin's antioxidant effect is based on scavenging superoxide radicals, whereas baicalein is a good xanthine oxidase inhibitor. Xanthine oxidase inhibitors are known to be therapeutically useful for the treatment of hepatitis and brain tumours (Gao et al 2001). Baicalin was also an efficient antioxidant in reducing hyperglycaemia-induced oxidative stress through the increased expression of antioxidant enzyme activities in rats (Waisundara et al 2011).

Oxidative stress plays an important role in the pathological process of neurodegenerative diseases, including Alzheimer's disease. The protective effects of baical flavonoids on the oxidative injury of neuronal cells have been demonstrated in vitro (Choi et al 2002, Gao et al 2001).

## Antiallergic

Various flavonoids from baical skullcap, including wogonin and baicalein, have been shown to inhibit chemically induced histamine release from rat mast cells in vitro (Kubo et al 1984). *Scutellaria baicalensis* inhibited passive cutaneous anaphylaxis reaction and decreased histamine release in rat peritoneal mast cells. In human mast cells *S. baicalensis* moderated the allergic response by restoring IL-8 and TNF- $\alpha$  expression and inhibiting MAP kinase expression (Jung et al 2012).

Luteolin and baicalein have been shown to inhibit IgE antibody-mediated immediate and late-phase allergic reactions in mice. In an in vitro study, luteolin and baicalein inhibited IgE-mediated histamine release from mast cells. Wogonin, wogonoside and 3,5,7,2',6'-pentahydroxyl flavanone isolated from baical skullcap decrease histamine, leukotriene B<sub>4</sub> and IgE in vitro (Lim 2004).

In rats and in human mast cells baical skullcap inhibits IgE-mediated allergic reactions by decreasing histamine, and suppressing IL-8 and TNF- $\alpha$  expression in human mast cells (Jung et al 2012, Kimata et al 2000).

Baicalein is 5–10-fold more potent than the anti-allergic drug azelastine. Baicalein significantly suppressed leukotriene C<sub>4</sub> release by polymorphonuclear leucocytes obtained from asthmatic patients compared with healthy subjects (Niitsuma et al 2001).

## Neuroprotective

Many in vitro and in vivo trials have demonstrated the neuroprotective effects of flavonoids derived from baical skullcap (Cho & Lee 2004, Heo et al 2004, Piao et al 2004, Shang et al 2006a, Son et al 2004). Gasiorowski et al (2011) suggest that the flavones of baical skullcap prevent neural injury through a strong antioxidant effect, by moderating inflammation and by increasing GABAergic signaling (anxiolytic and anticonvulsant effect) and that wogonin exerts neurogenerative action, based on in vitro and in vivo evidence.

Cerebral ischaemia can cause a significant elevation in the concentrations of amino acid neurotransmitters in the cerebral cortex. Baicalin administration can attenuate the elevations of glutamic acid and aspartic acid induced by cerebral ischaemia. This research demonstrates that baicalin may act as a neuroprotectant during cerebral ischaemia. Wogonin has been shown to exert a neuroprotective effect by inhibiting microglial activation, which is a critical component of pathogenic inflammatory responses in neurodegenerative diseases.

Baicalin (200 mg/kg) intraperitoneally injected into gerbils immediately after cerebral ischemia significantly improved neural dysfunction by reducing the damage to the gamma-aminobutyric acid (GABA)-inhibitory system, together with a protective effect observed at a protein-folding level (Dai et al 2013). In another gerbil model, baicalin injection immediately after induced ischaemia significantly reduced hippocampal neuronal damage at 100 and 200 mg/kg (Cao et al 2011). The investigators suspect the neuroprotective action is exerted via antioxidant (decreasing markers for lipid peroxidation), and antiapoptotic properties, increasing brain-derived neurotrophic factor, which inhibits caspase-3. These findings are significant as they suggest viable alternatives or adjuncts to the current treatment with thrombolytics. Comparatively, in a rat model of induced intracerebral haemorrhage, baicalin, injected intracerebrally, attenuated brain oedema and inhibited cell in a dose- and time-dependent manner, suggesting that baicalin has protective effects on intracerebral haemorrhage-induced brain injury (Zhou et al 2012).

An in vivo study in rats induced with permanent global ischaemia demonstrated that daily oral doses of baical skullcap flavonoids (35 mg/kg) for 19–20 days significantly increased learning and memory ability and attenuated neural injury (Shang et al 2005). A follow-up in vivo study demonstrated that the flavonoid fraction also reduced neural damage and memory deficits after permanent cerebral ischaemia (Shang et al 2006b). Huang lian jie du tang (HLJT) from China or oren gedoku to (Japan) is an important Asian multiherb combination remedy, containing *Scutellaria baicalensis*, which is clinically used to treat cerebral ischaemia (Zhu et al 2012).

It also appear that baical skullcap may have a role in neurogenerative disorders such as Parkinson's

disease and Alzheimer's dementia. In induced memory loss model in rats treated with 30 mg/kg baical skullcap, increased numbers of cholinergic neurons (associated with memory and learning) were observed, along with and protected by *N*-methyl-*D*-aspartic receptors, which are associated with neuroplasticity (Heo et al 2009).

Mu et al (2009) also observed an antiapoptotic effect in a rat model of Parkinson's disease, as well as reduced tremor. In test tube and in vivo mouse model, Zhang et al (2013) noted that intraperitoneal injections of baicalin for 8 weeks retarded plaque formation and disease pathogenesis.

Another in vivo study investigated the neuroprotective effects of baicalein in a parkinsonian experimental model and demonstrated improved motor coordination and a reduction in spontaneous motor activity (Cheng et al 2008). This was thought to be the result of increased dopamine and serotonin levels in the striatum, leading to increased dopaminergic neurons and an inhibition of oxidative stress. Baical skullcap is used in traditional Chinese medicine (TCM) for the treatment of stroke. Methanol extracts from the dried roots (0.1–10 mg/kg intraperitoneally [IP]) significantly protected neurons against 10 minute transient forebrain ischaemia. The extract inhibited microglial TNF- $\alpha$  and NO production, and protected cells from hydrogen peroxide-induced toxicity in vitro (Kim et al 2001).

### Hypotensive

Treatment with baicalein lowered blood pressure in hypertensive but not in normotensive rats according to one study (Takizawa et al 1998). Baical extract and baicalein have also been shown to lower blood pressure in rats and cats (Kaye et al 1997, Takizawa et al 1998). The exact mechanisms underlying the hypotensive action are unclear. One in vivo study has shown that *Scutellaria baicalensis* extract produces peripheral vasodilation (Lin et al 1980). A 2005 review concluded that baical skullcap is effective for renin-dependent hypertension and that in vivo effects may be due to the inhibition of lipoxygenase, reducing the production and release of arachidonic acid-derived vasoconstrictor substances (Huang et al 2005).

### Vascular activity

Monocyte chemoattractant protein-1 (MCP-1), a potent chemoattractant for monocytes, plays a crucial role in cases of early inflammatory responses, including atherosclerosis. Wogonin has been shown to inhibit MCP-1 induction by endothelial cells in a dose-dependent manner. Wogonin and baical skullcap may be potentially beneficial in inflammatory and vascular disorders (Chang et al 2001). Baicalein significantly suppressed intimal hyperplasia and cell proliferation in a vascular injury study in vivo (Peng et al 2008).

### Antiplatelet

Baical flavonoids have been shown to inhibit platelet aggregation in vitro (Kubo et al 1985). Baicalein

inhibited the elevation of calcium induced by thrombin and thrombin receptor agonist peptide. These findings suggest a potential benefit of baicalein in the treatment of arteriosclerosis and thrombosis (Kimura et al 1997).

### Cholesterol reduction

Flavonoids are known to reduce cholesterol. A 30-day study of induced hyperlipidaemia in rats found that baicalein, quercetin, rutin and naringin reduced cholesterol, with baicalein the most potent. Baicalein was also the most effective flavonoid in reducing triglyceride levels (De Oliveira et al 2002). In another in vivo study, rats were fed a cholesterol-laden diet and half were also given *S. baicalensis* radix extract (Regulska-Ilow et al 2004). The treatment rats displayed a significant reduction in plasma triglycerides and total cholesterol compared with control animals. The mechanism may be due to the increased activity of lecithin cholesterol acyltransferase (You et al 2008).

Mice treated with 10 mg/kg of wogonin for 2 weeks had significantly decreased insulin, cholesterol, fat and glycogen accumulation in the liver and slowed weight gain, when compared with the control group (Bak et al 2013). Similarly, in an obese mouse model baical skullcap at 200 mg/kg for 4 weeks improved weight, hypertriglyceridaemia and hyperinsulinaemia, reduced ALT levels (a marker of liver damage) and restored metabolic process and insulin signalling pathways (Song et al 2013).

### Anxiolytic

Wogonin, baicalein, scutellarein and baicalin (in reducing order of potency), which all contain a certain flavonoid phenyl benzopyrone nucleus, have been shown in vitro to bind with the benzodiazepine site of the GABA-A receptor (Hui et al 2000).

Oral administration of wogonin (7.5–30 mg/kg) has been shown to interact with GABA-A receptors and produce an anxiolytic response that was similar to diazepam in the elevated plus maze. Unlike benzodiazepines, wogonin was able to reduce anxiety without causing sedation or myorelaxation (Hui et al 2002, Kwok et al 2002).

Baicalin (10 mg/kg IP) and baicalin (20 mg/kg IP) have also been shown in vivo to produce an anxiolytic effect, mediated through activation of the benzodiazepine-binding sites of GABA-A receptors (Liao et al 2003).

Two other flavones, 5,7-dihydroxy-6-methoxyflavone (roxylin A) and 5,7,2'-trihydroxy-6,8-dimethoxyflavone (K36), also act as antagonists at the GABA-A recognition site and have demonstrated anxiolytic activity in vivo (Huen et al 2003a, 2003b).

A water extract of baical skullcap demonstrated anticonvulsant activity against electroshock-induced tonic seizures in vivo. Interestingly, the authors suggest that the effect might not be via the activation of the benzodiazepine-binding site of GABA-A receptors, but probably via the prevention of seizure

spread (Liao et al 2003, Wang et al 2000). A more recent study has shown that wogonin has anticonvulsive effects mediated by GABA (Park et al 2007).

### Hypnotic

In a rodent model baicalin exerted a biphasic effect on the sleep-wake cycle and exerted a delayed somnogenic effect by acting as a selective agonist of GABA receptors subtype A (Chang et al 2011). The authors speculate that the 8-hour delay to exert this effect may be due to low affinity for the receptor and also observe that another flavonoid, wogonin, has an antagonistic action on the same receptors, perhaps explaining why the whole plant is not traditionally noted for its hypnotic effect. An anxiolytic effect, via the GABA subtype A pathway and independently of a serotonergic effect, was also observed in a rodent model (de Carvalho et al 2011).

### Antimicrobial

Numerous studies have found that baical extract and flavonoids exert antibacterial, antiviral and antifungal actions. The antimicrobial effect of baical extract is mild and the clinical efficacy of baical in infectious diseases may be more associated with its anti-inflammatory rather than its antimicrobial activities.

### Antibacterial

Baical skullcap and its components have demonstrated antibacterial and bacteriostatic effects in vitro.

The addition of baicalein to standard antibiotic therapy for multiresistant *Staphylococcus aureus* (MRSA) prevents growth of the bacteria by increasing its susceptibility to the antibiotic ciprofloxacin, possibly by inhibiting the NorA efflux pump, which is known to pump the antibiotic out of the bacteria (Chan et al 2011). This finding provides optimism for the treatment of antibiotic-resistant bacterial strains.

Baical skullcap decoction was investigated for bacteriostatic and bactericidal activity against a selection of oral bacteria, including suspected periodontopathogens. At a concentration of 2%, the decoction was bacteriostatic for 8 of 11 bacteria tested, but a concentration of 3.13% or greater was required for bactericidal effect (Tsao et al 1982).

Baical aqueous extract, but not its flavonoids, baicalin and baicalein, demonstrated antibacterial effects against the enteric pathogen *Salmonella typhimurium*. The effect was compatible with commercial antibiotics, including ampicillin, chloramphenicol and streptomycin. In contrast, the growth of a non-pathogenic *Escherichia coli* strain was unaffected by baical (Hahm et al 2001). One study demonstrated that the addition of baical skullcap in vitro improved the responsiveness of antibiotics for the treatment of MRSA (Yang et al 2005). Baicalin has been shown to reduce the pathogenic effects of superantigenic staphylococcal exotoxins by inhibiting the signalling pathways activated by superantigens (Krakauer et al 2001).

Baicalin and *Scutellaria baicalensis* have been shown to be bactericidal against *Helicobacter pylori*, with the activity of the flavonoid baicalin greater than that of baical skullcap in assays (Wu et al 2008).

### Antiviral

Antiviral effects have been demonstrated for baical in numerous in vitro and in vivo tests. Baical extract significantly inhibits hepatitis C RNA replication in vivo (Tang et al 2003) and in vitro studies have found that:

- Chloroform and ethyl acetate extracts of baical skullcap inhibited replication of influenza A virus subtypes in vitro, including pandemic 2009 H1N1, seasonal H1N1 and H3N2, via inhibition of neuraminidase by baicalin (Hour 2013). These findings are valuable in the development of antiviral agents; however, it must be noted that the solvent preparations used in this study do not reflect the traditional preparations of herbal medicines from Chinese or Western traditions.
- Intraperitoneal and intranasal administration of baical flavonoids significantly inhibits influenza virus in vivo and in vitro (Nagai et al 1989, 1992a, 1992b, 1995a, 1995b).
- Baicalein inhibits HIV-1 infection at the level of viral entry (a process known to involve interaction between HIV-1 envelope proteins and the cellular CD4 and chemokine receptors) (Li et al 2000b).
- Baicalin inhibits human T-cell leukaemia virus type I (Baylor et al 1992).
- Aqueous extract inhibits HIV-1 protease (Lam et al 2000).
- Baicalin inhibits HIV-1 infection and replication (Li et al 1993).
- Baical flavonoids inhibit Epstein-Barr virus early antigen activation (Konoshima et al 1992).
- Wogonin suppresses hepatitis B virus surface antigen production without evidence of cytotoxicity (Huang et al 2000).
- 5,7,4'-trihydroxy-8-methoxyflavone inhibits the fusion of influenza virus with endosome/lysosome membrane (Nagai et al 1995a).
- Virus replication is suppressed, partly by inhibiting the fusion of viral envelopes with the endosome/lysosome membrane, which occurs at the early stage of the virus infection cycle (Nagai et al 1995b).
- The flavones in baical have potent influenza virus sialidase-inhibitory activity and anti-influenza virus activity in vivo (Nagai et al 1992b).
- Baicalin may selectively induce apoptosis of HIV-infected human T-leukaemia (CEM-HIV) cells, which have a high virus-releasing capacity, and stimulate proliferation of CEM-HIV cells, which have a relatively lower capacity of HIV production (Wu et al 1995).
- In cell cultures and in mice, combinations of baicalein and ribavirin provided better protection against H1N1 influenza infection than each compound used alone and could potentially be clinically useful (Chen et al 2011).

### Antifungal

Antifungal activity has been demonstrated by several studies (Blaszczyk et al 2000, Yang et al 1995). *Chlamydia trachomatis* was inhibited at doses of 0.12 and 0.48 mg/mL in vitro, by reducing CPAF expression, a protein which protects the infection was host immune defences (Hao et al 2009). Baical extract showed clear fungistatic activities in vitro against some cutaneous and unusual pathogenic fungi, and particularly against strains of *Candida albicans*, *Cryptococcus neoformans* and *Pityrosporum ovale*. The antifungal substance was isolated and found to be baicalein (Yang et al 1995). Of 56 Chinese antimicrobial plants, baical root extract had the highest activity against *Candida albicans* (Blaszczyk et al 2000).

### Antilcerogenic

Extracts prepared from grass and roots of *S. baicalensis* showed high antilcerogenic activity in vivo (Amosova et al 1998). Pretreatment for 1 h with the flavonoid wogonin attenuated the rodent gastric mucosal damage in a dose-dependent fashion (3, 10, 30 mg/kg), with the protective effect being superior to the indicated medication rebamipide (Park 2004). This protective effect is exerted by inhibiting COX and lipoxygenase enzymes in the arachadonic acid pathway and the early induction of the anti-inflammatory PGE<sub>2</sub> as well as preventive apoptosis induction.

### Antidiabetic

#### 5-alpha-aldose inhibition

Diabetic patients may accumulate intracellular quantities of the sugars sorbitol and dulcitol, because of an increase in the polyol pathway involving the enzyme 5-alpha-aldose. Oral baicalin and liquid extract of licorice (also rich in flavonoids) reduced the sorbitol levels in the red blood cells of diabetic rats (Lin et al 1980, Zhou & Zhang 1989). *Scutellaria baicalensis* enhanced the antidiabetic effect of metformin in streptozocin-induced diabetic rats by improving the antioxidant status. It also increased pancreatic insulin content as well as improved the lipid profile in these rats (Waisundara et al 2008). And in healthy mice, administration of 10 mg/kg of wogonin produced improved glucose tolerance, reduced cholesterol and insulin, and reduced hepatic liver droplets when compared with controls (Bak et al 2013).

#### Alpha-glucosidase inhibition

Alpha-glucosidase inhibitors (e.g. acarbose) are a class of oral medicine for type 2 diabetes, which blocks the enzymes that digest starches in food. The result is a slower and lower rise in blood glucose throughout the day, especially immediately after meals. Methanol extracts of *S. baicalensis*, *Rheum officinale* and *Paeonia suffruticosa* showed potent inhibitory activity against rat intestinal sucrase. The active

principles were identified as baicalein and methyl gallate (from the latter two plants). In addition to its activity against the rat enzyme, baicalein inhibited human intestinal sucrase in vitro (Nishioka et al 1998).

### Antiemetic

Pretreatment with baical root extract has been shown to decrease cisplatin-induced pica in rats (animal models use the level of kaolin [type of clay] intake as a measure of the intensity of nausea). This suggests that baical may help to reduce cisplatin-induced nausea and emesis during cancer therapy (Aung et al 2003, Mehendale et al 2004, Wu et al 1995), although clinical testing is required to confirm significance.

Two in vivo trials found that *S. baicalensis* significantly attenuated ritonavir-induced pica, and demonstrated possible efficacy for the management of ritonavir-induced nausea in HIV treatment (Aung et al 2005, Mehendale et al 2007).

### Renal-urinary tract activity

Baicalein inhibited angiotensin II-induced increases in the cellular protein content of aortic smooth-muscle cells in vitro (Natarajan et al 1994). In another in vitro study, baicalein prevented the angiotensin II-induced increase in renal vascular resistance by 50% and promoted glomerular filtration rate (Bell-Quilley et al 1993). Pretreatment with baicalein significantly inhibited a decrease in nephrotoxin-induced glomerular filtration rate and renal blood flow in vivo (Wu et al 1993). Oral intake of baical flavonoids and extract has been shown to produce a diuretic effect.

### Anticancer

#### Immunostimulation (in combination)

Sho-saiko-to has been shown to stimulate granulocyte colony-stimulating factor (G-CSF), which may explain its use in infectious diseases and cancer (Yamashiki et al 1992). Like growth hormone, IL-2 and IL-4 and interferon, G-CSF is a signalling ligand that stimulates immune function. G-CSF, a glycoprotein produced mainly by macrophages, induces proliferation of neutrophil colonies and differentiation of precursor cells to neutrophils. It also stimulates the activity of mature neutrophils (Hill et al 1993).

Sho-saiko-to is known to significantly suppress cancer development in the liver. Moderate regulation of the cytokine production system in patients with hepatitis C with Sho-saiko-to may be useful in the prevention of disease progression (Yamashiki et al 1997). One possible mechanism for the beneficial effects of this formula in patients with liver cirrhosis may be the improvement in production of IL-12, which is an important cytokine for maintenance of normal systemic defence and bioregulation. This effect of Sho-saiko-to is attributed to two of its seven herb components, baical and licorice root (Yamashiki et al 1999).

Patients who were given baical skullcap showed a tendency towards an increase in the relative number of T lymphocytes and their theophylline-resistant population during antitumour chemotherapy. The immunoregulation index in this case was approximately twice the background value during the period of investigation. The inclusion of baical skullcap in the therapeutic complex promoted an increase in the number of IgA at a stable level of IgG (Smolianinov et al 1997).

### Apoptosis induction

Baicalein, baicalin and wogonin have been shown to induce apoptosis, disrupt the mitochondria and inhibit proliferation in various human hepatoma cell lines (Chang et al 2002, Chen et al 2000). The platelet-type 12-lipoxygenase (12-LOX) pathway is a critical regulator of prostate cancer progression and apoptosis by affecting various proteins regulating these processes. Baicalein inhibits 12-LOX and may be a potential therapeutic agent in the treatment of prostate cancer (Pidgeon et al 2002) as well as breast cancer (Tong et al 2002) and lung cancer (Leung et al 2007). Crude ethanolic extracts of baical skullcap and its components baicalin, baicalein and wogonin are cytotoxic to lung cancer cell lines by inducing cell death, interfering with cell life cycles and regulating the expression of cyclin proteins (Gao 2010, Gao et al 2011).

### Antiproliferative

Baicalein, baicalin and wogonin have been shown to induce apoptosis and inhibit proliferation in various human hepatoma cell lines (Chang et al 2002).

Baicalin has been shown to inhibit the proliferation of prostate cancer cells in vitro. However, the response to baicalin differed among different cell lines (Chan et al 2000). Whereas a baicalin-deprived fraction of baical skullcap arrested the growth of, and induced apoptosis of, breast cancer cell lines in an in vitro model, a whole extract of baical skullcap actually promoted cell growth (Wang et al 2010). Similar outcomes were observed on multiple myeloma cells exposed to wogonin in vitro (Zhang et al 2013).

COX-2, which converts arachidonic acid to PGE<sub>2</sub>, is highly expressed in head and neck squamous cell carcinoma (HNSCC). *S. baicalensis*, but not baicalein, suppressed proliferation, cell nuclear antigen expression and PGE<sub>2</sub> synthesis. A 66% reduction in tumour mass was observed in the mice with HNSCC. Baical selectively and effectively inhibits cancer cell growth in vitro and in vivo and can be an effective chemotherapeutic agent for HNSCC (Zhang et al 2003).

In a study designed to determine the ability of baical skullcap to inhibit various human cancer cells in vitro, *S. baicalensis* demonstrated a significant dose-dependent growth inhibition on squamous cell carcinoma, breast cancer, hepatocellular carcinoma, prostate carcinoma and colon cancer cell lines (Ye

et al 2002). Prostate and breast cancer cells were particularly sensitive. Baical skullcap has also been shown to arrest mouse leukaemia cell proliferation in vivo (Ciesielska et al 2002, 2004). Inhibition of PGE<sub>2</sub> synthesis via suppression of COX-2 expression may be responsible for its anticancer activity (Ye et al 2002). Differences in the biological effects of baical compared with baicalein suggest synergistic effects among components in baical (Zhang et al 2003). Another study has shown complete inhibition of acute lymphatic leukaemia, myeloma and lymphoma cell lines in vitro (Kumagai et al 2007). Baicalein, baicalin and wogonin have been shown to reduce proliferation of human bladder cancer cell lines in a dose-dependent manner, but baicalin exhibited the greatest antiproliferative activity. In an in vivo study baical skullcap extract had a significant inhibition of tumour growth ( $P < 0.05$ ) (Ikemoto et al 2000).

Baical skullcap significantly inhibited prostate-specific antigen production and reduced PGE<sub>2</sub> synthesis via direct inhibition of COX-2 activity in vitro (Ye et al 2007). The extract also reduced cyclin D1, resulting in a G1 phase arrest, and inhibited cyclin-dependent kinase 1 (cdk1) expression and kinase activity, leading to a G2/M cell cycle arrest. An animal study reported a 50% reduction in tumour volume after 7 weeks (Ye et al 2007). Another study found that baicalein, wogonin, neobaicalein and skullcap flavone inhibited prostate cancer cell proliferation in vitro (Bonham et al 2005). Additionally, the in vivo phase of the study found that baicalein (20 mg/kg/day) reduced the growth of prostate cancer xenografts in mice by 55% after 2 weeks.

Wogonin inhibited phorbol 12-myristate 13-acetate-induced COX-2 protein and mRNA levels in human lung epithelial cancer cells (Chen et al 2008). It appears that this was due to activator protein 1 inhibition. *Scutellaria baicalensis* stem leaf total flavonoid inhibited the proliferation of vascular smooth-muscle cells directly by blocking cell cycle progression, and the ERK signal transduction way possibly participated in the cytoprotection of the flavonoid (Luo et al 2009).

### Adjunct to chemotherapy

Baical skullcap shows promise as an adjunct to cancer therapy. In a cardiomyocyte in vivo model, baical skullcap attenuated the production of reactive oxygen species, cell death and cardiotoxicity typically associated with the chemotherapy drug doxorubicin (Chang et al 2011). Similarly, wogonin selectively inhibited apoptosis induced by the chemotherapy drug etoposide in normal cells, while potentiating it in tumour cells (Enomoto et al 2011). These studies suggest that components of baical skullcap show promise as adjunctive therapy in cancer treatment.

In a mouse model the combination of *S. baicalensis* and Qing-Shu-Yi-Qi-Tang alongside chemotherapy drugs minimises drug-induced cachexia, is

actively anti-inflammatory, selectively cytotoxic to tumour cells and suppresses tumour growth (Wang et al 2012).

In experiments with murine and rat transplantable tumours, baical skullcap extract treatment improved cyclophosphamide and 5-fluorouracil-induced myelotoxicity and decreased tumour cell viability (Razina et al 1987). Wogonin has also demonstrated the ability to hasten etoposide-induced apoptotic cell death (Lee et al 2007). Another in vitro study found that wogonin increased apoptosis and induced cell cycle arrest at the G2/M phase (Himeji et al 2007).

### Prevention of metastases

The advancement of Pliss' lymphosarcoma in rats is associated with disorders of platelet-mediated haemostasis, presenting with either lowered or increased aggregation activity of platelets. Extract of baical was shown to produce a normalising effect on platelet-mediated haemostasis whatever the pattern of alteration. This activity is thought to be important for antitumour and, particularly, metastasis-preventing effects (Razina et al 1989).

Experiments in mice inoculated with metastasising Lewis lung carcinoma showed that the antitumour and antimetastatic effects of cyclophosphamide are potentiated by baical, rose root (*Rhodiola rosea*), licorice (*Glycyrrhiza glabra*) and their principal acting components, baicalin, paratyrosol and glycyrrhizin (Razina et al 2000).

### Chemoprevention

Baicalein prevents chemically induced DNA damage in a cell culture model (Chan et al 2002).

### Antiangiogenesis

Baicalein, wogonin and baicalin have demonstrated anticancer activity against several cancers in vitro. The flavonoids have also been shown to be potent inhibitors of angiogenesis in vitro and in vivo. Baicalein was found to be more potent than baicalin (Liu et al 2003). Wogonin also exerts a potent antiangiogenesis action on breast cancer cells lines, both in vivo and in vitro (Song 2013). Baical flavonoids inhibit hepatic cytochromes CYP1A2 and CYP3A2 in vitro and in vivo (de Boer et al 2005, Kim et al 2002).

### Noise-induced hearing loss

A controlled mouse model was used by Kang et al (2010) to observe the effect of baical skullcap, baicalein and baicalin fractions on noise-induced hearing loss (NIHL), by exposing the mice to various noise intensities over 35 days. The results indicated the baical skullcap is protective in mild NIHL rather than severe NIHL, and that the flavonoid baicalein is largely responsible for this action.

## CLINICAL USE

Baical skullcap is an ingredient in the very popular traditional Chinese/Japanese formulation, Minor

Bupleurum Combination, also known as Xiao Chai Hu Tang (Chinese) and Sho-saiko-to (Japanese). Minor Bupleurum Combination has been used in China for about 3000 years for the treatment of pyretic diseases.

Minor Bupleurum Combination (Sho-saiko-to) is now a prescription drug approved by the Ministry of Health and Welfare of Japan and widely used in the treatment of chronic viral liver diseases. Since 1999, Sho-saiko-to has been administered to 1.5 million patients with chronic liver diseases, because it can significantly suppress cancer development in the liver (Yamashiki et al 1999). Sho-saiko-to is also used for the treatment of bronchial asthma in Japan (Nakajima et al 2001). As such, many studies have been conducted with the herbal combination, making it difficult to determine the role of baical skullcap as a stand-alone treatment.

### Respiratory infection

Sixty patients with respiratory infection (mainly hospital-acquired pneumonia) were treated by injection of either baical compound or piperacillin sodium (intravenously). The total efficacy was evaluated after treatment for 1 week, after which it was found that total effective treatment rates were 73.3% for baical compared with 76.7% in the antibiotic treatment group. Body temperature was decreased similarly and symptoms disappeared or were relieved in  $11.67 \pm 6.75$  days with the herb and  $11.53 \pm 7.30$  days with the antibiotic. In the piperacillin sodium group, fungal infections occurred in 4 of 30 patients, but there were none in the baical treatment group (Lu 1990).

### Bone marrow stimulation during chemotherapy

Haemopoiesis was studied in 88 patients with lung cancer during combination treatment with chemotherapy and a *S. baicalensis* extract. Administration of the plant preparation was associated with haemopoiesis stimulation, intensification of bone marrow erythrocytopoiesis and granulocytopenia, and increased numbers of circulating precursors of erythroid and granulomonocytic colony-forming units (Goldberg et al 1997).

### Epilepsy (in combination with other herbs)

Saiko-keishi-to, a spray-dried decoction of bupleurum (cinnamon, peony, ginger, licorice, ginseng, pinellia, zizyphus and baical) was administered to 24 people with epilepsy who had frequent uncontrollable seizures (3–5 seizures per day in the most severe case and 5 seizures per month in the mildest case) of various types, despite treatment with pharmaceutical anticonvulsants. Of them, six were well controlled with Saiko-keishi-to, whereas thirteen experienced improvement and three showed no effect. No patients experienced worsening of their condition. Two patients dropped out during treatment (Narita et al 1982).

### Chronic active hepatitis (in combination with other herbs)

In a double-blind, multicentre clinical study of 222 patients with chronic active hepatitis, Sho-saiko-to was found to significantly decrease AST and ALT values compared with placebo. The difference between the treatment and placebo groups in the mean value was significant after 12 weeks. In patients with chronic active hepatitis type B (HB), a tendency towards a decrease of HBe antigen and an increase of anti-HBe antibodies was also observed. No remarkable side effects were noticed (Hirayama et al 1989).

### Liver fibrosis (in combination with other herbs)

Minor Bupleurum Combination (Sho-saiko-to) has been shown to play a chemopreventive role in the development of hepatocellular carcinoma in cirrhotic patients in a prospective study, and several studies have demonstrated the preventive and therapeutic effects of Sho-saiko-to on experimental hepatic fibrosis (Shimizu 2000). Sho-saiko-to has been shown to inhibit the activation of hepatic stellate cells, the major collagen-producing cells. Sho-saiko-to has a potent antifibrotic effect by inhibiting oxidative stress in hepatocytes and hepatic stellate cells. It is proposed that the active components are baicalin and baicalein, because they both have chemical structures very similar to silybinin, the active compound in *Silybum marianum* (St Mary's thistle), which exhibits antifibrotic activities. Sho-saiko-to combined with silymarin in 90 patients with hepatitis B-related liver fibrosis due to chronic hepatitis B virus improved indexes of liver function and serum liver fibrosis in the therapy group, while clearance of hepatitis B virus was comparable to control group (Bing et al 2010).

### Gingivitis

In a randomised, controlled and blinded clinical gingivitis model, a topical preparation of 0.5% baical skullcap extract plus fluoride significantly reduced the severity of gingivitis and plaque development when compared with the control group, fluoride alone, which is an established therapy (Arweiler et al 2011). The participants rinsed with either preparation twice daily for 21 days, with the treatment group experiencing dramatic improvements. While the methods, including randomisation and blinding, are well described, a description of the type of extract, such as solvent, is not detailed.

### OTHER USES

Because of its wide range of pharmacological effects, baical skullcap is used for many different indications. Although controlled trials are not yet available to determine its effectiveness, evidence from in vitro and animal studies provides a theoretical basis for the following uses:

- chronic inflammatory conditions such as asthma, arthritis and allergies (antiallergic and anti-inflammatory effects)

- hepatitis (as a hepatoprotective agent)
- common infections such as the common cold (antimicrobial and immunostimulant effects)
- nausea and vomiting (antiemetic effect).
- In practice, baical skullcap is used in combination with other herbs for these conditions.

### DOSAGE RANGE

- Dried herb: 6–15 g/day (Bensky & Gamble 1986).
- Liquid extract (1:2): 30–60 mL/week or 4.5–8.5 mL/day in divided doses.

### ADVERSE REACTIONS

There have been several case reports of interstitial pneumonia and acute respiratory failure associated with Japanese kampo medicines, specifically the formula Sho-saiko-to, and the content of baicalin is thought to be responsible for the reactions (Makino et al 2008). The incidence is increased by co-administration of interferon, duration of medication use, with the risk being greater in elderly populations (Lee et al 2011). One case of Sho-saiko-to-induced pneumonia in a patient with autoimmune hepatitis was reported (Katou & Mori 1999); however, direct toxicity is very low. Makino et al (2008) suggest that it is the high amount of baicalin (319 mg/day) in Oren-ge-doku-to and Sho-saiko-to which is responsible for the adverse drug reactions, and that the small amount derived from a tea, 12–27 mg, is safe.

Toxicity studies of three different traditional Chinese/Japanese formulations containing baical suggest a very low acute or subchronic toxicity for the herbs in them. The studies found no herb-related abnormalities such as changes in body weight or food consumption, abnormalities on ophthalmological and haematological examination, urinalysis and gross pathological examination, changes in organ weight or optical microscopic examination (Iijima et al 1995, Kanitani et al 1995, Kobayashi et al 1995, Minematsu et al 1992, 1995). The acute lethal activity of wogonin is low, with an LD<sub>50</sub> of 3.9 g/kg (Kwok et al 2002).

### SIGNIFICANT INTERACTIONS

There are reports of baical flavonoids interacting with P450 enzymes. Baical flavonoids inhibit hepatic CYP1A2 (Kim et al 2002) and CYP2E1 expression (Jang et al 2003). Theoretically, inhibition of CYP1A2 and CYP2E1 may affect certain medical drugs metabolised by these P450 enzymes. There are, however, no clinical reports of such herb–drug interactions.

A theoretical interaction may occur in the co-administration of ciprofloxacin, whereby baical skullcap makes more of the drug available to the bacteria (Ben 2011). Similarly, wogonin could theoretically interact and reduce drug-resistant breast cancer lines to the chemotherapeutic agent, doxorubicin (Zhong et al 2012).

### Sho-saiko-to during interferon therapy

Sho-saiko-to, as well as interferon, is used for the treatment of chronic hepatitis. There have been reports of acute pneumonitis due to a possible interferon–herb interaction. Pneumonitis, also called extrinsic allergic alveolitis, is a complex syndrome caused by sensitisation to an allergen. The mechanism of the Sho-saiko-to–interferon interaction seems to be due to an allergic–immunological mechanism rather than direct toxicity (Ishizaki et al 1996) — contraindicated.

### Cyclosporin

A decoction of *Scutellaria baicalensis* has been reported to significantly decrease plasma levels of cyclosporin in rats. The co-administration of these two substances should be avoided until further research is available (Lai et al 2004).

### Warfarin/anticoagulants

Increased risk of bleeding is theoretically possible — use with caution.

#### **?** CONTRAINDICATIONS AND PRECAUTIONS

Baical skullcap and the formulation Sho-saiko-to (Minor Bupleurum Combination, Xiao Chai Hu Tang) are contraindicated during interferon therapy. Baical is contraindicated in cold conditions in TCM.

#### **S** PREGNANCY USE

Baical is used in TCM for restless fetus (threatened abortion) and toxæmia of pregnancy. A recent animal study found that baical skullcap combined with *Atractylodes macrocephala* had an antiabortive effect through inhibition of maternal–fetal interface immunity. The herbs prevented lipopolysaccharide-induced abortion by reducing natural killer cells and IL-2 activity (Zhong et al 2002). Although this is encouraging, safety in pregnancy is still unknown.

#### **!** PATIENTS' FAQs

##### *What can this herb do for me?*

Baical skullcap may be useful as an adjunctive therapy during cancer treatment to reduce nausea and immune suppression. Baical skullcap may also be beneficial in the treatment of vascular disorders, allergies, liver disease and infections, hypertension and arthritis; however, effectiveness is largely unknown.

##### *When will it start to work?*

For acute allergic and infectious conditions, the beneficial effects of baical skullcap should be noticeable within a few days. For chronic diseases, long-term use is recommended.

#### **Practice points/Patient counselling**

- Baical skullcap is a traditional Chinese herb used to treat fever, cough with thick yellow sputum, thirst and irritability, nausea, jaundice and diarrhoea.
- Baical skullcap extract, many of its constituents, and as part of herbal combination treatments, has been studied in many different experimental models. However, few clinical trials have been conducted using baical as a stand-alone treatment.
- It is used to treat chronic inflammatory conditions such as asthma, arthritis and allergy, because of its anti-inflammatory and antiallergic effects.
- It is used as a hepatoprotective agent in the treatment of hepatitis.
- Because of its antimicrobial and immunostimulant effects, baical is used to treat infections such as the common cold and bronchitis.
- Antiemetic effects suggest a role in nausea and vomiting.
- Hypotensive activity demonstrated in various animal models provides a basis for its use in hypertension.
- In practice, it is combined with other herbal medicines for a more targeted approach.
- Anti-inflammatory, antiallergic, antidiabetic, neuroprotective, antifibrotic and hepatoprotective effects of baical skullcap have been demonstrated repeatedly in in vitro and in vivo models.

#### *Are there any safety issues?*

Baical skullcap is a safe and non-toxic herb which is used in both acute and chronic conditions. It should only be used during pregnancy on the recommendation of a healthcare practitioner. Baical and the formulation Sho-saiko-to (Minor Bupleurum Combination, known as Xiao Chai Hu Tang in Mandarin) are contraindicated during interferon therapy.

# Bergamot

Bergamot is a common Italian citrus fruit and chiefly cultivated to produce essential oils. It is a natural hybrid fruit derived from bitter orange and lemon and produced almost exclusively on the south-eastern coast of Italy in the Reggio Calabria region, with an annual production of 25,000 tonnes (Pernice et al 2009). For centuries the essential oil obtained from the peel of *Citrus bergamia* was mainly used for its fragrant properties in perfumes, as an antiseptic, to facilitate wound healing, as an anthelmintic and also for heart disease (Bagetta et al 2010, Pernice et al 2009). It also provides the citrus aroma associated with Earl Grey tea.

## LATIN BINOMIAL/CLASS

*Citrus bergamia*, *Risso/Rutaceae* genus; subfamily Esperidea

## OTHER NAMES

Aceite de bergamota, bergamot orange, bergamota, bergamotier, bergamoto, bergamotte, bergamoto, bigarade orange, huile de bergamote, oleum bergamotte, oranger bergamotte, sweet orange

## PLANT PART USED

Bergamot is used mostly for production of the essential oil, obtained from the peel by wash-scraping the fruit. Until recently, bergamot juice (BJ) was considered a waste byproduct of this process; however, new research is finding potential uses for it.

## CHEMICAL COMPONENTS

### Bergamot juice

Present in the juice (BJ) are flavonoid and flavonoid glycosides and albedo, such as neoeriocitrin, neo-hesperidin, naringin, rutin, neodesmin, rhoifolin and poncirin. It is also rich in neohesperidosides of hesperetin and naringenin, such as melitidine and brutieridine (Mollace et al 2008).

Neoeriocitrin is one of the main flavonoids in BJ, accounting for 15%, whereas narirutin and naringin together represent only 14% of the total flavonoids (Pernice et al 2009).

The specific polyphenolic compounds in BJ include narirutin, naringin, isorhoifolin and rhoifolin and, to a lesser extent, rutin and other compounds: neoeriocitrin, neoponcirin, hesperidin and neodiosmin. Rhoifolin and isorhoifolin have been detected in substantial concentrations in BJ but are only present in very small amounts in orange, tangerine and grapefruit, and are completely absent in lemon (Pernice et al 2009).

### Bergamot essential oil (BEO)

According to the Farmacopea Ufficiale Italiana (1991), BEO is obtained by cold pressing of the epicarp and, partly, of the mesocarp of the fresh fruit. BEO has poor water solubility, low stability and limited bioavailability (Celia et al 2013).

BEO consists of a volatile fraction (93–96%) and a non-volatile fraction (4–7%). The volatile fraction contains the monoterpene and sesquiterpene hydrocarbons and oxygenated derivatives such as limonene,  $\gamma$ -terpinene and  $\beta$ -pinene, the monoterpene alcohol, linalool and the monoterpene ester, linalyl acetate which, altogether, constitute more than 90% of the whole oil (Sakurada et al 2011). The non-volatile fraction contains waxes, polymethoxylated flavones, coumarins and psoralens such as bergamot-tin and bergapten (Bagetta et al 2010, Sakurada et al 2011). This hydrocarbon fraction does not have a fundamental role in determining the olfactory character of BEO.

## MAIN ACTIONS

### Antioxidant

BJ has an extraordinary high antioxidant activity, with values about 2800 and 1300 times greater than data obtained for apple and apricot juices respectively when measured using the *N,N*-dimethyl-*p*-phenylenediamine method (Pernice et al 2009). This method of determining antioxidant activity is widely used in food science. The bergamot polyphenols and, possibly, bergamot flavanones are the most important contributors to the antioxidant activity.

### Lipid lowering

Experimental evidence obtained in animal models of diet-induced hypercholesterolaemia and renal damage as well as in the rat model of mechanical stress-induced vascular injury supports the hypolipemic and vasoprotective effects of bergamot constituents (Mollace et al 2011).

Long-term administration of BJ (1 mL/day) induced a significant reduction in serum cholesterol, triglycerides and low-density lipoprotein (LDL) levels and an increase in high-density lipoprotein (HDL) levels in vivo (Miceli et al 2007). The hypocholesterolaemic effect of BJ may be mediated by the increase in faecal neutral sterols and total bile acid excretion, as observed after treatment.

The main constituents thought to be responsible for lipid-lowering activity are the flavanone glycosides brutieridin and melitidin, which both contain a 3-hydroxy-3-methylglutaric acid (HMG) moiety (Di et al 2009). As such, they have been described as

structural analogues of statin drugs and it has been suggested that these compounds may interfere with the synthesis of mevalonate by mimicking endogenous HMG-CoA substrate (Leopoldini et al 2010).

Bruteridin and melitidin are present in bergamot fruit in concentrations of approximately 300–500 and 150–300 ppm respectively, as a function of the ripening stage (Di et al 2009).

### Antimicrobial

Bergamot peel is a potential source of natural antimicrobial agents that are active against Gram-negative bacteria. In vitro tests demonstrate that bergamot ethanolic fractions were effective against the Gram-negative bacteria *Escherichia coli*, *Pseudomonas putida* and *Salmonella enterica* (Mandalari et al 2007).

### Anxiolytic

BEO exhibits anxiolytic activity in vivo (Russo et al 2013). It has been shown to significantly increase gamma-aminobutyric acid levels in rat hippocampus. Rats exposed to bergamot aromatherapy also had a decrease in corticosterone levels; the combined effects provided a biological basis for an anxiolytic activity (Saiyudthong & Marsden 2011). Additionally, in vivo and in vitro results suggest that BEO induces release of glutamate, i.e. low concentrations stimulate exocytosis of the excitatory amino acid, possibly by activation of presynaptic receptors located on glutamate-releasing nerve endings; higher concentrations cause glutamate release via a  $Ca^{2+}$ -independent, carrier-mediated process (Bagetta et al 2010).

### Anti-inflammatory

Bergapten and citropten from bergamot are strong inhibitors of interleukin-8 expression (Borgatti et al 2011). They have been investigated as possible treatment candidates to reduce lung inflammation in patients with cystic fibrosis.

### Antinociceptive

In vivo research confirms antinociceptive activity for BEO (Russo et al 2013). Injected BEO has an antinociceptive effect and the isolated constituents linalool and linalyl acetate are even more potent. This suggests that the nociceptive effect of BEO may be dependent on the concentrations of linalool and linalyl acetate present. Interestingly, the effect of BEO and linalool appears to be opioid-mediated as naloxone abolishes activity (Sakurada et al 2011). Furthermore, an in vivo study identified that, when a combination of morphine (intraperitoneal and intrathecal) and intraplantar BEO or linalool was administered, a synergistic antinociceptive effect was seen for morphine. Of note, the morphine was administered at a subtherapeutic dose (Sakurada et al 2009).

### Neuroprotection

BEO reduced neuronal damage caused by excitotoxic stimuli in vitro (Corasaniti et al 2007). Results

obtained by using specific fractions of BEO suggested that monoterpene hydrocarbons were responsible for the neuroprotection afforded by BEO. Neuroprotection was also demonstrated in vivo as intraperitoneal injection of BEO reduced, in a dose-dependent manner, the brain damage caused by focal cerebral ischaemia in rats (Amantea et al 2009). It has been proposed that neuroprotection action may stem from its ability to enhance phosphorylation of Akt (Bagetta et al 2010).

### Antitumour

In one study, BJ exhibited an antiproliferative effect but not a cytotoxic effect (Delle et al 2013). BEO also exhibits antitumour activity. BEO demonstrated antiproliferative activity against SH-SY5Y human neuroblastoma cells in vitro and BEO-derived compounds, such as limonene, limonene-related monoterpenes, perillyl alcohol and perillic acid have also been shown to inhibit cell proliferation of breast cancer cells and provide a chemopreventive and chemotherapeutic effect in mammary tumour models (Celia et al 2013).

Russo et al (2013) investigated several individual constituents in BEO for cytotoxic activity in human SH-SY5Y neuroblastoma cultures. They found significant cytotoxicity when cells were co-treated with limonene and linalyl acetate, whereas single exposure to limonene or linalyl acetate did not have the same effect. Based on current research, it appears likely that the combination of monoterpenes in BEO is responsible for the observed effects, which include caspase-3 activation, poly (ADP-ribose) polymerase cleavage, DNA fragmentation, cell shrinkage, cytoskeletal alterations, together with necrotic and apoptotic cell death (Russo et al 2013).

As a means of improving BEO and BEO-bergapten-free (BEO-BF) solubility, a liposomal formulation was developed by Celia et al (2013) which reduced the viability of SH-SY5Y cells at far lower concentrations than their free drug counterparts. The BEO-BF proved to be more efficacious than BEO when either administered as a free compound or encapsulated within a liposome.

### OTHER ACTIONS

BEO contains several different constituents which can cause phototoxic reactions, such as bergapten, citropten, bergamoten and other furocoumarins (Kejlova et al 2007). Bergapten is one of the key constituents responsible for the phototoxicity of BEO, therefore, a bergapten-free extract of the essence (BEO-BF), together with a natural essence deprived of the hydrocarbon fraction and of bergapten (BEO-HF/BF) is prepared by extractive industries for perfumery and cosmetic uses (Bagetta et al 2010).

### CLINICAL USAGE

Bergamot is traditionally used as an essential oil in aromatherapy or topical preparations, although recent research has suggested possible benefits for

the juice or its isolated polyphenolic fraction when ingested orally.

### Hypercholesterolaemia

Many naturally derived polyphenol compounds show potential benefits as therapeutic agents in cardiovascular disease and have been tested as a means of reducing blood lipids and addressing other underlying factors which may contribute to disease, such as inflammation and oxidative stress.

Recently, orally administered bergamot-derived polyphenols have been investigated in both animal models of diet-induced hyperlipidaemia and in patients with metabolic syndrome, where it was observed to significantly reduce serum cholesterol, triglycerides and glycaemia (Mollace et al 2011). A significant improvement in vascular reactivity was also seen in patients with both hyperlipidaemia and raised serum glucose, suggesting a possible role in metabolic syndrome.

A double-blind randomised controlled trial involving 237 participants tested three different dosages of bergamot fruit extract (500 mg/day, 1000 mg/day and 1500 mg/day) against placebo (Mollace et al 2011). The active treatment consisted of a bergamot preparation containing 26–28% of five main flavonoids: neoeriocitrin ( $7.7\% \pm 0.4\%$ ), naringin ( $6.3\% \pm 0.33\%$ ), neohesperidin ( $7.2\% \pm 0.35\%$ ), melitidin ( $1.56\% \pm 0.11\%$ ) and brutieridin ( $3.32\% \pm 0.17\%$ ). Patients were divided into subgroups: people with elevated cholesterol, hyperlipidaemia (elevated cholesterol and triglycerides) and those with mixed lipidaemia and glycaemia over 110 mg/dL who received either 500 or 1000 mg/day. A fourth group was comprised of 32 people who stopped statin therapy due to muscle pain and elevated serum creatine phosphokinase, and they received the highest dose (1500 mg/day) after a 60-day washout.

Bergamot treatment (500 and 1000 mg/day) resulted in a significant reduction in total cholesterol and LDL-cholesterol and a significant increase in HDL-cholesterol in most subjects in the first three subgroups. In particular, the group with metabolic syndrome experienced substantial effects on lipids and a highly significant ( $P < 0.0001$ ) reduction in blood glucose levels (mean value of  $-18.9\%$  with 500 mg/day and  $-22.4\%$  with 1000 mg/day).

Both doses significantly lowered total cholesterol; however the higher dose of 1000 mg/day was significantly more effective at raising HDL-cholesterol.

For patients ( $n = 32$ ) considered statin-intolerant, bergamot extract (1500 mg/day) produced a mean reduction in total cholesterol of 25% and 27.6% for LDL in 30 patients. Importantly, there was no reappearance of the side effects experienced with statin therapy.

More recently, a prospective, open-label study was conducted to determine whether natural bergamot-derived polyphenolic fraction (BPF) reduced total cholesterol when used as stand-alone therapy and also whether it could be used as an

adjunct to statin therapy, allowing for a dose reduction in statin medication in patients with mixed hyperlipidaemia (Glozzi et al 2013, Walker et al 2012).

The placebo-controlled study of 77 volunteers with LDL-cholesterol levels of  $>4.1$  mmol/L and triglyceride levels  $>2.54$  mmol/L were divided into five groups and received one of placebo, BPF 1000 mg/day, rosuvastatin 10 mg/day, rosuvastatin 20 mg/day or BPF (1000 mg/day) + rosuvastatin (10 mg/day) for 30 days. In addition, all groups were to follow a low-fat diet during the study duration.

Oral administration of BPF (1000 mg/daily for 30 consecutive days;  $n = 15$ ) in patients with mixed hyperlipidaemia led to a significant reduction in total cholesterol, LDL-cholesterol, triglyceride and enhanced HDL-cholesterol levels, whereas no significant change was observed in the placebo group. The groups receiving rosuvastatin (10 and 20 mg/daily;  $n = 16$  for each group) also experienced a significant reduction of total cholesterol and LDL-cholesterol compared to placebo; however, insignificant changes were seen for triglycerides at both doses and an elevation of HDL-cholesterol was found (Glozzi et al 2013).

When BFG was combined with rosuvastatin (10 mg/day), a significant decrease in total cholesterol and LDL-cholesterol serum levels was seen when compared to rosuvastatin alone. Furthermore, the combination of low-dose rosuvastatin and BPF produced an effect which was nearly the same as that produced by 20 mg/day of rosuvastatin.

Changes to urinary mevalonate indicated that adding BPF to rosuvastatin further inhibited HMG-CoA reductase. A decrease in malondialdehyde levels for the combination treatment also confirms that BFG enhanced the antioxidant effect of rosuvastatin and changes in a range of other biomarkers indicate that vasoprotective effects were further enhanced.

### Stress and anxiety

An open-label study of 54 elementary school teachers evaluated two 10-min sprays with bergamot oil aromatherapy for effects on stress. The BEO used was 100% pure and diluted to 2%. Exposure to BEO resulted in a significant decrease in blood pressure and heart rate when measured 5 min after exposure compared to 5 min before. Subgroup analysis revealed that aromatherapy was effective for high-anxiety and moderate-anxiety groups but not for people with mild anxiety (Chang & Shen 2011). While this was an open study measuring before and after effects to aromatherapy, there was strict control of the experimental environment, including subject's posture, measurement location and time, adding more rigour to the design.

A double-blind randomised controlled trial evaluating the effect of the respiratory administration of BEO or placebo on the anxiety, nausea and pain of 37 paediatric patients undergoing stem cell infusion and their parents found the treatment groups

experienced greater anxiety ( $P = 0.05$ ) and nausea ( $P = 0.03$ ) 1 h postinfusion. There was no significant change to pain or parental anxiety, which reduced for both groups but did not reach statistical significance (Ndao et al 2012). Clearly the treatment was ineffective when given this way and poorly tolerated.

### OTHER USES

Bergamot oil has been used for its fragrance properties in perfumes for generations; however these properties are quickly destroyed by exposure to sunlight.

Traditionally, BEO has been used in folk medicine as an antiseptic, to facilitate wound healing and as an anthelmintic agent. Today, it is still used for its antiseptic and antibacterial properties and by the cosmetic industries (e.g. in perfumes, body lotions, soaps and aromatherapy) (Bagetta et al 2010). It is also used in the food industries as aroma for the preparation of sweets, liquors and tea such as in Earl Grey tea.

### DOSAGE RANGE

#### According to clinical studies

Hyperlipidaemia — oral bergamot fruit extract: 500–1500 mg/day.

Oral BPF: 1000 mg/day.

Anxiety — used as aromatherapy: 100% pure BEO and diluted to 2%.

### ADVERSE REACTIONS

Phototoxic side effects can occur with bergamot application directly on the skin followed by exposure to sunlight (ultraviolet [UV]-A). This can result in oedema, long-lasting erythema and significant skin pigmentation. If a sunscreen-absorbing UV-A radiation is applied, the phototoxic reaction does not occur (Dubertret et al 1990).

BEO contains several different constituents which can cause phototoxic effects, such as bergapten, citropten, bergamoten and other furocoumarins (Kejlova et al 2007). Bergapten is one of the key constituents responsible for the phototoxicity of BEO; therefore, a bergapten-free extract of the essence together with a natural essence deprived of the hydrocarbon fraction and of bergapten are prepared by extractive industries for perfumery and cosmetic uses (Bagetta et al 2010).

The International Fragrance Association recommends a maximum of 0.4% of bergamot oil in the final leave-on products for application to areas of skin exposed to sunshine to avoid phototoxic and photocarcinogenic hazard. In order to guarantee safety, it is suggested to remove bergapten and other phototoxic components by distillation, the resulting oil being known as bergamot FCF (furocoumarin-free) (Kejlova et al 2007).

### SIGNIFICANT INTERACTIONS

No significant drug interactions are known for oral bergamot preparations.

There is a theoretical concern about possible interactions due to the presence of naringin in bergamot (Pernice et al 2009). This constituent is also found in grapefruit juice and, while it does not have any appreciable effect on cytochromes, it may inhibit OATP1A2 according to clinical research (Bailey et al 2007). Whether the concentration of naringin present in commercial bergamot preparations is sufficient to cause such an effect is unlikely. Until this can be confirmed, people taking drugs with a narrow therapeutic index which are also OATP1A2 substrates should use caution.

### CONTRAINDICATIONS AND PRECAUTIONS

Bergamot oil should not be applied directly to the skin, especially by people with fair skin, as phototoxic side effects can occur. Use a sunscreen absorbing UV-A radiation at the same time to reduce the risk (Dubertret et al 1990).

### PREGNANCY USE

Insufficient reliable information available to confirm safety in pregnancy.

### *Practice points/Patient counseling*

- Bergamot fruit extract is an effective treatment for reducing total and LDL-cholesterol and raising HDL-cholesterol according to randomised studies. It can be used together with statin drugs to enable a dose reduction to occur. The available research suggests it can also be used by people intolerant of statins.
- BEO is used in aromatherapy and may reduce anxiety in highly stressed individuals.
- Bergamot has a range of activities, including antioxidant, anti-inflammatory, antimicrobial, neuroprotective, antinociceptive (probably opiate-mediated) and antitumour.
- BEO can be phototoxic and should not be applied directly to the skin, particularly by fair individuals before sun exposure.

### PATIENTS' FAQs

#### *What will this herb do for me?*

Bergamot fruit extract taken orally can effectively reduce total and LDL-cholesterol and raise HDL-cholesterol.

BEO, diluted and used as aromatherapy, may induce relaxation in highly stressed individuals.

#### *When will it start to work?*

The cholesterol-lowering effects develop within 1 month of use.

The relaxation effect should occur within 5–10 min of aromatherapy exposure.

#### *Are there any safety issues?*

Don't apply the BEO directly to the skin as it can make it highly sensitive to sunlight.

## Beta-Carotene

### BACKGROUND AND RELEVANT PHARMACOKINETICS

#### Carotenoids

The carotenoids are a family of bright yellow, orange and red compounds found in fruit, vegetables and some animal products, such as salmon, lobster and egg yolk. Carotenoids can be divided into the provitamin A group, such as beta-carotene, and xanthophylls such as lutein, zeaxanthin and lycopene, which are important fat-soluble antioxidants. Of the 600 or so carotenoids known to exist in nature, approximately 20 are found in humans. In plants, carotenoids play a vital role in photosynthesis and participate in the energy-transfer process, as well as protecting plants from oxidative damage. The red, orange and yellow colours of these compounds is due to their preferential absorption of blue light, which is the most energetic and hence the most biologically damaging part of the visible spectrum.

In animals, carotenoids have many functions. In addition to providing direct photoprotection via absorption of blue light, carotenoids act as powerful fat-soluble antioxidants linked to oxidation prevention. They also play a role in cellular communication, including stimulation of gap-junction communication, which is important for cancer prevention, by regulating cell growth, differentiation, apoptosis and angiogenesis. Carotenoids may also be involved in detoxification of carcinogens, DNA repair and immunosurveillance. These properties are believed to contribute to their antioxidant, immune-enhancing, anticarcinogenic and photoprotective activity.

Beta-carotene was the first of the carotenoids to be discovered, being initially isolated from carrots. The bioavailability of beta-carotene is dependent on its source. In raw foods such as carrots it forms part of a protein-polysaccharide matrix, and absorption is only about 20% of that from supplemental forms. Although beta-carotene is lipid soluble, its

absorption requires only a limited amount of fat (Roodenburg et al 2000); however, there is a wide individual variation in serum response to beta-carotene administration (Bowen et al 1993, Pryor et al 2000).

Although it has been suggested that different carotenoids compete for absorption, this was not confirmed by a postprandial study (Tyssandier et al 2002). Beta-carotene is absorbed in the intestine and released into the lymphatic circulation within chylomicrons. It is then taken up by hepatocytes and released into the blood, and transported predominantly within LDLs. It is distributed to adipose tissue and the skin and excreted in the faeces (Micromedex 2003). The time to reach peak concentration is up to 4–6 weeks with oral dosing (Mathews-Roth 1990a).

Animal feeding studies suggest that a natural algae-derived beta-carotene isomer mixture is more readily absorbed than synthetic all-*trans* beta-carotene, and that this higher bioavailability can be enhanced by increasing dietary lipid levels (Mokady & Ben-Amotz 1991). Studies on isomerisation that occurred following cooking further suggest that the food matrix may play a role in the effects of cooking on beta-carotene isomerisation (O'Sullivan et al 2010). Natural algal beta-carotene has also been shown to have higher accumulation in rat liver than synthetic all-*trans* beta-carotene (Ben-Amotz et al 1989, Takenaka et al 1993) with at least a 10-fold higher accumulation having been observed in chick and rat liver (Ben-Amotz et al 1989).

Animal studies suggest that there is some bioconversion within the body between different stereoisomers of beta-carotene (Ben-Amotz et al 2005). Further studies in humans suggest that, regardless of the isomer mix, there is preferential absorption or transport of the all-*trans* isomer in comparison with the 9-*cis* isomer, with plasma levels of the all-*trans* isomer being around 10 times that of the 9-*cis* form (Gaziano et al 1995b, Jensen et al 1987, Morinobu et al 1994, Stahl & Sies 1993, Tamai et al 1993).

It is suggested that *Helicobacter pylori* infection may impair the protective role of alpha-tocopherol and beta-carotene in the stomach, because infected people have been found to have reduced beta-carotene concentrations in gastric juice, and the presence of gastric atrophy and intestinal metaplasia is associated with reduced mucosal alpha-tocopherol and beta-carotene concentrations (Zhang et al 2000).

### Chemical components

Beta-carotene comes in natural and synthetic forms. The natural form is derived mainly from algal sources and consists of roughly equal amount of 9-*cis* and all-*trans* isomers, with small amounts of the 13-*cis* isomer. Synthetic beta-carotene is primarily composed of the all-*trans* isomer, with small residues of the 13-*cis* isomer (PDRHealth 2005). Although all-*trans* beta-carotene is converted into vitamin A, which plays an essential role in vision, growth,

reproduction, immune function and maintenance of the skin and mucous membranes (see *Vitamin A* monograph), the 9-*cis* isomer is not converted into vitamin A, but does act as a powerful antioxidant (Ben-Amotz & Levy 1996).

### Food sources

Carrots are the major contributors of beta-carotene in the diet, but it is also found in rockmelon, broccoli and spinach. Carotenoids have emerged as the best single tissue marker for a diet rich in fruits and vegetables, and measurements of plasma and tissue carotenoids have an important role in defining the optimal diets for humans (Handelman 2001).

Natural beta-carotene for use in supplements is generally obtained from palm oil or the micromarine algae (phytoplankton) *Dunaliella salina* (also known as *D. bardawil*), which is the richest natural source of beta-carotene. Whole dried *D. salina* is also available in a supplemental form that contains between 1% and 2% beta-carotene. The typical Western diet is estimated to provide approximately 2–4 mg/day of beta-carotene (Pryor et al 2000).

### Deficiency signs and symptoms

Beta-carotene is considered a conditionally essential nutrient and becomes an essential nutrient when the dietary intake of retinol (vitamin A) is inadequate.

Low serum beta-carotene levels have been associated with male gender, younger age, lower non-HDL-cholesterol, greater ethanol consumption and higher BMI (Brady et al 1996), insulin resistance (Arlöv et al 2009), increased lipoprotein density and the presence of inflammation (Kritchevsky 1999), high C-reactive protein (Erlinger et al 2001, Wang et al 2008), high blood glucose (Abahusain et al 1999), hypertension (Coudray et al 1997), exposure to environmental tobacco smoke (Farchi et al 2001), as well as all measures of obesity (Wallstrom et al 2001), including obesity in children (Strauss 1999).

Low serum beta-carotene and/or low beta-carotene intake has also been associated with a number of clinical conditions, such as breast cancer (Hacisevki et al 2003), non-melanoma and melanoma skin cancer (Gollnick & Siebenwirth 2002), rheumatoid arthritis (Kacsur et al 2002), Alzheimer's dementia (Jimenez-Jimenez et al 1999), age-related macular degeneration (Cooper et al 1999a), metabolic syndrome (Revet 2008, Sugiura et al 2008), poor glycaemic control and type 2 diabetes (Abahusain et al 1999, Arlöv et al 2009, Coudray et al 1997). It has been further shown that the inverse association between serum carotenoid and metabolic syndrome is more evident in current smokers (Revet 2008, Sugiura et al 2008).

Low serum beta-carotene has been independently associated with an increased all-cause mortality risk in older men. Apparently, a synergistic effect occurs between low beta-carotene and high inflammation burden in predicting higher mortality rates (Hu et al 2004). In another study of 668 hospitalised

patients aged 70 years or over and 104 healthy controls, the diseased elderly people had reduced plasma levels of retinol, beta-carotene and alpha-tocopherol (Tebi et al 2000). It is unclear whether these observed low levels of beta-carotene seen in disease states are a cause or a result of disease processes.

## MAIN ACTIONS

### Pro-vitamin A

Beta-carotene is converted to retinoic acid (vitamin A — see *Vitamin A* monograph) by an enzyme found in the intestinal mucosa and liver, with 2 mcg of all-*trans* carotene being equal to 1 mcg of all-*trans* retinol (vitamin A) or 3.33 IU (PDRHealth 2005). This conversion is regulated by vitamin A status and may be enhanced by alpha-tocopherol (Wang & Krinsky 1998). Zinc may also be important for bio-conversion, as indicated by a double-blind, placebo-controlled trial of 170 pregnant women which found that supplementation zinc improved the post-partum vitamin A status of both mothers and infants (Dijkhuizen et al 2004).

### Immunomodulation

The mechanisms by which beta-carotene influences immune function are not well understood, and both direct and indirect effects on immune function, via its pro-vitamin A activity, have been demonstrated (Watson et al 1991). Beta-carotene directly influences immune function by reducing oxidative damage to cell membranes and their receptors, by influencing the activity of redox-sensitive transcription factors and the production of cytokines and prostaglandins, and by enhancing cell-to-cell communication (Hughes 2001).

These actions are influenced by several factors, such as dose and timing of supplementation, age and health status of the individual. A double-blind, placebo-controlled, randomised crossover study in 25 healthy adult-male non-smokers found that 15 mg/day of beta-carotene enhanced cell-mediated immune responses, with significant increases in the percentages of monocytes expressing the major histocompatibility complex class II molecule HLA-DR and adhesion molecules, as well as increased ex vivo tumour necrosis factor alpha (TNF-alpha) secretion by blood monocytes (Hughes et al 1997). Beta-carotene has also been shown to increase plasma levels of TNF-alpha in patients given 30 mg/day for the treatment of oral leucoplakia (Prabhala et al 1993).

In controlled trials, supplementation with 30 mg beta-carotene was shown to protect against UV-induced photosuppression of immune function in young men (Fuller et al 1992), as well as in older men, with serum beta-carotene levels being significantly associated with maintenance of the delayed-type hypersensitivity response (Herraiz et al 1998). Another controlled trial found that 60 mg/day beta-carotene for 44 weeks increased the CD4-CD8

ratio after 9 months without affecting NK cells, virgin T-cells, memory T-cells or cytotoxic T-cells in healthy male non-smokers; supplementation with 60 mg/day beta-carotene for 4 weeks was shown to significantly increase lymphocyte counts and CD4<sup>+</sup> in a pilot study of seven patients with AIDS (Murata et al 1994).

Natural killer-cell activity was also found to increase in older adults in a dose-finding study in which 30 mg/day beta-carotene for 2 months significantly increased in a dose-dependent manner the percentage of lymphoid cells with surface markers for T-helper and NK cells, and cells with IL-2 and transferrin receptors (Watson et al 1991). In a further study of 59 men participating in the Physicians Health Study, 10–12 years of supplementation with 50 mg beta-carotene on alternate days was found to increase NK cell activity without increasing the percentage of NK cells, IL-2 production or receptor expression in elderly but not middle-aged men (Santos et al 1996).

Although beta-carotene supplementation has been shown to enhance NK cell responses, there are a number of randomised controlled trials (RCTs) that suggest it does not influence other aspects of immune activity in healthy individuals. In separate RCTs, supplementation with 90 mg beta-carotene for 3 weeks or 50 mg on alternate days for more than 10 years was not found to influence T-cell-mediated immunity of healthy elderly people (Santos et al 1997), and supplementation with 30 mg beta-carotene was not found to affect the T-lymphocyte proliferative response to phytohaemagglutinin in healthy lactating and non-lactating women (Gossage et al 2000). Another study found that supplementation with 8.2 mg/day of beta-carotene for 12 weeks did not influence several markers of T-cell-mediated immunity in well-nourished, healthy elderly individuals (Corridan et al 2001).

### Antioxidant

Beta-carotene has consistently demonstrated antioxidant activity in vitro, although the mechanism of action is poorly understood. At low partial pressures of oxygen, such as those found in most tissues under physiological conditions, it exhibits good radical-trapping antioxidant behaviour; this capacity is lost at high oxygen pressures in vitro with auto-catalytic, pro-oxidant effects observed (Burton & Ingold 1984).

Beta-carotene has been shown to quench singlet oxygen, scavenge peroxy radicals and inhibit lipid peroxidation in vitro; however, there is ongoing debate about its ability to act as an antioxidant in vivo, with some evidence suggesting this varies from system to system for reasons that are poorly understood (Pryor et al 2000).

Beta-carotene acts synergistically with other antioxidants, such as vitamins E and C, or other dietary components as part of the antioxidant network (see *Vitamin E* monograph). A combination of beta-carotene and alpha-tocopherol has been shown to

inhibit lipid peroxidation significantly more than the sum of the individual inhibitions in a membrane model (Palozza & Krinsky 1992), and a synergistic effect has also been demonstrated in vitro and in vivo with vitamins E and C (Bohm et al 1997, 1998a).

### In vivo studies

A number of studies have demonstrated that beta-carotene has antioxidant activity in vivo. Supplementation with 180 mg of beta-carotene for 2 weeks was found to increase the beta-carotene content of LDL and significantly reduce plasma lipid peroxidation and LDL susceptibility to oxidation, as analysed by malondialdehyde generation (Levy et al 1996). Similarly, lipid peroxidation, as measured by breath pentane output, was found to be significantly reduced in healthy subjects by 4 weeks of daily supplementation with 120 mg of beta-carotene (Gottlieb et al 1993). In a case-controlled trial involving 20 patients with long-standing type 1 diabetes mellitus, as well as age- and sex-matched controls, supplementation with 60 mg/day of natural algae-derived beta-carotene for 3 weeks was found to significantly reduce malondialdehyde and lipid peroxide production and the increased susceptibility towards LDL oxidation seen in the diabetic subjects (Levy et al 2000). Beta-carotene supplementation was also found to significantly reduce serum lipid peroxidation in a dose-dependent manner in a number of double-blind, placebo-controlled trials (Greul et al 2002, Lee et al 2000). Beta-carotene supplementation has also been demonstrated to significantly reduce lipid peroxidation of erythrocyte membranes in people with beta-thalassaemia (Mahjoub et al 2007).

These results contrast with those from a number of studies that failed to demonstrate any in vivo antioxidant activity. A study of 79 healthy volunteers found that normal concentrations of carotenoids in plasma and tissues did not correlate with total antioxidant capacity of the plasma or breath pentane measurements (Borel et al 1998). In other studies supplementation was seen to increase LDL beta-carotene without changing LDL susceptibility to oxidation (Princen et al 1992, Reaven et al 1993).

It is possible that beta-carotene is more likely to demonstrate antioxidant activity in conditions of increased oxidative stress. This is suggested by the results of a randomised, double-blind controlled trial that involved 42 non-smokers and 28 smokers who received either 20 mg of beta-carotene or a placebo; this trial showed that beta-carotene reduced lipid peroxidation as indicated by breath pentane output in smokers, but not in non-smokers (Allard et al 1994). This is further supported by a study of whole-body irradiation in rats that found supplementation with natural algae-derived beta-carotene protected against the reduction in growth rate and the selective decline in 9-*cis* beta-carotene and retinol seen in irradiated animals, as well as partially

reversing the effect of irradiation when given after the irradiation (Ben-Amotz et al 1996). Algae-derived beta-carotene was also found to protect against CNS oxygen toxicity in rats, as indicated by a significant increase in the latent period preceding oxygen seizures in supplemented animals (Bitterman et al 1994).

### Isomer difference

Individual isomers and isomer mixtures demonstrate different antioxidant properties in vivo. The 9-*cis* isomer, which is present in greater amounts in natural beta-carotene, exhibits higher antioxidant potency than the all-*trans* isomer in vitro (Levin & Mokady 1994). Natural beta-carotene, such as that obtained from algal sources, also exhibits greater antioxidant activity than synthetic beta-carotene in vivo (Takenaka et al 1993).

In humans, supplementation with natural algal beta-carotene containing a 50:50 mix of all-*trans* and 9-*cis* isomers has been shown to be a more effective lipophilic antioxidant than all-*trans* beta-carotene (Ben-Amotz & Levy 1996). Human supplementation with natural algal and synthetic beta-carotene has also been shown to produce similar reductions in LDL oxidation, despite the fact that synthetic beta-carotene produced double the rise in LDL beta-carotene content (Levy et al 1995).

These studies contrasted with in vitro studies that suggest that 9-*cis* beta-carotene and all-*trans* beta-carotene have equal antioxidant activities (Liu et al 2000), and that synthetic beta-carotene is twice as effective as algal beta-carotene in inhibiting LDL lipid peroxidation following LDL incubation with copper ions (Lavy et al 1993).

### Photoprotection

Beta-carotene, together with other carotenoids, is present in all photosynthetic organisms where it serves an important photoprotective function, either by dissipating excess excitation energy as heat or by scavenging reactive oxygen species and suppressing lipid peroxidation (Penuelas & Munne-Bosch 2005). Studies in bacteria, animals and humans have demonstrated that carotenoids can prevent or lessen photosensitivity by endogenous and exogenous photosensitisers (Mathews-Roth 1993). High doses of beta-carotene (from 180 mg/day up to 300 mg/day) have been used to treat the photosensitivity associated with erythropoietic protoporphyria (Mathews-Roth 1987). There is also consistent evidence from animal and human studies that beta-carotene has photoprotective effects.

Beta-carotene is present at the target sites of light-induced damage in the dermis, epidermis and stratum corneum, with levels varying in skin areas with higher concentration in the forehead and palms (Alaluf et al 2002). Skin levels are related to the levels found in the plasma (Sies & Stahl 2004). Beta-carotene and other endogenous antioxidants are reduced in both skin and blood by UV exposure (Gollnick et al 1996).

Although it is presumed that beta-carotene exerts a light-protective function by quenching excited species such as singlet oxygen and free radicals (Mathews-Roth 1987), there are a number of other ways that beta-carotene may contribute to photoprotection (i.e. protection against the absorption of UV light). These include the protection of target molecules through its antioxidant activity, enhancement of the repair of UV damage, modulation of enzyme activity and gene expression, enhancement of cell-to-cell communication and suppression of cellular responses and inflammation (Sies & Stahl 2004). It is also suggested that the UVA protection provided by beta-carotene is due to the siting of beta-carotene deep inside membranes in proximity to the UVA chromophores that initiate the cell damage (Bohm et al 1998b).

As a strong natural pigment, beta-carotene produces a yellow-orange colouration in the skin that adds to the red colouration from haemoglobin and the brown colouration from melanin to create the normal human skin colour (Alaluf et al 2002). Beta-carotene acts as a blue light filter by absorbing light in the range of 360–550 nanometers (Pathak 1982), with the *cis* isomers having been found to exhibit an additional absorption maximum in the UV range (Sies & Stahl 2004), thus suggesting a possible advantage for natural beta-carotene over synthetic all-*trans* beta-carotene in providing photoprotection.

As with titanium dioxide, the beta-carotene in the skin takes the form of finely dispersed particles that can increase the natural pigment action. This was observed in a human trial involving 20 subjects which found that supplementation with 50 mg of natural algal beta-carotene for 6 weeks increased the reflection capacity of the skin 2.3-fold, irrespective of the wavelength (Heinrich et al 1998). A study on whole albino hairless mouse skin and epidermis, however, suggests that although beta-carotene did impart a visible change in skin colour its absorbance was insufficient to impart significant photoprotection, which indicates that its photoprotective action is mediated through processes in addition to blue light absorption (Sayre & Black 1992).

In a controlled study injection of phytoene, the colourless triene precursor of beta-carotene was found to significantly reduce radiation-induced erythema in guinea pigs (Mathews-Roth & Pathak 1975); however, a further study on albino hairless mice found that 10 g/kg feed of beta-carotene and 200 mg/kg feed of 13-*cis* retinoic acid for 12 weeks did not prevent UVB-induced dermal damage (Kligman & Mathews-Roth 1990).

An in vitro study on human keratinocytes suggests that beta-carotene dose-dependently suppressed UVA-induction of matrix metalloproteases through quenching of singlet oxygen and that this action was not enhanced by vitamin E (Wertz et al 2004). Further studies suggest that beta-carotene also interferes with UVA-induced gene expression by

multiple pathways, including inhibition of UVA-induced extracellular matrix degradation, enhanced UVA induction of tanning-associated protease-activated receptor-2, promotion of keratinocyte differentiation and synergistic induction of cell cycle arrest and apoptosis (Wertz et al 2005).

Beta-carotene has also been observed to have synergistic effects with other antioxidants in protecting cultured human fibroblasts from UVA, although only additive effects were observed for UVB (Bohm et al 1998b). The interaction between different antioxidants and/or other as yet unidentified phytochemicals has been used to explain the finding that UV carcinogenesis was enhanced with a beta-carotene-supplemented semi-defined diet in mice (Black 2004, Black & Gerguis 2003, Black et al 2000).

### Enhanced intercellular communication

In addition to its antioxidant activity, beta-carotene enhances gap junction intercellular communication by upregulation of the gap junction protein connexin 43. This action may be important in its control of tumour growth (Yeh & Hu 2003), and is likely to be independent of its ability to quench singlet molecular oxygen (Stahl et al 1997).

Animal studies have indicated that a beta-carotene dose of 50 mg/kg/day for 5 days inhibits, whereas a lower dose (5 mg/kg/day) increases gap junction intercellular communication in rat liver. Further in vitro studies suggest that the observed inhibition is due, at least in part, to oxidised beta-carotene (Yeh & Hu 2003).

### Anticarcinogenic activity

Observational epidemiological studies have consistently shown a relationship between dietary beta-carotene intake and low risk of various cancers (Cooper et al 1999b, Pryor et al 2000). In animal studies beta-carotene has been found to be chemoprotective, with inhibition of spontaneous mammary tumours (Fujii et al 1993, Nagasawa et al 1991), as well as prevention of skin carcinoma formation (Ponnampereuma et al 2000), UV-induced carcinogenesis in mice (Epstein 1977, Mathews-Roth 1982) and oral cancer in laboratory and animal models (Garewal 1995). Studies in ferrets suggest that the beta-carotene molecule becomes unstable in smoke-exposed lungs and that when given with alpha-tocopherol and ascorbic acid to stabilise the beta-carotene molecule, there is a protective effect against smoke-induced lung squamous metaplasia (Russell 2002).

A review of carotenoid research by the International Agency for Research on Cancer suggests there is sufficient evidence that beta-carotene has cancer-preventive activity in experimental animals, based on models of skin carcinogenesis in mice and buccal pouch carcinogenesis in hamsters (Vainio & Rautalahti 1998), despite a review suggesting that beta-carotene does not protect against lung cancer in animals (De Luca & Ross 1996).

Whether beta-carotene has anticancer properties in humans is unclear. It has been suggested any such effects could be mediated through multiple mechanisms that may include: antioxidant activity preventing oxidative damage to DNA and inhibition of lipid peroxidation; stimulation of gap junction communication; effects on cell transformation and differentiation; inhibition of cell proliferation and oncogene expression; effects on immune function; and inhibition of endogenous formation of carcinogens (Cooper et al 1999a). Additional mechanisms may include the metabolic conversion of beta-carotene to retinoids, which may in turn modulate the gene expression of factors linked to differentiation and cell proliferation. The modulation of enzymes that metabolise xenobiotics and inhibition of endogenous cholesterol synthesis by modulation of HMG-CoA reductase expression may also lead to a possible inhibition of cell proliferation and malignant transformation (PDRHealth 2005).

None of these mechanisms has been conclusively found to contribute to the prevention of cancer in vivo, and there is ongoing debate about the role of beta-carotene in cancer prevention (Cooper et al 1999a, Patrick 2000). This debate has been further fuelled by the findings of two large intervention studies: the Alpha-Tocopherol Beta-Carotene (ATBC) Cancer Prevention Study (the 'Finnish study': Heinonen et al 1994) and the Carotene and Retinol Efficacy Trial (CARET: Omenn et al 1996b), which found a significantly increased risk of lung cancer in high-risk individuals supplemented with synthetic beta-carotene (see *Clinical use* for more details).

The mixed findings from beta-carotene intervention trials have produced much controversy in the scientific literature and although it has been suggested there is no known biologically plausible explanation for the findings, a number of hypotheses have been put forward (Bendich 2004). It has been suggested that the dose, duration of study and/or choice of synthetic all-*trans*-beta-carotene may have been inappropriate in the intervention trials (Cooper et al 1999b), and that supplementation with monotherapy using synthetic beta-carotene may have inhibited the absorption of other carotenoids (Woodall et al 1996). It is also suggested that, although beta-carotene may be effective in the prevention of lung cancer before or during the phases of initiation and early promotion of cancer, the intervention studies that involved heavy smokers and asbestos workers probably included individuals in whom these processes were already initiated (Bendich 2004).

Additional possible explanations for the observed increase in lung cancer risk with beta-carotene supplementation include possible pro-oxidant activity of beta-carotene or its oxidative metabolites in the high-oxygen environment of smokers' lungs, with oxidised beta-carotene metabolites inducing carcinogen-bioactivating enzymes, facilitating the binding of metabolites to DNA, enhancing retinoic

acid metabolism by P450 enzyme induction and acting as pro-oxidants, causing damage to DNA (Russell 2002), as well as inhibition of retinoid signalling (Wang et al 1999). It is further suggested that the beta-carotene molecule may become unstable due to the presence of a lower level of antioxidants, such as ascorbic acid, in smokers than in non-smokers (Bohm et al 1997), together with the presence of significant oxidative stress in smokers who consume high amounts of alcohol (PDRHealth 2005).

It has further been suggested that beta-carotene may increase lung cancer risk in smokers because of its ability to improve lung function. Thus smokers supplemented with beta-carotene may have increased lung capacity, resulting in deeper breathing of carcinogens and other oxidants. It is also suggested that beta-carotene may improve smokers' immune responses and thus reduce the number of days they suffer from upper respiratory tract infections, which enables them to smoke more (Bendich 2004).

The suggestion that beta-carotene may have pro-oxidant effects is supported by an in vitro study showing that although cell viability and DNA integrity were not affected by beta-carotene, they were significantly and dose-dependently decreased by oxidised beta-carotene (Yeh & Hu 2001). There was a dose-dependent increase of beta-carotene cleavage products, together with increasing genotoxicity in vitro when beta-carotene was supplemented during oxidative stress induced by hypoxia/reoxygenation (Alija et al 2004, 2005). Carotenoid cleavage products have also been found to impair mitochondrial function and increase oxidative stress in vitro (Siems et al 2002, 2005), as well as produce a booster effect on phase I carcinogen-bioactivating enzymes in the rat lung (Paolini et al 1999). Beta-carotene has also been shown to be degraded by stimulated polymorphonuclear leucocytes in vitro, producing highly reactive and potentially toxic cleavage products (Sommerburg et al 2003). These pro-oxidant effects have not been conclusively demonstrated in vivo, and beta-carotene at a dose of 50 mg/day for several years was not found to have pro-oxidant effects in either smokers or non-smokers, as measured by urinary excretion of F<sub>2</sub>-isoprostanes (Mayne et al 2004).

### Cardiovascular protection

There are a number of ways in which beta-carotene may act to protect against cardiovascular disease. Free-radical scavenging may prevent cellular transformations leading to atherosclerosis, and protection of LDL oxidation may further act to protect against atheroma formation (Halliwell 1993). Other mechanisms proposed for the possible favourable effect of antioxidants include an increase of HDL cholesterol and the preservation of endothelial functions (Tavani & La Vecchia 1999). Patients with acute myocardial infarction (AMI) have also been shown to have reduced plasma antioxidant vitamins and enhanced lipid peroxidation upon thrombolysis, suggesting

that antioxidants may reduce free-radical generation processes in reperfusion injury in AMI (Levy et al 1998).

In an animal study, atherosclerosis was inhibited in rabbits fed a high-cholesterol diet supplemented with all-*trans* beta-carotene. In that study all-*trans* beta-carotene was undetectable in LDL, although tissue levels of retinyl palmitate were increased, suggesting that any anti-atherogenic effect is separate from the resistance of LDL to oxidation and that metabolites of beta-carotene may inhibit atherosclerosis in hypercholesterolaemic rabbits, possibly via stereospecific interactions with retinoic acid receptors in the artery wall (Shaish et al 1995). A randomised, placebo-controlled trial in 149 male smokers taking 20 mg/day of beta-carotene for 14 weeks, however, found no influence on haemostatic measures, suggesting that it is unlikely that cardiovascular protection from beta-carotene is via an effect on haemostasis (Van Poppel et al 1995).

### OTHER ACTIONS

An animal study found that rats supplemented with beta-carotene-rich algae had improved reproduction and body growth, with a markedly lower stillbirth rate, a higher litter size or rearing rate, and enhanced body growth in male offspring (Nagasawa et al 1989).

### CLINICAL USE

#### Vitamin A deficiency

In a series of large, double-blind, cluster-randomised, placebo-controlled field trials involving as many as 44,000 Nepalese women, weekly supplementation with 42 mg of *trans*-beta-carotene was found to reduce the prevalence of selected illness symptoms such as loose stools, night blindness and symptoms of high fever during late pregnancy, at the time of birth and during 6 months post-partum (Christian et al 2000b). Beta-carotene was further found to reduce maternal, but not infant, mortality among smokers and non-smokers by approximately 50%, with a protective effect becoming evident after 18 months of supplementation (Christian et al 2004, West et al 1999). Beta-carotene supplementation has also been found to reduce the five-fold increased risk of infection-related mortality in women who were night-blind because of vitamin A deficiency (Christian et al 2000a). In a randomised-controlled trial of children in rural China it was found that beta-carotene supplementation had a similar effect on correcting childhood vitamin A deficiency to retinol supplementation, with reduced morbidity and increased weight. The authors concluded that, considering the health risk of vitamin A supplementation and the easier acquisition and antioxidant value of dietary beta-carotene, dietary beta-carotene supplementation should be recommended for addressing vitamin A deficiency in this population (Lin et al 2009).

These studies contrast with one that found an association between self-reports of poor night vision and beta-carotene consumption in women involved in the Blue Mountain Eye Study, in which the authors concluded that perceived poor night vision caused an increase in carrot consumption in women (Smith et al 1999).

### Cancer prevention

There are at least 35 observational epidemiological studies, including prospective cohort and case-controlled studies, involving smoking and non-smoking men and women from diverse regions of the world, that have found a positive association between dietary or serum beta-carotene levels and reduced risk of cancer (Cooper et al 1999a). This association, however, does not necessarily imply a causal link, because it may be an association between beta-carotene ingestion and other dietary or lifestyle factors (Peto et al 1981). Beta-carotene intake is linked to a variety of healthy dietary and lifestyle factors, as well as being highly correlated with the intake of many other protective dietary phytochemicals and nutrients (Cooper et al 1999a). Furthermore, these results have not always been consistent with a 6-year study of 137,001 European men, which found no link between plasma carotenoids and prostate cancer risk (Key et al 2007), and with a pooled analysis of 11 cohort studies suggesting no link with colorectal cancer risk (Männistö et al 2007). Similarly a pooled analysis of 10 cohort studies involving 521,911 women found no association between dietary carotenoids and the risk of ovarian cancer (Koushik et al 2006).

While the protective effect of dietary carotenoids on cancer risk is still being debated, findings of two large intervention trials have reported an increased lung cancer risk with synthetic beta-carotene supplementation (Heinonen et al 1994, Omenn et al 1996a).

The ATBC Cancer Prevention Study (Finnish study) was the first large intervention trial to test the hypothesis that beta-carotene reduces the risk of lung cancer. This double-blind, placebo-controlled primary-prevention trial involved 29,133 male smokers, 50–69 years of age, who were randomly selected to receive daily supplementation with alpha-tocopherol (50 mg/day) alone, synthetic (all-*trans*) beta-carotene (20 mg/day) alone, or both. After a follow-up period of 5–8 years, the results suggested that there was an unexpected 18% increase in the incidence of lung cancer with an associated 8% higher mortality among those who received beta-carotene (Heinonen et al 1994). Subgroup analysis revealed that the increased risk with beta-carotene supplementation was only greater for those who smoked at least 20 cigarettes per day, with the risk of those who smoked 5–19 cigarettes/day being no greater than that of the placebo group. An increased risk was also observed for those who consumed more than 11 g/day alcohol compared with

those with a lower alcohol intake (Albanes et al 1996). Further analysis found no effect of beta-carotene supplementation on the risk of pancreatic cancer (Rautalahti et al 1999), colorectal cancer (Albanes et al 2000), urothelial or renal cell cancer (Virtamo et al 2000), or gastric cancer (Malila et al 2002).

The CARET trial tested the effect of synthetic, all-*trans* beta-carotene (30 mg) and retinyl palmitate (25,000 IU) on the incidence of lung cancer, other cancers and death in 18,314 participants who were at high risk of lung cancer because of a history of heavy smoking or asbestos exposure. CARET was stopped ahead of schedule in January 1996 because participants who were randomly assigned to receive the active intervention were unexpectedly found to have a 28% increase in incidence of lung cancer, a 17% increase in incidence of death and a higher rate of cardiovascular disease mortality compared with participants in the placebo group (Omenn et al 1996b). Further analysis revealed results similar to the ATBC study, with the increased risk of lung cancer being greatest for heavy smokers and those with the highest alcohol intake, while former smokers were found to have a similar risk to that of those taking the placebo (Omenn et al 1996b).

The finding of an increased risk of lung cancer in smokers taking beta-carotene in the ATBC and CARET studies is consistent with a number of other studies. A prospective cohort study of 59,910 French women found that self-reported supplemental use of beta-carotene was directly associated with double the risk of cancers among smokers, yet dietary beta-carotene intake was associated with less than half the risk of tobacco-related cancers among non-smokers in a statistically significant dose-dependent relationship (Touvier et al 2005). Similarly, the results of a case-control study of 362 adenoma cases and 427 polyp-free controls suggest a protective effect for colon cancer with beta-carotene in non-smokers and an adverse effect in smokers (Senesse et al 2005). Alcohol intake and cigarette smoking were also observed to modify the effect of beta-carotene supplementation on the risk of colorectal adenoma recurrence in another double-blind, placebo-controlled clinical trial involving 864 patients randomised to receive either beta-carotene (25 mg), vitamin C (1000 mg) or vitamin E (400 mg), beta-carotene with vitamins C and E, or a placebo. After 4 years this trial found no evidence that supplementation reduced the incidence of adenomas (Greenberg et al 1994). Subgroup analysis from this study, however, found that beta-carotene supplementation was associated with a marked decrease in the risk of one or more recurrent adenomas among subjects who neither smoked cigarettes nor drank alcohol, but conferred a modest increase in the risk of recurrence among those who either smoked or drank alcohol and doubled the risk for those who both smoked and drank (Baron et al 2003).

The results of these studies are contrasted with those from the Physicians' Health Study, which found that beta-carotene supplementation had no effect on cancer risk in smokers or non-smokers. This RCT of 50 mg of synthetic beta-carotene given on alternate days involved 22,071 US male doctors, 11% of whom were smokers. After more than 12 years of follow-up, no overall effect on cancer incidence was evident with beta-carotene supplementation (Hennekens et al 1996) and no benefit or harm was observed for lung, prostate or colon cancer (Cook et al 2000), or for squamous cell carcinoma (Friedling et al 2000). Subgroup analysis of this study population revealed that total cancer was modestly reduced with supplementation among those aged more than 70 years, and total cancers and colon cancer was reduced in those who drank alcohol daily (Cook et al 2000). Total cancers and prostate cancer were also reduced in those in the highest BMI quartile (Cook et al 2000) and those with low baseline beta-carotene levels (Cook et al 1999), while those with high baseline levels had a non-significant increased risk of prostate cancer with beta-carotene supplementation (Cook et al 1999).

Similar to the results of the Physicians' Health Study the results of the Women's Health Study, which involved 39,876 women supplemented with 50 mg of beta-carotene on alternate days for 2 years, found no benefit or harm from beta-carotene supplementation on the incidence of cancer or cardiovascular disease in apparently healthy women, and no benefit or harm observed for the 13% of women who were smokers at baseline (Lee et al 1999).

In contrast to these results, an RCT performed on a poorly nourished population found a lower cancer incidence with beta-carotene supplementation. This study involved 29,584 adults aged between 40 and 69 years from Linxian County, China, which has one of the world's highest rates of oesophageal/gastric cardia cancer and a persistently low intake of several micronutrients. In this study people were randomised to receive retinol and zinc, riboflavin and niacin, vitamin C and molybdenum, or beta-carotene, vitamin E and selenium, at doses that ranged from one- to two-fold the US RDI for a period of 6 years. Results revealed a significantly lower total mortality rate among those receiving supplementation with beta-carotene, vitamin E and selenium, mainly attributable to lower cancer rates, especially stomach cancer (Blot et al 1993).

#### Possible reasons for the mixed results

The mixed results from the beta-carotene intervention studies have created significant debate. The results of a review of carotenoid research by the International Agency for Research on Cancer suggest there is a lack of cancer-preventive activity for beta-carotene when it is used as a supplement at high doses (Vainio & Rautalahti 1998). This is

supported by a more recent study that examined the relationship between dietary beta-carotene and lung cancer, using pooled data from seven cohort studies that involved 399,765 participants and 3155 lung cancer cases. This study found that dietary beta-carotene intake was not associated with increased or decreased lung cancer risk in those who had never smoked, past or current smokers (Männistö et al 2004). Similarly, a more recent systematic review and meta-analysis of six randomised clinical trials examining the efficacy of beta-carotene supplements and 25 prospective observational studies assessing the associations between carotenoids and lung cancer suggests that beta-carotene supplementation is not associated with a significant altered risk of developing lung cancer (Gallicchio et al 2008).

The mixed results from beta-carotene intervention studies may also be a reflection of a difference between natural and synthetic beta-carotene, as the negative intervention studies have all used synthetic rather than natural beta-carotene. These studies, however, do provide consistent evidence for a link between dietary and serum beta-carotene levels and reduced cancer risk. Even in the studies that found an adverse effect of beta-carotene supplementation, study participants with the highest intake and serum concentrations of beta-carotene at baseline developed fewer subsequent lung cancers, regardless of their intervention assignment (Albanes 1999, Holick et al 2002). Therefore, although monotherapy with synthetic beta-carotene is no longer generally recommended, there continues to be a consistent call for an increased consumption of beta-carotene-containing foods to assist in the prevention of cancer (Mayne 1996, Pryor et al 2000).

### Oral leucoplakia

Beta-carotene consumption has been found to be inversely associated with precancerous lesions of the oral cavity in tobacco users (Gupta et al 1999), and it is suggested that there is a significant role for antioxidant nutrients in preventing oral cancer (Garewal & Schantz 1995). This is supported by the findings of multiple clinical trials in which beta-carotene and vitamin E have been shown to produce regression of oral leucoplakia, a premalignant lesion for oral cancer (Garewal 1994, Wright et al 2007).

In a more recent, double-blind RCT involving 160 people, 360 mg/week of beta-carotene for 12 months was found to induce regression in oral precancerous lesions, with half of the responders relapsing after ceasing supplementation. Similarly, another multicentre, double-blind, placebo-controlled trial found improvement in dysplasia with 60 mg/day of beta-carotene for 6 months (Garewal et al 1999).

These studies are contrasted with a subgroup analysis involving 409 white male cigarette smokers from the ATBC study, which suggested that beta-carotene supplementation does not play an essential role in preventing oral mucosal changes in smokers (Liede et al 1998).

### Cardiovascular disease

Epidemiological studies support the idea that a diet rich in high-carotenoid-containing foods is associated with a reduced risk of heart disease (Kritchevsky 1999). A review of observational and intervention studies on beta-carotene and the risk of coronary heart disease found that seven cohort studies (Gaziano et al 1995a, Gey et al 1993, Knekt et al 1994, Manson et al 1991, Morris et al 1994, Rimm et al 1993, Street et al 1994) reported relative risks between 0.27 and 0.78 for high serum beta-carotene levels or high dietary intake; the review found this was supported by case-control studies (Bobak et al 1998, Bolton-Smith et al 1992, Kardinaal et al 1993, Torun et al 1994, Tavani et al 1997) which reported odds ratios between 0.37 and 0.71, with a possible stronger protection for current smokers (Tavani & La Vecchia 1999). More recently, a 16-year cohort study of 1031 Finnish men aged 46–65 years from the Kuopio Ischemic Heart Disease Risk Factor (KIHD) cohort, found that after controlling for other factors, low serum beta-carotene concentrations increased the risk of cardiovascular disease and total mortality in men and that men in the lowest tertile of serum concentrations of beta-carotene had a two-fold increased risk of sudden cardiac death compared to those in the highest tertile and men with the lowest quartile of beta-carotene had almost three-fold increased risk of congestive cardiac failure (Karppi et al 2013a, Karppi et al 2013b). This study further reported that the strongest risk of CVD mortality was observed among smokers with lowest levels of beta-carotene (Karppi et al 2012). These results contrast with those of four more recent cohort studies (Knekt et al 1994, Kushi et al 1996, Pandey et al 1995, Todd et al 1995) and five large RCTs (Hennekens et al 1996, Lee et al 1999, Redlich et al 1999, Vlot et al 1995) which have not reported any significant prevention of cardiovascular disease with beta-carotene supplementation.

The final results of the Physicians' Health Study (see *Cancer prevention* above) indicated that beta-carotene supplementation exerted no significant benefit or harm on cancer or cardiovascular disease during more than 12 years of treatment (Hennekens et al 1996). Similarly, the results of the Women's Health Study, involving 39,876 women aged 45 years or older, found that beta-carotene supplementation of 50 mg on alternate days did not influence cardiovascular disease after 2 years of supplementation and 2 years of further follow-up. Subgroup analysis revealed that beta-carotene supplementation had an apparent benefit on subsequent vascular events among 333 men with prior angina or revascularisation (Christen et al 2000c).

In contrast, analysis of the data from the ATBC cancer prevention study, which involved 23,144 male smokers, found that beta-carotene supplementation slightly increased the risk of angina (Rapola et al 1996) and intracerebral haemorrhage, while having no overall effect on the risk of stroke

(Leppala et al 2000a, 2000b), abdominal aortic aneurysm (Tornwall et al 2001), or symptoms and progression of intermittent claudication (Tornwall et al 1999). Beta-carotene, however, was found to decrease the risk of cerebral infarction modestly among a subgroup with greater alcohol consumption (Leppala et al 2000a, 2000b). In a 6-year post-intervention follow-up study, beta-carotene was found to increase the risk of first-ever myocardial infarction, while continuing to have no overall effect on the incidence of stroke (Tornwall et al 2004). An analysis of 52 men from the CARET study concluded that there was no significant effect on total, HDL or LDL cholesterol levels, which could account for the increase risk of cardiovascular disease observed in this study (Redlich et al 1999).

A pooled analysis of four randomised trials of beta-carotene therapy, ranging from 20 mg to 50 mg, involving 90,054 patients, found beta-carotene supplementation to be associated with a significant increase in all-cause mortality and cardiovascular death in patients at risk of coronary disease, with the increased risk being greatest in smokers. A further meta-analysis of eight randomised trials involving 138,113 patients found that supplementation with 15–50 mg of beta-carotene was associated with a small but significant increase in all-cause mortality and a slight increase in cardiovascular death (Vivekananthan et al 2003).

The apparent discrepancy between the findings of observational and intervention studies may be due to several factors, including the length and nature of the intervention (Tavani & La Vecchia 1999). For example, the intervention trials involved supplementation with synthetic beta-carotene in isolation or with other single nutrients, whereas the observational studies involved the consumption of beta-carotene-rich foods containing a range of additional antioxidant vitamins, phytonutrients and micronutrients.

### Photoprotection

Excessive exposure to solar radiation, especially UVA (320–400 nm) and UVB (290–320 nm), may induce UV-carcinogenesis and erythema in the skin (Lee et al 2000). There have been a number of controlled clinical trials that have demonstrated that supplementation with beta-carotene alone, or in combination with other antioxidants, can reduce UV-induced erythema (Gollnick et al 1996, Heinrich et al 1998, Heinrich et al 2003, Lee et al 2000, Mathews-Roth et al 1972, Sies & Stahl 2004, Stahl et al 2000). These studies suggest that at least 8–10 weeks of supplementation required before protection against erythema becomes evident and that doses of at least 24 mg/day of beta-carotene are required (Sies & Stahl 2004).

In uncontrolled studies, a protective effect against UV-induced erythema was observed after supplementation with 180 mg of beta-carotene for 10 weeks (Mathews-Roth et al 1972) and with 50 mg for 6 weeks (Heinrich et al 1998). These results are

supported by more rigorous studies that have shown photoprotective activity with smaller doses of beta-carotene. An RCT involving supplementation with 30 mg of natural beta-carotene for 8 weeks, with the dose increasing to 60 mg for a further 8 weeks and then to 90 mg for another 8 weeks, found a dose-dependent reduction in UVA- and UVB-induced erythema (Lee et al 2000). In another RCT, supplementation for 12 weeks with 24 mg/day of natural beta-carotene or a natural carotenoid mix supplying similar amounts of beta-carotene, lutein and lycopene also significantly reduced UV-induced erythema (Heinrich et al 2003). Similarly, a randomised trial found that supplementation with 25 mg of natural algal beta-carotene for 12 weeks significantly reduced UV-induced erythema, with the effect enhanced by the addition of alpha-tocopherol (Stahl et al 2000). Yet another trial suggests that the photoprotective action of beta-carotene enhances the action of topical sunscreens. In this randomised, placebo-controlled, double-blind study of 20 healthy young females, 30 mg/day beta-carotene for 10 weeks reduced UV-induced erythema and protected against UV-induced drop in serum beta-carotene levels and UV-induced reduction in Langerhans cells; beta-carotene combined with topical sunscreens was more effective than sunscreen cream alone (Gollnick et al 1996). A protective effect against photo-immunosuppression was demonstrated in another study in which 30 mg/day of beta-carotene for 4 weeks protected against UV-induced suppression of delayed-type hypersensitivity in young men (Fuller et al 1992).

It has been suggested that the duration of supplementation may be more important than the dose, as the studies that have not demonstrated significant reduction in UV-induced erythema have all involved supplementation of relatively short duration (Lee et al 2000). No photoprotective effects were observed with supplementation of 90 mg beta-carotene for 3 weeks (Garmyn et al 1995), 150 mg/day for 4 weeks (Wolf et al 1988) or 15 mg/day for 8 weeks (McArdle et al 2004).

It has also been suggested that a combination of antioxidants may be more effective than the sum of the separate components because the skin's antioxidant defence system appears to involve an intricate connection between individual antioxidants (Steenvoorden & Beijersbergen van Henegouwen 1997). This is supported by a randomised, double-blind, placebo-controlled study that found that short-term (2-week) supplementation with an antioxidative combination containing beta-carotene and lycopene, as well as vitamins C and E, selenium and proanthocyanidins, significantly decreases the UV-induced expression of matrix metalloproteinases, with a non-statistically significant trend towards reduced minimal erythema dose (Greul et al 2002).

Although beta-carotene supplementation may provide some degree of protection against sunburn, the effect is modest and there is still some debate

about its use for routine photoprotection (Biesalski & Obermueller-Jevic 2001, Fuchs 1998). However, beta-carotene is likely to be clinically useful in providing photoprotection for people with specific photosensitivity. High doses (180 mg/day, up to 300 mg/day) have been shown to reduce photosensitivity in people with the genetic condition erythropoietic protoporphyria in a number of case series (Mathews-Roth et al 1970, 1974, Thomsen et al 1979), and the results of a double-blind RCT suggest that beta-carotene may be useful in conjunction with canthaxanthin in preventing polymorphous light eruptions (Suhonen & Plosila 1981).

The ability of beta-carotene to protect against UV-induced erythema and photosensitivity does not appear to extend to protecting against non-melanotic skin cancer. In a randomised placebo-controlled trial involving 1805 subjects with recent non-melanotic skin cancer, daily supplementation with 50 mg beta-carotene for 5 years had no effect on the incidence of new or recurring non-melanotic skin cancers, with similar results for those with low-baseline beta-carotene levels and smokers (Greenberg et al 1990). Similarly, in another randomised, placebo-controlled trial of 1621 adults aged between 25 and 74 years, daily supplementation with 30 mg beta-carotene did not reduce the development of solar keratoses over the 3-year study period (Darlington et al 2003, Green et al 1999). These results are supported by an analysis of data from the Physicians' Health Study which found that 12 years of beta-carotene supplementation had no effect on the incidence of non-melanotic skin cancer (Frieling et al 2000); a subgroup analysis from this study also found no effect on non-melanotic skin cancer in men with low-baseline plasma beta-carotene levels (Schaumberg et al 2004). In a further randomised, placebo-controlled study of 62 patients with numerous atypical naevi, 25 mg of beta-carotene given twice daily for 36 months resulted in a non-significant reduction in newly developed naevi, with a significant reduction observed for the lower arm and feet, but not for 10 other body sites (Bayerl et al 2003).

### Oxidative stress

There are a number of human studies that suggest supplementation with beta-carotene can reduce the oxidative stress associated with different pathological conditions or stressors such as intense exercise or radiation. Supplementation with beta-carotene (30 mg/day) and vitamin E (500 mg/day) for 90 days has been found to enhance the antioxidant enzyme activity of superoxide dismutase and catalase in the neutrophils of sportsmen (Tauler et al 2002). Similarly, in a study of 13 professional basketball players, 35 days of antioxidant supplementation with 600 mg alpha-tocopherol, 1000 mg ascorbic acid and 32 mg beta-carotene led to a significant decrease in plasma lipid peroxides, with a significant decrease of lactate dehydrogenase serum activity and a non-significant increase in the anabolic/catabolic balance

being observed during a 24-hour recuperation time after exercise (Schroder et al 2001).

The results of an Israeli study of 709 children exposed to radiation from the Chernobyl accident suggest that natural algae-derived beta-carotene may act as an *in vivo* lipophilic antioxidant or radioprotector. This study found that exposed children had increased susceptibility to lipid oxidation and that supplementation with 40 mg of natural 9-*cis* and all-*trans* equal isomer mixture beta-carotene twice daily for a period of 3 months reduced plasma markers of lipid oxidation (Ben-Amotz et al 1998).

A double-blind study has also found that beta-carotene supplementation reduced the severity, but not the incidence, of post-endoscopy pancreatitis, which is thought to be mediated by oxidative stress (Lavy et al 2004). A further small, controlled trial involving 15 patients with rheumatoid arthritis found that 3 weeks of supplementation with natural beta-carotene resulted in a significant increase in plasma antioxidants, but did not change indicators of disease (Kacsur et al 2002).

There is also evidence that beta-carotene may protect against the oxidative stress caused by chemotherapy and radiotherapy. A study on conditioning therapy found antioxidant protection after supplementation with 45 mg beta-carotene, 825 mg alpha-tocopherol and 450 mg ascorbic acid daily for 3 weeks preceding bone marrow transplantation. The conditioning therapy, which consists of high-dose chemotherapy and total body irradiation, has acute and delayed toxic effects that are considered to be due to peroxidation processes and exhaustion of antioxidants. Supplementation, however, was found to increase serum antioxidant levels and reduce the post-conditioning rise in plasma lipid hydroperoxides in patients receiving the conditioning therapy before transplantation (Clemens et al 1997). A higher than usual dietary intake of beta-carotene has also been found to reduce the occurrence of severe adverse effects of radiation therapy and decrease local cancer recurrence in people with head and neck cancer (Meyer et al 2007).

Contrasting with the above studies are two small studies showing no change in oxidative stress in healthy subjects after beta-carotene supplementation. Normal concentrations of carotenoids in plasma and tissues were not correlated with clinical markers of antioxidant and oxidative stress in a study of 79 healthy volunteers (Borel et al 1998), and a placebo-controlled, single-blind study found that daily supplementation with 15 mg of beta-carotene for 3 months did not significantly improve biomarkers of oxidative stress in healthy males (Hiningert et al 2001).

### Immune function

Beta-carotene supplementation of 15 mg/day has been shown to significantly reduce IgE and respiratory rate and improve recovery of pneumonia among children aged 6–36 months (Mohamed et al 2008). In a study of 652 non-institutionalised elderly

people, the incidence of acute respiratory infections was reduced for those with the highest plasma levels, suggesting that beta-carotene may improve the immune response and result in decreased risk of infectious diseases (van der Horst-Graat et al 2004).

In contrast to these findings, analyses of male smokers who participated in the ATBC study found that supplementation with synthetic beta-carotene had no overall effect on the risk of hospital-treated pneumonia or the incidence of the common cold (Hemila et al 2002, 2004), but instead increased the risk of colds in subjects carrying out heavy exercise at leisure but not at work (Hemila et al 2003).

### Asthma and chronic obstructive pulmonary disease

Studies have shown increased oxidative stress in patients with chronic airflow limitation (Ochs-Balcom et al 2005) and accumulating evidence suggests that dietary antioxidant vitamins are positively associated with lung function (Schunemann et al 2001), with serum beta-carotene levels being associated with improved forced expiratory volume in the first second (FEV<sub>1</sub>) (Grievink et al 2000). Thus it has been suggested that antioxidant protection is important for protecting the lungs against high oxygen levels and that oxidative stress may contribute to respiratory pathology such as asthma (Rahman et al 2006, Wood et al 2003). This is supported by the finding of a significant association between serum vitamin C, vitamin E, beta-cryptoxanthin, lutein/zeaxanthin, beta-carotene and retinol with FEV<sub>1</sub> (Schunemann et al 2001), together with a study involving a subset from the CARET study of 816 asbestos-exposed men with a high rate of current and former cigarette smoking, which found that serum beta-carotene was associated with a significant improvement in forced expiratory volume in 1 second (FEV<sub>1</sub>) and forced vital capacity (FVC) (Chuwers et al 1997).

Studies on the correlation between serum beta-carotene levels and asthma, however, have produced mixed results. A recent meta-analysis of 10 studies on the incidence of dietary antioxidant intake and the risk of asthma found no positive association between intakes of beta-carotene or vitamin E and asthma risk (Gao et al 2008). One small study of 15 asthmatic subjects and 16 healthy controls found that despite similar dietary intake, whole blood levels of total carotenoids — including beta-carotene, lycopene, lutein, beta-cryptoxanthin and alpha-carotene — were significantly lower in the asthmatics, with no differences in plasma or sputum carotenoid levels (Wood et al 2005). Another small study found that beta-carotene, alpha-tocopherol and ascorbic acid were significantly lower in asthmatics at remission compared to controls, and that beta-carotene was significantly lower and lipid peroxidation products significantly higher during attacks than in periods of remission (Kalayci et al 2000). A further small study found that increased dietary

consumption of beta-carotene was associated with better quality of life (Moreira et al 2004).

These results are supported by an analysis of 7505 youths (4–16 years) from the Third National Health and Nutrition Examination Survey, which found that increased serum beta-carotene was associated with reduced asthma prevalence (Rubin et al 2004). Another analysis involving 4093 children from the same study, 9.7% of whom reported a diagnosis of asthma, found that asthma diagnosis was associated with lower levels of serum beta-carotene, vitamin C, alpha-carotene and beta-cryptoxanthin (Harik-Khan et al 2004).

In contrast to these findings, a much larger study involving 771 people with self-reported asthma, 352 people with former asthma and 15,418 people without asthma found that asthma status was not significantly associated with serum antioxidant concentrations (Ford et al 2004). Similarly, in a study of 15 mild asthmatics and 15 age- and sex-matched controls, oxidative stress was found to be increased in the asthmatics, with no difference in plasma dietary antioxidant vitamins (Wood et al 2000).

Although the role of antioxidant vitamins in prevention and/or treatment of asthma remains to be determined (Kalayci et al 2000), the results of one intervention study suggest that there may be a role for beta-carotene in exercise-induced asthma. This randomised, double-blind, placebo-controlled trial involved 38 subjects with proven exercise-induced asthma and found that supplementation with 64 mg/day of natural algal beta-carotene for 1 week protected against post-exercise reduction in FEV<sub>1</sub> (Neuman et al 1999).

### Cystic fibrosis

Cystic fibrosis (CF) is characterised by exocrine pancreatic insufficiency and reduced absorption of fat-soluble vitamins, as well as by chronic lung inflammation and an associated increased oxygen free-radical generation. Patients with CF have been found to have lower levels of beta-carotene, and it has been suggested that they would benefit from beta-carotene supplementation (Cobanoglu et al 2002, Walkowiak et al 2004). This suggestion is supported by a study of 52 patients with CF, which found a statistically significant correlation between serum beta-carotene and the clinical course of the disease as indicated by faecal elastase-1 and FEV<sub>1</sub> (Walkowiak et al 2004), together with a study showing that the plasma levels of beta-carotene and vitamin E increased and the plasma levels of TNF-alpha and malondialdehyde decreased after 6 months of beta-carotene supplementation (Cobanoglu et al 2002). This is further supported by a RCT of 24 CF patients who were supplemented with up to 50 mg/day beta-carotene for 12 weeks and 10 mg/day beta-carotene for a further 12 weeks; a significant decrease in oxidative stress, correction of total antioxidant capacity and improved pulmonary response to treatment were found in the supplemented group (Rust et al 2000).

## Cataracts

Although a high intake of foods containing beta-carotene has been associated with the prevention of cataracts, the role of supplementation is uncertain. An assessment of dietary beta-carotene intake in a subgroup of 472 non-diabetic female participants aged 53–73 years in the Nurses' Health Study found that the odds of posterior subcapsular cataracts were 72% lower in those with the highest intakes of beta-carotene who had never smoked, whereas beta-carotene intake and cataract risk were not associated in current or past smokers (Taylor et al 2002). In contrast to this finding, intervention studies have shown that beta-carotene may help prevent cataracts in smokers (Christen et al 2003, 2004a). Two years of beta-carotene treatment was found to have no significant beneficial or harmful effect on the development of cataract in a randomised, double-masked, placebo-controlled trial of 39,876 female health professionals aged 45 years or older who participated in the Women's Health Study, although a subgroup analysis suggests a possible beneficial effect in smokers (Christen et al 2004a). Similarly, the Physicians' Study (see above) found that 12 years of supplementation did not reduce the overall incidence of cataracts or cataract extraction; however, in a subgroup of smokers the risk of cataract was reduced by approximately 25% (Christen et al 2003).

In two randomised, double-masked trials that involved 5390 nutritionally deprived subjects in Linxian, China, supplementation with selenium, alpha-tocopherol and beta-carotene for 5–6 years was found to significantly reduce the prevalence of nuclear, but not cortical, cataracts in older subjects (Sperduto et al 1993). This contrasts with the finding that 500 mg of vitamin C, 400 IU of vitamin E and 15 mg of beta-carotene had no apparent effect on the 7-year risk of development or progression of age-related lens opacities or visual acuity loss in a relatively well-nourished older adult cohort of 4629 people, aged from 55 to 80 years, who participated in the Age-Related Eye Disease (AREDS) study (Kassoff et al 2001).

## Age-related macula degeneration

Although beta-carotene and other nutrients may have been found to be beneficial for preventing age-related macula degeneration (ARMD), the carotenoids lutein and zeaxanthin appear to provide the most protection (see monograph *Lutein and zeaxanthin*).

A high intake of beta-carotene-containing foods has been associated with the prevention of ARMD, and observational and experimental data suggest that carotenoid supplements may delay progression of both ARMD and vision loss. This is supported by the findings from the AREDS study, in which an 11-centre, double-masked clinical trial involving 3640 participants with ARMD found that supplementation with vitamin C 500 mg, vitamin E 400 IU, beta-carotene 15 mg and zinc 80 mg for 6

years significantly reduced the development of advanced ARMD and moderate visual acuity loss (Kassoff et al 2001). A 5-year follow-up of 3549 participants from the AREDS study found that the beneficial effects of the AREDS formulation persisted for development of neurovascular age, but not central geographic atrophy NV age-related macular degeneration, and not for CGA (Chew et al 2013). This result contrasts with findings from the Physicians' Study (see above), which found no beneficial or harmful effects of beta-carotene supplementation on the incidence of ARMD (Christen et al 2007).

## Erythropoietic protoporphyria and photosensitivity

Studies in bacteria, animals and humans have demonstrated that carotenoid pigments can prevent or lessen photosensitivity to endogenous photosensitisers, such as chlorophyll or porphyrins, as well as to exogenous photosensitisers (Mathews-Roth 1993). High doses of beta-carotene (between 180 and 300 mg/day) have been used to effectively prevent or lessen photosensitivity in most patients with erythropoietic protoporphyria and in some patients with other photosensitivity diseases such as solar urticaria, hydroa aestivale, porphyria cutanea tarda and actinic reticuloid (Mathews-Roth 1986, 1987, Mathews-Roth et al 1977).

## Cognitive function

A study of cognitive function in high-functioning older people found that beta-carotene may offer protection from cognitive decline in people with a greater genetic susceptibility, as evidenced by the presence of the apolipoprotein E4 allele (Hu et al 2006). There is also evidence to suggest that long-term supplementation with beta-carotene may provide cognitive benefits, whereas short-term supplementation does not. A study examining cognitive function in 5956 participants older than 65 years in the Physicians' Health Study found significant higher cognitive function in the beta-carotene group when 4052 continuing participants who had been receiving either beta-carotene supplementation or a placebo for an average of 18 years were examined, but no difference was found between the beta-carotene and placebo groups in 1904 newly recruited subjects after 1 year of intervention (Grodstein et al 2007).

## DOSAGE RANGE

Consumption of the recommended five or more servings of fruits and vegetables per day provides 3–6 mg of beta-carotene. Supplemental intake of beta-carotene ranges from 3 to 30 mg/day, although medicinal doses to treat erythropoietic protoporphyria or prevent a reaction to sun in patients with polymorphous light eruption range from 30 to 300 mg/day (PDRHealth 2005). The dose required to provide photoprotection is greater than 24 mg/day for more than 2 months (Sies & Stahl 2004).

To enhance absorption, supplementation should be taken with meals.

### TOXICITY

Beta-carotene is readily converted into vitamin A when required by the body and is considered to be non-toxic, even when given in doses as high as 300 mg/day (Mathews-Roth 1990b, 1993).

A review of the literature on adverse effects of carotenoids on human and animal development suggests that beta-carotene does not have any genotoxic effects (Mathews-Roth 1988), and a toxicity study performed on rats suggests a no-observed-adverse-effect-level (NOAEL) is at a dietary level of at least 5%, or more than 3000 mg/kg/day (Nabae et al 2005). Beta-carotene overdose is not reported in the literature.

#### Practice points/Patient counselling

- Beta-carotene is an antioxidant found in carrots, other vegetables and fruits, as well as in seaweed and algae. Together with other carotenoids, it is an effective marker for a diet rich in fruits and vegetables.
- Beta-carotene is fat soluble and should be consumed with meals.
- Although beta-carotene is converted into vitamin A in the body, unlike vitamin A it is considered non-toxic, even in large doses.
- When supplementing with beta-carotene, it is preferable to use supplements containing natural beta-carotene from the algae *Dunaliella salina* or palm oil, rather than synthetic beta-carotene.
- Beta-carotene is a powerful pigment that contributes to the normal yellow component of skin, and increased beta-carotene intake may protect from the effects of excessive exposure to sunlight and the symptoms of sunburn.
- Consumption of beta-carotene-rich food is associated with reduced risk of cancers, heart disease and eye disease; however, these benefits have not been found in large studies that have used synthetic beta-carotene, with two studies finding an increase in lung cancer in heavy smokers and asbestos workers taking large doses of synthetic beta-carotene.

### ADVERSE REACTIONS

At doses greater than 30 mg/day, beta-carotene may cause an orange-yellow colouration of the skin (carotenoderma), which is usually seen first as yellowness of the palms and soles. This condition is harmless and reversible when intake ceases (Micozzi et al 1988). Carotenoderma is distinguished from jaundice by the absence of yellowed ocular sclerae. For some people, this skin colouration is actually considered desirable (Mathews-Roth 1990a) and is utilised in tanning tablets to produce a natural-looking skin tan (DerMarderosian & Beutler 2002).

At present it is unclear if there is a true link between increased lung cancer risk and long-term beta-carotene supplementation in smokers, because supplementation studies with synthetic beta-carotene have produced mixed results: two studies demonstrated an increased lung cancer risk in heavy smokers or those with high asbestos exposure (Group 1994, Heinonen et al 1994, Omenn et al 1996a), while other studies found either no effect (Hennekens et al 1996, Lee et al 1999) or a protective effect (Blot et al 1993).

The association between increased lung cancer risk and beta-carotene has not been found with natural beta-carotene, and there is no suggestion that heavy smokers should reduce their intake of beta-carotene-rich foods. A review suggests that there is no evidence at present that consuming small amounts of supplemental beta-carotene in a multivitamin tablet at amounts that exist in foods (< 6 mg) is unwise for any population (Pryor et al 2000).

### SIGNIFICANT INTERACTIONS

#### Drugs reducing fat absorption

Drugs that reduce fat absorption, such as cholestyramine, colestipol and orlistat, may also reduce absorption of beta-carotene (PDRHealth 2005). This can be avoided by spacing the administration of these substances by at least 2 hours. Plant sterols have been found to reduce beta-carotene bioavailability by approximately 50% in normocholesterolaemic men (Richelle et al 2004).

#### Fibrates

There may be a positive interaction between fibrate and natural beta-carotene, which has been found to significantly increase HDL cholesterol levels in fibrate-treated mice and humans (Shaish et al 2006).

#### CONTRAINDICATIONS AND PRECAUTIONS

Heavy smokers should be advised not to take synthetic beta-carotene supplements for long periods of time.

#### PREGNANCY USE

Beta-carotene crosses the placenta. Adequate and well-controlled studies in humans have not been documented. No problems with pregnancy have been documented in women taking up to 30 mg beta-carotene daily (Micromedex 2003). As vitamin A is vital for the development of the fetus and the newborn baby, it has been recommended that pregnant women increase their vitamin A intake by 40% and breastfeeding women by 90%. It is further suggested that increasing dietary beta-carotene is an effective way for women to maintain their vitamin A levels (Strobel et al 2007).

## Valproate

Epileptic patients who gain weight with valproate therapy have been found to have reduced plasma concentrations of beta-carotene and other fat-soluble antioxidant vitamins; this is reversible after valproate withdrawal (Verrotti et al 2004).

## ! PATIENTS' FAQs

### What will this supplement do for me?

Beta-carotene supplementation will ensure you maintain adequate vitamin A levels. It may possibly assist in preventing cancer and cardiovascular disease, help maintain a healthy immune system, prevent sunburn and photoageing of the skin, assist with asthma, and deal with oxidative stress.

### When will it start to work?

It may take up to 2–3 months to see a benefit with UV protection, whereas other benefits may be observable only over many years.

### Are there any safety issues?

Beta-carotene is considered non-toxic. Large doses may cause a yellowing of the skin, but this is harmless and reversible.

## Bilberry

**HISTORICAL NOTE** Bilberries have been used as a food for many centuries and are valued for their taste and high nutritional content. They are still commonly used to make jams, pies, syrups and beverages. Medicinally, the berries have been used internally to treat diarrhoea and haemorrhoids and externally for inflammation of the mouth and mucous membranes as they have significant astringent activity. According to folklore, World War II British Royal Air Force pilots noticed that their night vision seemed to improve after consuming bilberries or bilberry preserves, sparking a renewed interest in the medicinal properties of the fruits.

### COMMON NAME

Bilberry

### OTHER NAMES

Baies de myrtille, Blaubeeren, dwarf bilberry, European bilberry, European blueberries, huckleberry,

hurtleberry, heidelbeeren, petit myrtle, whortleberry, wine berry

### BOTANICAL NAME/FAMILY

*Vaccinium myrtillus* (family Ericaceae)

**Clinical note — Tannins**

Tannins are polyphenolic compounds that have an affinity for proteins. They also complex with alkaloids and therefore should not be mixed with alkaloid-containing herbs.

Anthocyanosides are condensed tannins. When they come into contact with mucous membranes they have an astringent action, making the mucosa less permeable. This activity has been used therapeutically in a variety of ways.

Taken internally, herbs with a high tannin content such as bilberry have been used to treat diarrhoea; applied externally, a styptic action occurs that reduces blood loss.

**Clinical note — Cataract**

Growing evidence suggests that senile cataract development may in part be linked to the endogenous generation of free radical molecules, such as superoxide derived from oxygen and light in the aqueous humour and lens (Varma & Richards 1988, Varma et al 1982, 1994). As such, substances with significant antioxidant activity such as anthocyanins, vitamin C and vitamin E have been investigated as potential prophylactic treatments.

**PLANT PARTS USED**

Dried ripe fruit or fresh fruit (berries)

**CHEMICAL COMPONENTS**

The fruit contains catechin tannins (up to 10%), invert sugar, fruit acids, flavonol glycosides including astragalol, hyperoside, isouercitrin and quercitrin, phenolic acids, pectins, triterpenes, and polyphenols such as anthocyanosides. The volatile oil includes methyl salicylate, farnesol, vanillin, myristicin and citronellol. Bilberry also contains vitamin C and chromium, which are suspected of playing a role in its pharmacological activities.

Some of the anthocyanosides are responsible for the deep blue pigment of the fruit (Kahkonen et al 2001). As the fruit ripens the anthocyanoside content increases. Some commercially available extracts are standardised to anthocyanoside content. Recent research indicates that the anthocyanidin content is particularly high in the pulp of the fruit; however, all parts of the fruit are potential sources of phenolic compounds (Riihinen et al 2008). Anthocyanin (the aglycone and sugar moieties delphinidin, cyanidin, petunidin, peonidin and malvidin) concentration in the fresh fruit is approximately 0.1–0.5%, while concentrated bilberry extracts (BEs) are usually standardised to 25% anthocyanins (Ichiyanagi et al 2004, Yue & Xu 2008, Zhang et al 2004).

**MAIN ACTIONS**

The pharmacological actions of bilberry have not been significantly investigated in clinical studies, so information is generally derived from in vitro and animal studies or based on known information about key constituents found within the herb. Most of the research undertaken to understand the pharmacology of the herb has focused on the anthocyanin and anthocyanoside content.

**Antioxidant**

Many of the clinical effects attributed to bilberry are thought to be due, in some part, to the herb's antioxidant activity.

Anthocyanosides are the main phenolic constituents in bilberry and have well-established antioxidant activity (Bao et al 2010, Kahkonen et al 2001, Roy et al 2002). This activity is believed to be primarily due to their chemical structure (Mozafarieh et al 2008, Yao & Vieira 2007). Anthocyanosides have exhibited direct superoxide radical scavenging properties, indirect antioxidant activity by amplifying endogenous antioxidant systems and cytoprotective activity against oxidative damage in animal models (Valentová et al 2007).

The observation that anthocyanosides induce clinical antioxidant effects has long puzzled researchers as these constituents have relatively poor bioavailability when orally ingested. A study examining the effect of both crude and standardised extracts of bilberry and blueberry on four different cell lines concluded that the small amount of bioavailable anthocyanosides that occurs after ingestion of a normal dietary serve is enough to promote a significant antioxidant response, particularly in vascular and hepatic cells (Bornsek et al 2012). It is thought that anthocyanosides enter the cell via active transport across the cell membrane, enabling small concentrations to promote an intracellular amplification of endogenous antioxidant systems.

**Hepatoprotective**

Several studies have focused on the protective effect of BE on hepatic mitochondrial response to stress (Bao et al 2008, 2010). These animal models have shown that bilberry protects mice mitochondria from stress-induced changes in cytochrome function and electron transport chain activity, and cellular membrane potential reduction. Bilberry also restored alanine aminotransferase and reactive oxygen species to normal levels. In another study (Domitrović & Jakovac 2011), mice with liver fibrosis induced by carbon tetrachloride were treated with 10 mg/kg BE, which reduced oxidative stress (measured by glutathione activity), decreased cytokines associated with fibrosis and resolved hepatic collagen deposits.

**Cardioprotective**

Two animal studies have shown BE may be protective against doxorubicin-induced cardiotoxicity, a dose-limiting side effect of this chemotherapy drug

(Ashour et al 2011, Choi et al 2010). Cardioprotection is most likely to be due to an antioxidant mechanism. While these results are promising, more studies are required to ensure that BE does not also reduce the therapeutic effects of doxorubicin.

In vitro studies show anthocyanins have antioxidant effects in cardiac mitochondria of rats (Trumbeckaitė et al 2013), which may reduce cytochrome c and protect against apoptosis of cardiac tissue during ischaemia (Skemiene et al 2013).

### Antiatherogenic

A study involving apolipoprotein E-deficient mice confirmed that BE reduces atherosclerotic lesion development via the modulation of gene expression in the aorta. Treatment with BE resulted in over 1200 genes being modified; many were involved in atherogenic processes, including those known to influence oxidative stress, inflammation, angiogenesis and transendothelial migration. Additionally, total cholesterol was reduced by 20% whereas triglycerides and body weight remained unchanged (Mauray et al 2010).

### Reduces ischaemic reperfusion injury

Bilberry anthocyanosides have been shown to improve ischaemic damage, preserve capillary perfusion, inhibit increased permeability of reperfusion and save arteriolar tone in an animal model of ischaemic reperfusion injury (Bertuglia et al 1995, Zibera et al 2013).

### Anti-inflammatory and antioedema activity

These effects have been demonstrated in both experimental studies and human trials.

Biochemical and histochemical data show that the anthocyanins in bilberry decrease vascular permeability and alter capillary wall dynamics. This is mainly due to an increase in the endothelial barrier effect as a result of stabilising membrane phospholipids and increasing the synthesis of the mucopolysaccharides in the connective ground substance, thereby restoring the altered pericapillary sheath (Mian et al 1977). These effects have been demonstrated in animal models for both oral administration and topical application of bilberry anthocyanins (1% alcohol solution) and were seen to be stronger and longer-lasting than those of rutin (Lietti et al 1976).

Bilberry (dried) and anthocyanins reduced inflammatory cytokines and decreased histological severity in experimental colitis in mice (Piberger et al 2011).

Anti-inflammatory activity has also been demonstrated in human studies. A small randomised controlled trial (RCT) of 27 people with metabolic syndrome looked at the effect of a diet enriched with bilberries (400 g/daily) on inflammatory markers. The special diet resulted in small decreases in a variety of inflammatory markers (C-reactive protein [CRP], interleukin-6 [IL-6], IL-12 and lipopolysaccharide) and an overall lower inflammatory score ( $P = 0.024$ ) (Kolehmainen et al 2012).

Similar results were achieved in an RCT of 62 people with cardiovascular disease with the treatment group receiving bilberry juice (not described further). The treated group experienced significant reductions in CRP, IL-6, IL-12 and interferon-gamma (Karlsen et al 2012).

### Astringent

The astringent properties of bilberry are well established and attributed to its significant tannin content.

### Improves visual function

Epidemiological investigations have indicated that moderate consumption of anthocyanin-containing herbs such as BE is associated with an improvement in visual function (Hou 2003). Several animal studies suggest a positive effect on dark adaptation (Canter & Ernst 2004). More specifically, bilberry enhances regeneration of rhodopsin in the retina, which is essential for optimal functioning of the rods and therefore light adaptation and night vision (Blumenthal et al 2000). Other possible mechanisms of action in the eye include accelerated modulation of retinal enzyme activity and improved microcirculation (Canter & Ernst 2004).

Jang et al (2005) demonstrated that two anthocyanins from bilberry were potent antioxidants that suppressed photo-oxidative processes initiated in retinal pigment epithelial cells by A2E, a component of retinal epithelial cells which is associated with ageing and some inherited forms of retinal degeneration (Kim et al 2008). Matsunaga et al (2009) also demonstrated in vitro and in vivo that anthocyanins from bilberry protected against chemically induced damage to retinal ganglion cells through mainly antioxidant processes. Other animal models found significant protection of bilberry in endotoxin-induced uveitis in mice (Miyake et al 2012, Yao et al 2010).

### Gastroprotective activity

In vitro tests have found that a specific anthocyanin found in bilberry causes an increase in the efficiency of the gastric mucosal barrier (Cristoni et al 1989). When administered orally in an animal model it retarded the development of gastric ulcers induced by stress, non-steroidal anti-inflammatory drugs, ethanol, reserpine and histamine (Magistretti et al 1988).

### Hypoglycaemic activity

This activity has been demonstrated in animal models and at least one human study.

A dried hydroalcoholic extract of bilberry leaf administered orally to streptozotocin-induced diabetic rats for 4 days decreased plasma glucose levels by 26% (Cignarella et al 1996).

Takikawa et al (2010) studied the effects of an anthocyanin-rich bilberry diet on type 2 diabetic mice, resulting in a reduction in hyperglycaemia and insulin sensitivity via AMP-activated protein kinase (AMPK), activated in white adipose tissue, skeletal

muscle and liver tissue. AMPK is the target of drugs like metformin. Another effect of bilberry on the insulin pathway includes the inhibition of adipocyte differentiation (Suzuki et al 2011).

One clinical study tested the effects of two different strengths of bilberry beverage (10% and 47%) on the insulin index (II) in young healthy adults and compared them to two other beverages, a fermented oat-based drink and a 10% rosehip drink. The 10% bilberry beverage, 10% rosehip beverage and fermented oat drink had a similar glycaemic index of 95, but the bilberry 10% drink had a significantly lower II of 65 ( $P < 0.05$ ). The II dropped to 49 with the higher-strength 47% bilberry beverage, which also had a lower (non-significant) glycaemic index of 79 compared to the other drinks (Granfeldt & Bjorck 2011).

### Neuroprotective

The anthocyanoside content is chiefly responsible for reversing the course of neurodegeneration in animals by affecting calcium homeostasis and improving motor performance (Kolosova et al 2006, Landfield & Eldridge 1994).

### Anticarcinogenic activity

Preliminary research has found that components of the hexane/chloroform fraction of bilberry exhibit anticarcinogenic activity (Bomser et al 1996). Anti-angiogenic activity has also been identified (Matsunaga et al 2010, Roy et al 2002), as well as anticarcinogenic activity via inhibition of the nuclear factor-kappa B activation pathway (Aggarwal & Shishodia 2006). One animal study demonstrated significant reduction in colon cancer in animals fed an anthocyanidin mixture derived from bilberry (Cooke et al 2006), while growth and invasiveness were suppressed in human non-small-cell lung cancer cells by bilberry-derived anthocyanins in animal models (Kausar et al 2012).

### OTHER ACTIONS

BE inhibits platelet aggregation according to ex vivo tests (Pulliero et al 1989). There is also some early in vitro research investigating whether it provides ultraviolet protection of skin (Svobodová et al 2009), ameliorates pruritus in allergic dermatitis (Yamaura et al 2011), modifies amyloid in Alzheimer's disease (Vepsäläinen et al 2013) and reduces stress-induced depression mediated by the nitric oxide pathway (Kumar et al 2012).

According to an animal study, anthocyanins from bilberry induce vasorelaxation via a complex cascade of actions that start in the cell membrane and result in nitrous oxide release from the vascular endothelium (Ziberna et al 2013).

### CLINICAL USE

BEs are popular in Europe and have been investigated in numerous clinical trials, primarily in non-English-speaking European countries. As a result, many research papers have been published in other

languages. To provide a more complete description of the evidence available, secondary sources have been used when necessary. While many clinical trials are of a preliminary nature, several larger RCTs have been published in recent years.

### Ulcerative colitis

Positive results were obtained for bilberry supplementation in a small open pilot study of 13 people with well-characterised mild to moderate ulcerative colitis on stable conventional medicine (Biedermann et al 2013). A preparation equivalent to 600 g of fresh fruit per day was taken in four divided doses over a 6-week period, delivering a mean anthocyanin concentration of 210 mg per dose. Remission was achieved in 63.4% of patients with a clinical activity index (CAI)  $< 4$ , while 90.9% had a response (CAI value drop  $\geq 3$  points). Other endpoints such as the complete Mayo Score showed at least a 2-point drop in 100% of patients and a  $\geq 3$ -point drop in 54%; however the endoscopic Mayo Score was not as significant, with mean at baseline of 1.5 dropping to 1.2 after treatment.

There was a highly significant reduction in faecal calprotectin, with mean levels dropping from 778 mcg/g of stool to 134 mcg/g. After treatment ceased in week 7, calprotectin levels rose in some patients, while 4 maintained undetectable levels (Biedermann et al 2013).

### Non-specific acute diarrhoea

The considerable astringent activity of bilberry provides a theoretical basis for its use in non-specific acute diarrhoea. Commission E approved crude fruit preparations for this indication (Blumenthal et al 2000).

### Mild inflammation of the mouth and throat

The considerable astringent, anti-inflammatory and antioedema activity of bilberry provides a theoretical basis for its use as a topical application in these indications. Commission E approved this indication (Blumenthal et al 2000).

### Haemorrhoids, varicose veins, venous insufficiency

The considerable astringent, anti-inflammatory and antioedema activity of bilberry provides a theoretical basis for its use in these conditions. Several human case series and a single-blind trial report significant improvements in lower-extremity discomfort and oedema related to chronic venous insufficiency; however, further research is required to confirm these findings (Ulbricht & Basch 2005).

### Pregnancy

A bilberry product (Myrtocyan) was taken at a dose of 320 mg daily in the last trimester by women aged 24–37 years with pregnancy-induced lower-extremity oedema and found to significantly improve symptoms of burning and itching, heaviness, pain, diurnal and nocturnal leg cramps, oedema and

capillary fragility (Ghiringhelli et al 1978, as reported in Blumenthal 2003).

### Ophthalmic conditions

Bilberry preparations have been used to improve poor night vision, light adaptation and photophobia and myopia and to prevent or retard diabetic retinopathy, macular degeneration and cataracts. Primarily the collagen-enhancing and antioxidant activities of bilberry provide a theoretical basis for these indications.

### Visual acuity and light adaptation

Whether bilberry preparations have a significant effect on visual acuity and light adaptation is difficult to ascertain from the current available evidence. The safety of bilberry and lack of other safe and effective treatments for improving night vision should compel researchers to continue investigating this treatment and clinicians to consider recommending a trial to patients.

A systematic review of 12 placebo-controlled trials (five RCTs and seven placebo-controlled non-randomised trials) concluded that the anthocyanosides from *Vaccinium myrtillus* were not effective for improving night vision; however, the authors point out that the potential therapeutic role of these constituents should not yet be dismissed because confounding factors and supportive auxiliary evidence exist (Canter & Ernst 2004). Four of the RCTs showed no positive effects for *V. myrtillus* anthocyanosides on outcome measures relevant to vision in reduced light, whereas the fifth RCT and all seven non-randomised trials reported positive effects on outcome measures relevant to night vision. Seventeen other studies were located by Canter and Ernst, but not included in the analysis because they did not contain a placebo group. Sixteen of those studies produced positive results on measures relevant to night vision in either healthy subjects or patients with a range of visual disorders and only one was negative.

The authors point out several confounding factors, in particular the wide range of doses, possible geographical variations in extract composition, choice of subject (generally healthy) and methods used to obtain and interpret electroretinograms, which varied between older and newer studies. For example, two of the negative RCTs tested the lowest dose levels of any of the trials: 36 mg daily for acute treatment and  $\leq 48$  mg for short-term treatment.

A significant improvement in visual performance has been demonstrated for BE in people with retinitis pigmentosa and haemeralopia (inability to see distinctly in bright light), suggesting that effects may be more pronounced in cases of impaired visual acuity (Gloria & Peria 1966, Junemann 1967).

### Glaucoma

Available research suggests bilberry anthocyanosides may be beneficial in glaucoma.

In one small study of 8 patients, a single oral dose of 200 mg bilberry anthocyanosides was shown to improve glaucoma, as assessed by electroretinography (Caselli 1985).

The largest study to date involved 332 subjects diagnosed with normal-tension glaucoma and compared treatment with bilberry anthocyanins (120 mg twice daily), *Ginkgo biloba* extract (80 mg twice daily) or no treatment. Humphrey visual field (HVF) test and logarithm of the minimal angle of resolution best-corrected visual acuity (BCVA) were performed at baseline and after treatment. A chart review follow-up was performed at a mean time of 24 months, with improvement shown in the bilberry anthocyanin group in BCVA ( $P = 0.008$ ) and HVF ( $P = 0.001$ ) (Shim et al 2012).

### IN COMBINATION

A controlled but non-blinded trial testing of 38 volunteers testing the effects of Mirtogenol, a bilberry and marine pine bark supplement, on intraocular pressure found that treatment resulted in a significant mean drop from 25.2 mm to 22.2 mm after 3 months (Steigerwalt et al 2008).

### Retinopathy

In Europe, bilberry anthocyanoside extracts are recognised as highly effective in preventing or treating diabetic retinopathy, with clinical research supporting its use (Lietti et al 1976, Orsucci et al 1983, Perossini et al 1987, Scharrer & Ober 1981).

One double-blind study involving 40 patients with diabetic and/or hypertensive retinopathy showed that a dose of BE (Tegens) equivalent to 160 mg anthocyanosides taken twice daily for 1 month significantly improved ophthalmoscopic parameters and angiographic parameters (Perossini et al 1987). Another study of 31 subjects with different forms of retinopathy (diabetic retinopathy, retinitis pigmentosa, macular degeneration or haemorrhage due to anticoagulant use) found that treatment with BE (Difrarel 100) reduced vascular permeability and the tendency to haemorrhage in all patients (Scharrer & Ober 1981). A small open study by Orsucci et al of 10 subjects with diabetic retinopathy found that 6 months of treatment with BE (Tegens) equivalent to 240 mg anthocyanosides daily resulted in reduction or disappearance of haemorrhages and improvement in the retinal picture (Orsucci et al 1983, and reported in Blumenthal 2003).

### Myopia

Uncontrolled trials report a beneficial effect of the extract on patients with myopia (Canter & Ernst 2004).

Additional studies using purified anthocyanoside oligomers highlight significant improvements in subjective symptoms and objective contrast sensitivity in myopia patients with poor night vision (Lee et al 2005). However, as specificity of source is not provided, this information can only be used in

conjunction with the additional supportive evidence listed above.

### Cataract

In practice, bilberry has been recommended to delay cataract progression. A case series of 50 elderly subjects with early-stage cataract found that a combination of anthocyanosides extracted from bilberry and vitamin E slowed progression of lens opacities by 97% (Ulbricht & Basch 2005). Placebo-controlled trials are now required to confirm these results.

### Dry eye

A placebo-controlled study of 22 subjects with dry eye found that treatment with bilberry (160 mg twice daily) for 30 days produced a statistically significant improvement ( $P < 0.01$ ) compared to the placebo group (Anderson et al 2011).

### Asthenopia

Asthenopia is a condition characterised by tired, red, painful eyes, headaches, shoulder stiffness, low-back pain and frustration. It has been attributed in some part to refractory problems in the eye. A randomised, double-blinded parallel study compared the effects of omega-3-rich fish oil 1000 mg, bilberry anthocyanins 59 mg and lutein 75 mg per day taken for 4 weeks to placebo. Symptoms were catalogued via questionnaire, which was completed three times a week and included a visual analogue scale for fatigue. While there was a response to placebo for many symptoms, shoulder stiffness, low-back pain and frustration were significantly improved in the treatment group (Kawabata & Tsuji 2011).

### Hypercholesterolaemia

Treatment with a purified anthocyanin supplement 160 mg twice a day produced a significant increase in high-density lipoprotein and decrease in low-density lipoprotein in this randomised, double-blind, placebo-controlled study. The 24-week study of 150 people with hypercholesterolaemia also demonstrated that active treatment had a significant effect on inflammatory markers high sensitive CRP (hsCRP), soluble vascular cell adhesion molecule (sVCAM), IL-1 $\beta$  and tumour necrosis factor-alpha (TNF- $\alpha$ ), which were measured at 12 and 14 weeks, with hsCRP ( $P = 0.007$  and  $P < 0.001$ ) and sVCAM ( $P = 0.03$  and  $P = 0.14$ ) and IL-1 $\beta$  ( $P = 0.02$  and  $P = 0.02$ ) being significantly decreased in the treatment group compared to the placebo group, but no change in TNF- $\alpha$  in either group (Zhu et al 2013).

### OTHER USES

Traditionally, bilberry has been used to treat dysentery, diabetes, gastrointestinal inflammatory conditions, vaginal discharges and haemorrhoids, and to stop lactation. Externally, bilberry preparations have been used to treat wounds, ulcers and skin

infections. More recently, other uses include treatment for bleeding gums, nose bleeds, spider veins, capillary fragility, peptic ulcers, Raynaud's syndrome and venous insufficiency (such as claudication).

Additionally, a double-blind placebo-controlled study confirmed that bilberry improves peripheral vascular disorders by improving subjective symptoms after 30 days' treatment (Mills & Bone 2000).

### DOSAGE RANGE

#### Internal

- Fluid extract (1:1) standardised to provide 60–120 mg daily of anthocyanins: 6–12 mL/day taken in three divided doses.
- Oral dose forms: BEs providing 240–480 mg of anthocyanins daily.
- Decoction of dried herb: 5–10 g of crushed, dried fruit in 150 mL of cold water, which is then boiled for up to 10 minutes and strained while hot. For symptomatic treatment of diarrhoea, drink the cold decoction several times daily.
- Gargle: a 10% decoction of the above preparation.
- Fresh berries: 165–400 g daily.

#### TOXICITY

Rats administered high doses of up to 400 mg/kg showed no adverse effects (Murray 1995).

#### ADVERSE REACTIONS

No adverse effects were reported in a systematic review of 12 placebo-controlled trials of *V. myrtillus* anthocyanosides (Canter & Ernst 2004). According to the same authors, a postmarketing surveillance study of 2295 people identified that 4% experienced side effects related to the skin, nervous system or gastrointestinal tract.

#### SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore interactions are theoretical and based on evidence of pharmacological activity with uncertain clinical significance.

#### Anticoagulant and antiplatelet drugs

A theoretical risk exists that high doses (>170 mg anthocyanidins) may increase bleeding risk; however, this remains uncertain as there is inadequate clinical evidence (Aktaş et al 2011, Stargrove et al 2008).

#### Iron

Reduced absorption is theoretically possible if taken at the same time because of the tannin content of the herb — separate doses by 2 hours.

#### Hypoglycaemic agents

Additive effects are theoretically possible with leaf preparations — observe patient.

## Topoisomerase chemotherapy drugs

An in vitro study using human colon cancer cells showed that anthocyanin-rich berry extracts may be protective of DNA damage caused by topoisomerase drugs and therefore may reduce chemotherapy effectiveness. As the concentration required (>50 mcg/mL) to cause this effect is likely to be greater than could be achieved through oral ingestion, it remains theoretical.

### Practice points/Patient counselling

- Bilberry has antioxidant, anti-inflammatory and astringent actions and has considerable polyphenol content, and may therefore be of greatest benefit in the prevention of disorders where inflammation is a known precursor.
- BE is a popular treatment in Europe for preventing and treating retinopathy. It is also used to treat several other ophthalmic conditions, such as poor night vision, poor light adaptation and sensitivity to glare, photophobia, glaucoma, myopia, dry eye, asthenopia and cataract. Some clinical research suggests a possible role in glaucoma, retinopathy and dry eye, whereas the evidence for use in improving night vision is unclear.
- Some research also suggests that it is useful in venous insufficiency, peripheral vascular disorders (such as Raynaud's syndrome) and capillary fragility.
- There is new clinical research suggesting that BE has significant hypoglycaemic activity and lipid-lowering activity and that it may be beneficial in ulcerative colitis.
- Bilberry is approved by Commission E for the treatment of non-specific, acute diarrhoea and mild inflammatory conditions of the mouth and throat.
- Preliminary evidence suggests it may prevent peptic ulcer formation due to non-steroidal anti-inflammatory drugs or stress; however, clinical research is still required to confirm these effects.

### CONTRAINDICATIONS AND PRECAUTIONS

High doses (>170 mg anthocyanidins) should be used with caution by people with haemorrhagic disorders. Avoid use with topoisomerase chemotherapy drugs until safety can be established.

### PREGNANCY USE

A study investigating BE for pregnancy-induced lower-extremity oedema reported no adverse effects (Ulbricht & Basch 2005) — likely to be safe when berry is consumed in dietary amounts.

### PATIENTS' FAQs

#### What will this herb do for me?

Bilberry is used to relieve the symptoms of mild diarrhoea and improve poor night vision, sensitivity

to glare, photophobia, peptic ulcers, varicose veins, venous insufficiency and haemorrhoids when taken internally. It is also used as a mouthwash, gargle or paint for mild inflammation of the mouth or throat, such as gingivitis or pharyngitis. Clinical research also shows it may be useful for some ophthalmic conditions and as a treatment in ulcerative colitis, glaucoma and reducing low-density lipoprotein cholesterol while raising high-density lipoprotein cholesterol.

#### When will it start to work?

This depends on the indication. Improvements in night vision, photophobia and glare sensitivity have been reported within 2–4 weeks of use in some people whereas preventive effects are likely to require long-term use. In peripheral vascular disease, 30 days' treatment may be required before effects are noticed. In ulcerative colitis progressive symptom relief may occur over 6 weeks.

#### Are there any safety issues?

Bilberry is considered a safe herb which is well tolerated. Theoretically, it may reduce blood glucose levels so should be used carefully in diabetics on hypoglycaemic medication. Theoretically, it may increase the risk of bleeding when used at very high doses, and should be avoided with certain chemotherapy drugs. Due to its high tannin content, bilberry will reduce the absorption of iron if taken at the same time as iron-containing substances, so a 2-hour separation of doses is recommended.

# Bitter melon

**HISTORICAL NOTE** Bitter melon is used as a traditional medicine wherever it is found. It has a long history of use in Asia, Africa and Latin America and has been widely acclaimed as an important remedy for diabetes mellitus since ancient times. The genus name *momordica* means 'to bite' and refers to the jagged edges of the leaf, which appear as if bitten. Bitter melon has been used to treat fevers, viral infections and as an emmenagogue in reproductive health. It has also been used to treat gastrointestinal complaints, worms, constipation, headaches, skin conditions and diabetes. The fruit is used topically for wound healing. The plant has also been used in traditional ceremonies and considered a powerful charm, which is worn as a necklace, wrist or ankle bracelet or crown (Beloin et al 2005). The ritual ceremonial importance of the plant is accompanied by its considerable reputation as a medicinal plant for the treatment of disease.

## OTHER NAMES

African cucumber, balsam pear, bitter gourd, kakara, karela, ku gua, sushavi, wild cucumber

## BOTANICAL NAME/FAMILY

*Momordica charantia* (family Curcubitaceae)

## PLANT PARTS USED

Fruit, leaves

## CHEMICAL COMPONENTS

It contains several biologically active constituents that include glycosides (e.g. momordicins I and II, 25 $\xi$ -isopropenylchole-5 [Liu et al 2012], taiwacin A(1),23,24,25,26,27-pentanorcucurbitane [Lin et al 2011]), steroidal saponins (e.g. charantins, Kuguacin J [Pitchakarn et al 2012]), alkaloids, fixed oils and proteins (e.g. MAP 30: *Momordica* anti-HIV protein; molecular weight, 30 kDa). The immature fruits are a good source of vitamin C and also provide vitamin A, phosphorus and iron (Grover & Yadav 2004).

## MAIN ACTIONS

Bitter melon has been the subject of countless studies and has demonstrated significant pharmacological activity in a variety of experimental models.

### Antidiabetic

The antidiabetic potential of bitter melon has been the subject of intense investigation, with over 140 studies having investigated the hypoglycaemic activity of various constituents of *Momordica charantia* in animal models and human studies.

The hypoglycaemic activity of bitter gourd is well established in normal, streptozocin- or alloxan-induced diabetic animals and in genetic models of diabetes (Ahmed et al 2004, Bailey et al 1985, Chaturvedi 2005, Day et al 1990, Harinantenaina et al 2006, Jayasooriya et al 2000, Kar et al 2003, Kumar et al 2008, Mamun 2011, Miura et al 2001, 2004, Ojewole et al 2006, Reyes et al 2006, Sarkar et al 1996, Shibib et al 1993, Shetty et al 2005). All parts of the plant (fruit pulp, seeds, leaves and whole plant) have shown activity. Superfine powdered

bitter melon showed a higher antidiabetic effect than hot air-dried powder in vivo (Ying et al 2012). Whether the effect is sufficient to have a significant clinical effect in people with type 2 diabetes is uncertain, according to a recent systematic review of four clinical trials (Ooi et al 2012).

A systematic study comparing the hypoglycaemic activity of three extracts in vivo found that the methanolic extract of dried whole fruits and seeds reduced blood glucose by 49% at the end of the first week, which became 39% by week 5. The aqueous extract of fresh, unripe, whole fruits reduced fasting blood glucose by 50%, which was consistent until the study ended, and the chloroform extract of dried whole fruits and seeds showed almost no hypoglycaemic activity (Virdi et al 2003). These observations have special significance when one considers that the whole bitter gourd is cooked in water and consumed in many cultures, particularly in India.

Multiple mechanisms of action have been identified for bitter gourd. It also suggests that consideration should be made of the extraction used when interpreting human studies. In general, it appears to stimulate pancreatic insulin secretion (Fernandes et al 2007, Welihinda et al 1982), improve peripheral glucose uptake (Fernandes et al 2007, Welihinda & Karunanayake 1986) and improve insulin sensitivity and signalling (Sridhar et al 2008).

It has been demonstrated that *Momordica charantia* has a protective effect on pancreatic  $\beta$ -cells via downregulation of mitogen-activated protein kinases and nuclear factor kappa-light-chain enhancer of activated B cells (Kim & Kim 2011). Aqueous and alcohol extracts of *M. charantia* have been shown to stimulate glucose-6-phosphatase dehydrogenase and inhibit fructose 1,6-diphosphatase, glucose-6-phosphatase activities (Shetty et al 2005). Also, other biochemical and physiological processes such as glucose utilisation in skeletal muscles, intestinal glucose uptake inhibition and suppression of gluconeogenic enzymes have been inferred through in vivo and in vitro studies (Ahmed et al 2004). A study of streptozocin-induced diabetic animals further reveals a beneficial role for bitter gourd in controlling

glycoconjugate- and heparan sulfate-related kidney complications in diabetes, thus prolonging late complications of diabetes (Kumar et al 2008).

The hypoglycaemic activity is attributed to a mixture of steroidal saponins known as charantins, insulin-like peptides and alkaloids that are concentrated in the fruit (Grover & Yadav 2004), whereas several different fractions of *M. charantia* extract may make different contributions to its cell-repairing activity and its ability to stimulate insulin secretion (Xiang et al 2007).

### Lipid lowering

Lipid-lowering activity has been reported in studies of normal and diabetic animals for the fruit extract, flavonoids extracted from bitter melon or a methanolic fraction of the plant (Ahmed et al 2001, Anila & Vijayalakshmi 2000, Chaturvedi 2005, Chaturvedi et al 2004, Senanayake et al 2004, Singh et al 1989). Typically, decreases in triglyceride and low-density lipoprotein levels and increases in high-density lipoprotein levels are seen.

### Antiviral

Several constituents found in bitter melon (e.g. alpha- and beta-momorcharin, lectin and MAP 30) have demonstrated in vitro antiviral activity against Epstein-Barr, herpes simplex virus type 1 (HSV-1), HIV, coxsackievirus B3 and polioviruses (Beloin et al 2005, Bourinbaiar & Lee-Huang 1996, Foa-Tomasi et al 1982, Grover & Yadav 2004, Sun et al 2001).

A study using a lyophilised extract of *Momordica charantia* against HSV-1 suggests that the presence of light may be important for antiviral activity (Beloin et al 2005). The active antiviral constituents are not the main bitter principles momordicins I and II, as these have not shown activity against HSV-1 (Beloin et al 2005). One constituent, referred to as MAP 30, has received special attention, as it exhibits potent inhibition of HIV-1 and HSV (Schreiber et al 1999).

### Antibacterial and antiprotozoal

Broad-spectrum antibacterial activity has been demonstrated for the leaf extracts (aqueous, ethanol and methanol) (Grover & Yadav 2004). In vitro antimicrobial activity has been demonstrated against *Escherichia coli*, *Salmonella paratyphi*, *Shigella dysenteriae* and *Streptomyces griseus* (Grover & Yadav 2004, Ogata et al 1991, Omoregbe et al 1996). A recent study found that both the aqueous and the ethanol extracts of bitter melon leaf inhibited the growth of *Staphylococcus aureus*, *Bacillus subtilis*, *Escherichia coli* and *Pseudomonas aeruginosa* (Mada et al 2013). In a phase II study, the leaf extracts inhibited the growth of *Mycobacterium tuberculosis* in vitro, using the BACTEC 460 susceptibility test method (Frame et al 1998).

Tests with an extract of the entire plant demonstrated antiprotozoal activity against *Entamoeba histolytica* (Grover & Yadav 2004) and a fruit extract exhibited activity against *Helicobacter pylori* (Yesilada et al 1999).

### Anti-inflammatory

Bitter gourd extract has been found to suppress lipopolysaccharide-induced tumour necrosis factor-alpha production in vitro and, more recently, the butanol-soluble fraction was also found to strongly suppress lipopolysaccharide-induced tumour necrosis factor-alpha production (Kobori et al 2008).

### Anthelmintic

The anthelmintic activity of the leaves of *Momordica charantia* against *Caenorhabditis elegans* was identified and described as high in one study (Beloin et al 2005). Triterpene glycosides of bitter melon (momordicins I and II) were found to be very active nematocides. A preparation of *M. charantia* exhibited stronger anthelmintic activity in vitro than piperazine hexahydrate against *Ascaridia galli* (Lal et al 1976). A recent in vitro study reported significant anthelmintic activity of ethanol extract of bitter melon leaf against *Ascaris suum* (Tjokropranoto et al 2011).

### Abortifacient

Experimental studies with mice have demonstrated that bitter melon has abortifacient activity (Chan et al 1984, Tam et al 1984). According to an in vivo study, the glycoproteins alpha- and beta-momorcharin isolated from the seeds are effective in inducing early and midterm abortions (Chan et al 1986) and the momorcharins were teratogenic in cultured mouse embryos (Chan et al 1986).

### Antifertility

A study on rats using bitter melon seed and pulp extract showed significant spermicidal activity in male rats and prolonged oestrous cycle in female rats, suggesting that bitter melon fruit may have antifertility activity (Sheeja et al 2012).

## OTHER ACTIONS

### Anticancer

Various preliminary studies (in vitro and in vivo) with crude bitter melon extract and its various constituents (e.g. MAP 30, momordin I, alpha-momorcharin) have shown anticancer activity (Basch et al 2003). An in vitro study on cucurbitane triterpenoids demonstrated antiproliferative activity on human breast adenocarcinoma, human medulloblastoma, human laryngeal carcinoma and human colon adenocarcinoma tumour cell lines (Hsiao et al 2013).

### Analgesic

An in vivo study identified a dose-dependent analgesic effect for a methanolic extract of bitter melon seeds (Biswas et al 1991). The dose that produced a 50% response was 5 mg/kg subcutaneously. Analgesic activity was rapid and short-lived. The opiate pathway was not involved, as naloxone pretreatment did not modify the analgesic response.

### Lipid lowering

A study on human preadipocytes treated with bitter melon juice demonstrated inhibition of lipogenesis and stimulation of lipolysis (Nerurkar et al 2010).

### Wound healing

*Momordica charantia* Linn. fruit powder, in the form of an ointment (10% w/w dried powder in simple ointment base), was evaluated for wound-healing potential in an excision, incision and dead-space wound model in rats (Prasad et al 2006). The *Momordica* ointment produced a statistically significant response ( $P < 0.01$ ), in terms of wound-contracting ability, wound closure time, period of epithelialisation, tensile strength of the wound and regeneration of tissues at wound site when compared with the control group. These results were comparable to those of the reference drug used, which was povidone-iodine ointment. In an experimental study on wounds in streptozotocin-induced diabetic rats, topical application of a bitter melon extract resulted in enhanced wound closure and an increase in protein content, suggesting faster cellular proliferation and healing (Teoh et al 2009).

### CLINICAL USE

The clinical use of bitter melon is largely based on traditional evidence with mechanistic studies further providing a rationale for its use. Most clinical investigation has focused on its potential role in diabetes management.

#### Diabetes

Bitter melon has shown promising effects in prevention as well as delay in progression of diabetic complications (e.g. nephropathy, neuropathy, cataract and insulin resistance) in experimental animals (Grover & Yadav 2004).

Various bitter melon preparations, such as bitter melon fruit juice, dried fruit, seeds and tea, have been investigated for hypoglycaemic activity. Some preparations have demonstrated hypoglycaemic activity in clinical studies and experimental models; however, sample sizes are consistently small and statistical analyses are vaguely described (Dans et al 2007).

A Cochrane systematic review included four randomised controlled trials (RCTs) ( $n = 479$ ) that assessed the effects of bitter melon for type 2 diabetes (Ooi et al 2012). Study duration varied from 4 weeks to 3 months and study preparations also varied. Two of the RCTs compared preparations from different parts of the bitter melon plant (tablets prepared from shade-dried whole fruit equivalent to 1 g three times a day and capsules prepared from the plant fruits and seeds) but found no statistically significant improvement in glycaemic control for bitter melon over the placebo. In a study comparing three doses of capsules prepared from oven-dried fruit pulp (500 mg/day, 1000 mg/day, 2000 mg/day) against metformin there was a significant reduction in mean fructosamine levels from baseline for both bitter melon 2000 mg/day ( $-10.2$  micromol/L; 95% confidence interval [CI]  $-19.1$  to  $-1.3$  micromol/L) and

metformin 1000 mg/day ( $-16.8$  micromol/L; 95% CI  $-31.2$  to  $-2.4$  micromol/L), and the difference between the two treatments was and statistically significant ( $P = 0.43$ ). The largest study that included 260 participants taking tablets prepared from the leaves showed statistically significant reductions in fasting blood glucose and HbA<sub>1c</sub> that were comparable to low-dose glibenclamide (2.5 mg twice daily). There were also comparable improvements in polyuria, polyphagia, polydipsia, weight loss and nocturia. The four included trials used preparations from different parts of the plant and all were assessed as having a high risk of bias. Due to the supportive evidence of hypoglycaemic activity and other mechanisms that would benefit diabetics, further research is warranted to identify the most effective extract, dose and plant part in humans.

#### Cancer

Controlled studies are not available to determine the clinical significance of the encouraging experimental findings. Bitter melon juice extracts have shown anticancer effects both in vivo and in vitro, especially against pancreatic carcinoma. Bitter melon juice extract resulted in strong apoptotic death of human pancreatic carcinoma cells and apoptosis is linked to the activation of the biomarker adenosine monophosphate-activated protein kinase (AMPK). Bitter melon juice extract displayed similar effects of inhibition of cancer cell proliferation, induction of apoptosis and activation of AMPK in mice, therefore suggesting possible clinical usefulness of bitter melon in pancreatic cancer (Kaur et al 2013).

#### HIV

Nine case reports of people with HIV taking bitter melon, sometimes in combination with other herbal medicines, suggest that it may normalise the CD4:CD8 ratio; however, further investigation is required (Zhang & Khanyile 1992). An in vitro study demonstrated that juice of bitter melon had a significant lipid-lowering effect on HIV-1 protease inhibitor-treated HepG2 cells, suggesting bitter melon's potential for decreasing hyperlipidaemia in HIV-infected patients with protease inhibitor-associated hyperlipidaemia (Nerurkar et al 2006).

#### OTHER USES

Traditionally, bitter melon has been used as a treatment for a variety of conditions, such as diabetes, gastrointestinal complaints, worms, constipation, headaches, skin conditions, viral infections and as an emmenagogue in reproductive health. Experimental studies support its use in some of these indications; however, controlled studies are still required to determine its role in practice.

#### DOSAGE RANGE

##### General guide

- Capsule of powdered bitter melon: 500–1000 mg/day.
- Juice: 50–100 mL/day.

### According to clinical studies

- Diabetes: aqueous extract of bitter melon fruit juice containing 100 g of fruit in 100 mL of extract taken daily or oven-dried fruit pulp 2000 mg/day

### ADVERSE REACTIONS

Gastrointestinal symptoms are the most common adverse effects seen. Clinically, this occurs as epigastric discomfort, pain and diarrhoea, which cease once treatment is stopped.

There are two case reports of bitter melon tea inducing hypoglycaemic coma and convulsions in children (Basch et al 2003). Headaches have been reported with ingestion of the seeds (Ulbricht & Basch 2005).

#### Practice points/Patient counselling

- Bitter melon is used as a traditional remedy for diabetes mellitus. Evidence from experimental studies and case reports supports moderate hypoglycaemic activity; however, evidence from clinical studies using a leaf extract or freeze-dried fruit pulp show better results.
- Traditionally, bitter melon has also been used as a treatment for gastrointestinal complaints, worms, constipation, headaches, skin conditions, viral infections and as an emmenagogue.
- According to experimental studies, bitter melon and/or its various constituents exert lipid-lowering, antibacterial, anthelmintic, abortifacient, antifertility, antineoplastic and analgesic activities.
- Bitter melon is contraindicated in pregnancy and people with glucose-6-phosphate dehydrogenase deficiency.
- Avoid bitter melon seed and the outer rind, which have toxic lectins.

#### CONTRAINDICATIONS AND PRECAUTIONS

Avoid bitter melon seed and the outer rind due to the presence of toxic lectins and avoid use of bitter melon in people with glucose-6-phosphate dehydrogenase deficiency (Ulbricht & Basch 2005).

When low doses of bitter melon extract were ingested for up to 2 months in experimental models, no signs of nephrotoxicity, hepatotoxicity or adverse effects on food intake, growth organ weights and haematological parameters were observed. However, toxicity and even death in laboratory animals have been reported when extracts in high doses were administered intravenously or intraperitoneally (Kusamran et al 1998).

### SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

#### Hypoglycaemic agents

Theoretically an additive effect is possible, resulting in increased hypoglycaemic effects — caution. Possible beneficial interaction when used under professional supervision.

#### PREGNANCY USE

Based on experimental studies in animal models and traditional use, bitter melon is contraindicated in pregnancy until safety is established. It should also not be used by men attempting to father a child.

#### PATIENTS' FAQs

##### What will this herb do for me?

According to preliminary research, bitter melon may lower blood glucose levels and aid in the management of diabetes.

##### When will it start to work?

This is difficult to predict. Diabetics should monitor their blood glucose readings when taking bitter melon, as they may require medication modification.

##### Are there any safety issues?

Bitter melon is contraindicated in pregnancy and people with glucose-6-phosphate dehydrogenase deficiency. The seeds and outer rind should be avoided because they contain toxic lectins. Diabetic patients should monitor their blood glucose when taking bitter melon to prevent hypoglycaemia.

# Bitter orange

B

**HISTORICAL NOTE** The root word for orange is the Arabic, *narandj* (Sellar 1992). The orange is a symbol of innocence and fertility. Some scholars believe the 'golden apple' Paris presented to Venus was actually an orange. In return, Venus bestowed Helen on Paris as a reward for selecting her in a beauty contest, which eventually caused the Trojan War. The orange tree is indigenous to eastern Africa, Arabia and Syria and it is believed that the crusaders may have introduced the orange to Europe when they returned from the crusades. Unripe dried fruits and the fruit peel are incorporated into various products, including foods such as marmalade, alcoholic beverages, such as Curaçao, and medicinal products including weight-loss products. The essential oil is used in perfumes, cosmetics and aromatherapy (Leung & Foster 1996), as food flavouring and to disguise the unpleasant taste of medicines. Orange blossom water has been used for centuries in Mediterranean countries to flavour cakes and beverages (Jeannot et al 2005). Orange oil is used in various alcoholic beverages such as Grand Marnier, Curaçao, Triple Sec and Chinotto (*Citrus aurantium myrtifolia*), and in Chinese medicine (*Citrus aurantium daidai*). *Citrus aurantium* extract is also used in Chinese medicine.

## COMMON NAME

Orange

## OTHER NAMES

Bitter orange, *Citrus sinensis*, green orange, Seville orange, Zhi Shi

## BOTANICAL NAME/FAMILY

*Citrus aurantium* var. *dulcis* (sweet orange) and *Citrus aurantium* var. *amara* (bitter orange or neroli) (family Rutaceae).

## PLANT PARTS USED

Dried outer peel of the ripe fruit (expressed essential oil), flowers (Neroli oil). Floral water is obtained during the extraction of essential oils from orange flowers (orange blossom water) and petitgrain essential oil from the leaves. Neroli and petitgrain are obtained by steam distillation or carbon dioxide extraction.

## CHEMICAL COMPONENTS

### Bitter orange peel

Essential oil (0.2–0.5%), monoterpenes linalyl acetate, pinene, limonene, linalool, nerol, geraniol, bitter substances, flavonoids and methyl anthranilate, the alkaloid synephrine and *N*-methyltyramine (Blumenthal et al 2000, Pellati et al 2002). Synephrine is also known as oxedrine in Australia.

Synephrine is considered the most biologically active component of the peel in regards to oral use. Synephrine levels are higher in unripe fruit, possibly because synephrine levels decrease as the fruit matures (Rossato et al 2011).

### Essential oils

Terpeneless/deterpenated or concentrated orange oil is sometimes available. Although the terpenes are removed, terpeneless orange oils retain all their other chemical components, including the furanocoumarins, which are in larger amounts, increasing their

Essential oil species	Major components	Minor components
<i>Citrus aurantium</i> var. <i>dulcis</i>	Limonene 89%	Linalool
	Myrcene 1.7%	Neral
	Beta-bisabolene 1.29%	Geranial, neral, citronellal, sabinene, myracene
<i>Citrus aurantium</i> var. <i>amara</i>	<i>d</i> -limonene 89–96%	Nerol, geraniol, linalyl acetate
		Bergaptene 0.069–0.073%
		Furanocoumarins (in cold pressed but not in steam distilled oils)

(From Price and Price 1995, Sellar 1992, Verzera et al 2004)

phototoxic potential. Therefore, the safe concentration in blends containing terpeneless oils is less than 0.2% (Tisserand & Balacs 1995). Methyl anthranilate is an important compound that may give orange flowers their aroma (Jeannot et al 2005). The composition of orange essential oils is described by the International Standards Organisation (ISO) under the following standard numbers 1340: 2005

9844: 1991	Bitter orange <i>C. aurantium</i> var. <i>amara</i>
8901: 2003	<i>C. aurantium</i> (petitgrain)
3517: 2002	<i>C. aurantium</i> var. <i>amara</i> (neroli)
4735: 2002	Oils of citrus

## MAIN ACTIONS

### Sympathomimetic

*C. aurantium* (CA) contains biologically active adrenergic amines, and may exert sympathomimetic

**Clinical note — Three different essential oils are obtained from the orange tree**

*C. aurantium* var. *dulcis* (sweet orange) and *C. aurantium* var. *amara* (bitter orange or neroli) are obtained from the peel and are usually expressed oils.

Neroli essential oil is obtained from the flowers of *C. aurantium* var. *amara* by steam distillation or carbon dioxide extraction and very occasionally enfleurage and is known as Neroli Bigarade, which is said to be the best Neroli essential oil available. Neroli essential oil obtained from *C. aurantium* var. *dulcis* is known as Neroli of Portugal.

Petitgrain is obtained from the leaves of *C. aurantium* var. *amara* by steam distillation.

Each of these oils has a different chemical profile and, therefore, different uses. Basically, distilled essential oils are used in food flavourings and expressed and steam distilled essential oils in aromatherapy and perfumes because of their stronger fragrance (Tisserand & Balacs 1995). This monograph concentrates on expressed sweet orange and bitter orange essential oils, together with oral extracts of the plant.

activity. One of the most studied is *p*-synephrine, the primary protoalkaloid in *Citrus aurantium* (Kaats et al 2013), also known as oxedrine. It is also present in many other *Citrus* species and found in Seville oranges, nova tangerines, grapefruit, clementines and other orange-related species. Due to the structural similarity of *p*-synephrine found in bitter orange and ephedrine and phenylephrine (*m*-synephrine), it is assumed that *p*-synephrine exhibits somewhat similar pharmacological activities to these other amines and have a significant sympathomimetic action. However, there are several, small structural differences between *p*-synephrine and ephedrine and phenylephrine that result in markedly different binding characteristics, possibly accounting for the relative lack of sympathomimetic activity associated with oral bitter orange preparations and *p*-synephrine.

To clarify, *p*-synephrine has a hydroxyl group in the *para* position on the benzene ring of the molecule, whereas phenylephrine has a hydroxyl group in the *meta*-position on the benzene ring and is not found in plants in general (Kaats et al 2013). Additionally, ephedrine does not contain a *para*-substituted hydroxy group and *p*-synephrine lacks the methyl group on the side chain found in ephedrine. As a result of these structural differences, *p*-synephrine has different characteristics to ephedrine, such as being far less lipid soluble and less able to enter the CNS compared to ephedrine and able to be broken down by monoamine oxidase. Additionally, *p*-synephrine has very poor oral bioavailability.

Receptor binding studies further indicate that *p*-synephrine binds much more poorly to  $\alpha$ ,  $\beta$ -1

and  $\beta$ -2 adrenergic receptors than ephedrine and phenylephrine (*m*-synephrine) (Stohs et al 2011). To provide further perspective, in 1988 Brown et al identified that *p*-synephrine was 1000-fold less active binding to  $\alpha$ -1 and  $\alpha$ -2 adrenergic receptors than noradrenaline, and in 2010, Ma et al suggested that *p*-synephrine was in fact acting as an antagonist to human  $\alpha$ -2a- and  $\alpha$ -2c adrenergic receptors.

Whether CA has significant effects on blood pressure and heart function is unclear as inconsistent results have been obtained in various studies.

An *in vivo* study found no significant effects on blood pressure when two concentrations of *C. aurantium* tincture (standardised to 4% synephrine or 6% synephrine) were administered (Calapai et al 1999). However, analysis of myocardial electrical activity detected ECG alterations such as ventricular arrhythmias with enlarged QRS complex. The effect was present after 5 days of treatment and became significant at day 10 and was still evident after 15 days. This suggests a possible association between synephrine consumption and the occurrence of ventricular arrhythmias and increased cardiac output.

In 2008, a prospective, randomised, double-blind study of healthy adults with a BMI < 30 found that consumption of a single dose containing 900 mg of CA extract standardised to 6% of synephrine produced a significant increase in systolic pressure between 1 and 5 hours after the treatment (Bui et al 2006). More recently, a double-blind, placebo-controlled study found no significant changes to systolic or diastolic blood pressure for patients taking oral CA capsules providing a daily dose of 98 mg *p*-synephrine per day for 60 days alone and in combination with naringin and hesperidin. In relation to heart rate, a small, statistically significant difference was observed between the *p*-synephrine plus naringin and hesperidin treated group and the group receiving *p*-synephrine alone for 60 days as well as the placebo control group (Kaats et al 2013). Both differences were about 3 beats/min, a clinically insignificant finding, which was also observed for the placebo group, further casting doubt on the relevance of this finding.

Effects on blood pressure have been exhibited with the administration of intravenous synephrine where it is used to treat hypotension (Fugh-Berman & Myers 2004). The inconsistent effects on BP with oral use, but obvious effect when administered intravenously, may be due to the very poor oral bioavailability of *p*-synephrine.

**Appetite suppressant and thermogenic**

*P*-synephrine affects the human metabolism by stimulating lipolysis, raising metabolic rate and enhancing fat oxidation through increased thermogenesis (Pellati et al 2002). The thermogenic activity of bitter orange and synephrine appears to be dose-dependent with higher doses effectively promoting

thermogenesis in humans, hamsters and guinea pigs (Carpene et al 1999). The dose-dependent effect is suggested because a later study found neither a single administration of 300 mg/kg of *p*-synephrine orally nor bitter orange extracts (5000 and 10,000 mg/kg standardised to contain 2.5% of *p*-synephrine) significantly altered body temperature in mice (Arbo et al 2008).

A controlled in vivo study of *C. aurantium* fruit hydro-alcoholic extracts standardised to synephrine 4% (Ci. au. 4%) and 6% (Ci. au. 6%) found that repeated administration of the extract significantly and dose-dependently reduced food intake and body weight (Calapai et al 1999). More recently, a reduction in body weight gain was seen in an animal study for *p*-synephrine 30 or 300 mg/kg given by oral gavage over 28 consecutive days (Arbo et al 2009).

Due to these combined actions, it appears to have potential benefits for use in obesity and weight management.

#### Antibacterial

Seville orange has strong in vitro antibacterial activity against *Escherichia coli* and *Staphylococcus aureus* (Melendez & Capriles 2006).

#### Antiviral

The fruit of *C. aurantium* has a potent inhibitory activity on rotavirus infection (Kim et al 2000). The active components are neohesperidin and hesperidin.

#### Antifungal

Bitter orange essential oil has been shown to be effective against resistant fungal skin conditions (Ramadan et al 1996).

#### Digestive effects

The essential oil of *C. aurantium* var. *dulcis* is believed to aid digestion by stimulating the flow of gastric juice and has antispasmodic and carminative actions. The essential oil of *C. aurantium* var. *amara* is considered to be a liver stimulant, reduces gastric spasm and relieves symptoms of indigestion (Price & Price 1995, Wichtl & Bisset 1994). It is also thought to lower cholesterol.

#### Aromatherapy effects

The essential oil of *C. aurantium* var. *dulcis* is considered to convey warmth and happiness and improve mood (Battaglia 1997), reduce stress, aid sleep by reducing stress (Miyake et al 1991) and aid concentration. The essential oil of *Citrus aurantium* var. *amara* is considered to have a calming anxiolytic effect (Faturi et al 2010) and is considered one of the most effective sedative essential oils (Battaglia 1997, Price & Price 1995, Wichtl & Bisset 1994). Anecdotally, many aromatherapists regard orange as the 'oil of joy and communication'.

## OTHER ACTIONS

### Antioxidant

Natural antioxidants obtained from 'citrus oils' have been shown to inhibit oxidation of LDL cholesterol in in vitro studies (Lv et al 2012, Takahashi et al 2003), possibly due to the gamma-terpinene content. Terpinolene and alpha-terpinene also have antioxidant properties. Takahashi et al suggested gamma-terpinene could be added to foods and beverages to prevent oxidation. Sellar (1992) suggested that sweet orange oil aids the absorption of vitamin C. Certain types of tissue damage are mediated by reactive oxygen species (free radicals) such as superoxide. Research suggests reactive oxygen metabolites (ROMS) are associated with inflammatory tissue injury and some antioxidants attenuate the inflammatory process by reducing ROMs, thereby attenuating the tissue injury (Lv et al 2012). Lv et al suggested a diet containing *C. aurantium* might improve oxidative injury and improve immunity in acute otitis media in rats. They showed essential oils obtained from orange peel reduced serum and cochlear malondialdehyde (MDA), immunoglobulins A (IgA), G (IgG) and immunoglobulin M (IgM) and increased the activity of antioxidant enzymes in rats. The clinical application requires further study.

### CLINICAL USE

Bitter orange extract and the isolated constituent *p*-synephrine (oxedrine) are used in oral weight-loss and weight management supplements, cholesterol-lowering herbal mixtures, and in sports supplements.

Orange essential oil is available in tablets, capsules and liquid oil.

### Heartburn and dyspeptic symptoms

A key indication for bitter orange tincture or extract is heartburn (Blumenthal et al 2000). The dried peel is officially listed in the British Pharmacopoeia (British Herbal Medicine Association Scientific Committee 1983) as a bitter tonic, and empirical evidence suggests that it acts as a carminative agent. Commission E approved the use of cut peel for loss of appetite and dyspeptic symptoms (Blumenthal et al 2000).

### Weight loss

*Citrus aurantium* extract is growing increasingly popular as an ingredient in weight loss products, and is being substituted for the banned herbal product ephedra in the United States. The main active ingredient, *p*-synephrine, produces effects on human metabolism that could theoretically reduce fat mass in obese humans because it stimulates lipolysis, raises metabolic rate and increases fat oxidation through increased thermogenesis. Interestingly, *m*-synephrine is a more potent adrenergic stimulant than *p*-synephrine and although not thought to be found

in nature, may be present in North American weight-loss products in order to achieve better results (Fugh-Berman & Myers 2004).

As a reflection of clinical use, most research has been conducted with bitter orange extract in combination with other ingredients, making it difficult to determine the effects of bitter orange on weight loss.

A randomised, pilot study of eight healthy subjects with body mass indexes of 25–40 kg/m<sup>2</sup> compared *Citrus aurantium* to placebo over 8 weeks for effects on body weight (Greenway et al 2006). The *Citrus aurantium* group gained 1.13 ± 0.27 (mean ± SEM) kg compared with 0.09 ± 0.28 kg in the placebo group (P < 0.04). Interestingly, resting metabolic rate at baseline rose more in the *Citrus aurantium* group, 144.5 ± 15.7 kcal/24 hours, than the placebo group, 23.8 ± 28.3 kcal/24 hours (P < 0.002) at 2 weeks, but not at 8 weeks.

Previously, two small clinical studies have been published and both suggest possible weight reduction (Preuss et al 2002); however, more research is required to confirm the effectiveness and safety of orange oil as an adjunct to weight loss.

### Ergogenic aid — used in sports

#### IN COMBINATION

A nutritionally enriched JavaFrit (JF) coffee (450 mg of caffeine, 1200 mg of garcinia cambogia, 360 mg of citrus aurantium extract, and 225 mcg of chromium polynicotinate) was tested for effects on resting oxygen uptake (VO<sup>2</sup>), respiratory exchange ratio (RER), heart rate (HR) and blood pressure (BP) in 10 healthy and physically active individuals using a randomised, double-blind methodology (Hoffman et al 2006). During each session, subjects reported to the Human Performance Laboratory after at least 3 hours post-absorptive state and were provided either 354 mL (1.5 cups) of freshly brewed JF or commercially available caffeinated coffee (P). The nutritionally-enriched coffee beverage increased resting energy expenditure in individuals that were shown to be sensitive to the caffeine and other herbal ingredients in addition to elevating their systolic blood pressure.

### Superficial dermatophyte infection

The oil of bitter orange (*C. aurantium* var. *amara*) was an effective topical treatment in treatment-resistant, superficial dermatophyte infection in a study involving 60 patients (Ramadan et al 1996). Patients with tinea corporis, cruris or pedis were treated with one of three treatments based on oil of bitter orange and cure was assessed by clinical and mycological examinations. One group used a 25% emulsion of oil three times per day, the second group used 20% oil in alcohol three times per day and the third group applied pure oil once per day. Treatment with the 25% oil emulsion was the most successful and resulted in 80% of patients being cured after 1–2 weeks and 20% in 2–3 weeks. The

group using the 20% oil in alcohol preparation also experienced substantial cure rates, but took longer to achieve. Application of the undiluted oil successfully cured 33% of subjects within the first week, 60% within 1–2 weeks and 7% in 2–3 weeks. The only side effect reported was mild irritation when the undiluted oil was used.

### Aromatherapy

*Citrus sinensis* administered in massage or via inhalation has been shown to improve mood and reduce anxiety in a range of health care settings. Lehmer et al (2000) demonstrated reduced anxiety and more positive mood compared to placebo, particularly for women, using 0.25 mL essential oil added to a diffuser in a dental waiting room (n = 72). Fitzgerald et al (2007) also showed a greater effect on mood in girls than boys in a multicultural paediatric integrative medicine clinic. Interestingly, the girls reported feeling more energetic after inhaling spearmint, whereas males felt more energetic after inhaling ginger. Overall, ginger and lavender were the least liked oils. The self-reported reductions in anxiety were supported by objective measures of autonomous function: blood pressure, respiratory and pulse rates and skin temperature (Hongratana-worakit & Buchbauer 2007). These subjects also rated themselves as being more cheerful. Likewise Fewell et al (2007) reported sedative effects of sweet orange oil administered in a massage.

Faturi et al (2010) suggested the anxiolytic effects were most likely to be due to limonene in *C. sinensis*, but anxiolytic activity may depend on the administration route.

#### *Citrus aurantium* var. *dulcis*

The essential oil is used to convey warmth and happiness and improve mood (Battaglia 1997), reduce stress and promote sleep (Miyake et al 1991). It is traditionally known as ‘the oil of communication and happiness’. It is also used to improve digestion and as a carminative to relieve gastric cramping and discomfort.

#### *Citrus aurantium* var. *amara*

The essential oil is used to reduce anxiety, muscle tension and promote relaxation, and best used in the bath before bedtime when treating insomnia (Battaglia 1997). It is used in cosmetics to repair broken capillaries, stimulate cell regeneration and to manage acne-prone skin.

### OTHER USES

Distilled orange oil is often added to foods and beverages to enhance their flavour and to medicines to reduce the unpleasant taste.

Orange blossom water or hydrosol contains small proportions of essential oils and is used on the skin as an astringent and orally as a gastrointestinal carminative (Jeannot et al 2005). There are no terpenes in orange hydrosol, so the likelihood of causing skin

irritation is significantly reduced. It is also used topically as an astringent for acne-prone skin and to calm babies and induce sleep (Bellakhdar 1997, Hmamouchi 2000).

The essential oil of *C. aurantium* var. *amara* is used as an ingredient in perfumes.

## DOSAGE RANGE

### Bitter orange peel products

- General dose information: 4–6 g daily of cut peel for teas or other galenic preparations used for oral administration.
- Infusion: 2 g of cut peel in 150 mL boiling water taken three times daily.
- Weight loss: bitter orange 975 mg (used with caffeine 528 mg and St John's wort 900 mg in a small double-blind study) — efficacy uncertain

### Essential oils

- Oral LD<sub>50</sub> dose: 5 g/kg (rat).
- Dermal LD<sub>50</sub> dose: >5 g/kg (rabbit) (Citrus and Allied Essences 2004).
- Oral LD<sub>50</sub> dose for a 15-kg child: 83 g/kg.
- Oral LD<sub>50</sub> dose for a 70-kg adult: 389 g/kg.
- Oral doses in teas and other preparations: 4–6 g/day or 2 g in 150 mL of boiled water as an infusion (American Botanical Council 1999). The inhalation LD<sub>50</sub> dose has not been established.
- Topical application dose of bitter orange to skin exposed to UV rays: 1.4% of a blend. However, even when topical application is combined with inhalation, blood concentrations of *d*-limonene, a component of most citrus oils, during 20 minutes of massage is low (≤0.008 microgram/mL). It is detectable in the blood within 10 minutes, which represents an uptake of more than 1% of the dose administered (Fewell et al 2007).

## ADVERSE REACTIONS

### Skin sensitisation

The oils of both *C. sinensis* and *C. amara* are mild skin irritants, but are considered to be low risk. Skin reactions are more likely if undiluted oils are applied directly to the skin or when used on broken or inflamed skin, or when other skin pathology is present. Skin reactions are idiosyncratic and can be difficult to predict. Skin sensitisation with topically applied orange oil is largely due to the components citral and cinnamic acid and *d*-limonene and is dose dependent (Tisserand & Balacs 1995). It often occurs after long-term exposure (Verzera et al 2004).

### Photosensitisation

Expressed *C. sinensis* essential oil is not normally phototoxic (Tisserand & Balacs 1995), whereas *C. amara* oil is moderately phototoxic due to its furanocoumarin content, although the risk is considered low unless higher than recommended concentrations are used or more than one potentially phototoxic oil is combined in a blend. The risk may be

increased in fair-skinned individuals. Other phototoxic essential oils include *Citrus bergamia* (bergamot) and *Citrus limon* (lemon). Sensitivity to sunlight or UVB light after topical application increases in the first hour after application and declines over the following 8 hours. A general caution is to avoid UV exposure for at least 12 hours after topical application and use a sunscreen during this period. An early study (Zaynoun 1977) (*n* = 63) showed no significant differences in phototoxic reactions to bergamot oil for eye colour, age, gender or tanning, but smaller amounts of oil produced an effect in light-skinned people. It is not clear whether this also applies to orange essential oil.

### Gastrointestinal symptoms

Abdominal pain, nausea, vomiting, diarrhoea and dizziness have been reported with oral use of the oil (Citrus and Allied Essences 2004).

### Cardiotoxicity

Bitter orange, standardised to 4–6% synephrine, demonstrated cardiovascular toxicity (ventricular arrhythmias with enlargement of QRS complex) and mortality in rats (Calapai et al 1999). However, a more recent double-blind, placebo-controlled trial found that bitter extract treatment delivering 98 mg *p*-synephrine daily over 60 days produced no effects to systolic or diastolic blood pressure and no adverse effects with respect to the cardiovascular, hepatic, renal or haemopoietic systems (Kaats et al 2013). Intravenous administration of synephrine raises blood pressure (Fugh-Berman & Myers 2004) and is likely to have a different safety profile to the oral use of bitter orange extract preparations as *p*-synephrine has very poor oral bioavailability.

Many commercial products contain synephrine or *Citrus aurantium* (CA) in combination with other ingredients such as caffeine which makes it difficult to interpret case reports. In Canada, between January 1998 and February 2004, 16 cases of severe cardiovascular symptoms associated with weight-loss products containing CA or synephrine were reported and of these, only one contained CA as a sole ingredient. There is also some suspicion that ephedrine, which continues to be detected in adulterated dietary supplements found in North America, may be responsible for some cardiac adverse effects and that safety issues really increase when synephrine is taken as part of a combination with other sympathomimetic ingredients (Rossato et al 2011).

In 2010, Health Canada published new guidelines for the use of synephrine in natural products, establishing a daily limit of 30 mg as the maximum allowable dose for synephrine in these products and prohibiting caffeine in synephrine-containing products unless clinical evidence of its safe use in humans was demonstrated (Health-Canada 2010).

### SIGNIFICANT INTERACTIONS

There are no known interactions between the essential oils and conventional medicines; however,

interactions may occur with the fruit and fruit products.

Theoretically, an interaction exists for CYP3A and P-gp substrates, as human studies indicate that the juice made from *C. aurantium* (Seville orange) inhibits CYP3A and possibly P-glycoprotein (Di Marco et al 2002, Malhotra et al 2001) — use with caution.

More specifically, clinical research shows bergamottin and 6',7'-dihydroxybergamottin found in Seville oranges inactivate intestinal CYP3A4. Other furanocoumarins, including bergapten, could also be involved (Malhotra et al 2001).

## CONTRAINDICATIONS AND PRECAUTIONS

### With aromatherapy use

Do not apply essential oils to eyes or undiluted to mucous membranes. Orange essential oil is flammable and should not be vapourised near sources of heat or open flames. Therefore, candle vapourisers are not recommended. Skin sensitisation and phototoxicity are possible with the essential oils, so exposure to UV light sources should be avoided for at least 12 hours after dermal application. The risk is increased in fair-skinned individuals and when a blend that also contains other phototoxic essential oils is used.

### With internal use of CA preparations containing synephrine

Supplements are generally considered safe if they contain 3 mg or less of synephrine in a daily dose, based on a long tradition of safe use (Health Canada 2010). Doses above this should be used with caution by people with hypertension or known cardiac disease and not consumed with high doses of caffeine or other CNS stimulants.

In 2009, synephrine was added to the Monitoring Program in Competitions of the World Anti-Doping Agency (WADA). This program includes substances which WADA wishes to monitor in order to avoid misuse in sport such as caffeine, nicotine, phenylephrine stimulants (WADA 2013). However, synephrine is not a banned substance under WADA.

### PREGNANCY

Bitter orange peel and associated products are not recommended for use in pregnancy (Blumenthal et al 2000).

Orange essential oil used in recommended doses is generally safe in pregnancy, but general safety precautions apply.

### PATIENTS' FAQs

#### *What will this herb do for me?*

Orange essential oil can be used in a vapouriser or massage to aid focus and concentration and facilitate communication. Neroli oil is mostly used to reduce stress and promote sleep and relaxation. In teas and

tinctures, cut peel may aid digestion and relieve dyspeptic symptoms. There is some evidence that orange oil may be an effective treatment for treatment-resistant fungal skin infections.

Taking bitter orange preparations containing synephrine may aid in weight loss or weight maintenance; however, this remains uncertain as more clinical research is required to confirm effects.

#### *When will it start to work?*

When used in aromatherapy, it usually acts soon after inhalation. When the oil or oil products are applied topically to fungal infections, results may be seen within 1–2 weeks; however, 3–4 weeks of treatment may be required. Used internally in capsules, tablets or lozenges, bitter orange peel products should provide symptom relief quickly. Used in the bath before bedtime to promote sleep, neroli oil should produce relaxing effects within half an hour.

#### *Are there any safety issues?*

Skin irritation and phototoxicity (chemical burn) are possible after topical application of the oil if the skin is exposed to UV light such as sunlight. Use in recommended doses and do not use more than 15% of orange essential oil in a blend. Oral use of bitter orange peel products is not recommended in pregnancy and Seville orange juice can induce multiple drug interactions. Oral bitter orange preparations containing more than 3 mg of *p*-synephrine should be used with caution by people with high blood pressure or heart conditions and not used with other stimulants.

### Practice points/Patient counselling

- Bitter orange peel and associated products are used to improve digestion, relieve dyspeptic symptoms and improve appetite, according to traditional use.
- *Citrus aurantium* extract is growing increasingly popular as an ingredient in weight-loss products; however inconsistent research results means it is unclear whether it is effective.
- The oil of bitter orange (*Citrus aurantium* var. *amara*) is an effective topical treatment in treatment-resistant, superficial dermatophyte infection according to one study.
- Topical application of orange oil and bitter orange oil can induce skin sensitisation, which is more likely to occur if old orange essential oil is used because of its tendency to oxidise. Appropriate storage reduces oxidation. A patch test is recommended for atopic people or those who have a tendency to skin reactions to fragrance compounds, cosmetics or essential oils.
- Topical application of orange oil and bitter orange oil can induce photosensitivity in some individuals. After topical application, exposure to sunlight or UVB light should be avoided for at least 12 hours. The risk of phototoxicity increases if high concentrations of phototoxic essential oils are used or a blend contains several phototoxic essential oils or if used by fair-skinned people.

## Black cohosh

**HISTORICAL NOTE** Native Americans first used black cohosh many centuries ago, mainly as a treatment for female reproductive problems, including pain during childbirth, uterine colic and dysmenorrhoea, and also for fatigue, snakebite and arthritis. It was widely adopted by European settlers, eventually becoming a very popular treatment in Europe for gynaecological conditions. It was also a favourite of the Eclectic physicians in North America, who also used it for female reproductive conditions, myalgia, neuralgia and rheumatic conditions.

**COMMON NAME**

Black cohosh

**OTHER NAMES**

Baneberry, black snakeroot, bugbane, rattle-root, rattle-top, rattleweed, squawroot, traubensilberkerze, wanzenkraut

**BOTANICAL NAME/FAMILY**

*Cimicifuga racemosa* now known as *Actaea racemosa* Linnaeus (family Ranunculaceae)

**PLANT PARTS USED**

Rhizome and root

**Clinical note — Selective oestrogen receptor modulators (SERMs)**

These are compounds that, in contrast to pure oestrogen agonists or antagonists, have a mixed and selective pattern of oestrogen agonist-antagonist activity, which largely depends on the tissue targeted. The therapeutic aim of using these substances is to produce oestrogenic actions in those tissues in which it would be beneficial (e.g. bone, brain, liver), and have either no activity or antagonistic activity in tissues, such as breast and endometrium, where oestrogenic actions (like cellular proliferation) might be deleterious. They are a relatively new class of pharmacologically active agents and are being used by women who cannot tolerate pharmaceutical HRT or are unwilling to use it. The most actively studied SERMs are tamoxifen and raloxifen (Hernandez & Pluchino 2003).

**CHEMICAL COMPONENTS**

Black cohosh contains numerous triterpene glycosides, including cimicifugoside, actein and 27-deoxyactein, *N*-methylcytosine and other quinolizidine alkaloids, phenolic acids, including isoferulic and fukinolic acid, salicylic acids, resins, fatty acids and tannins.

Until recently, the isoflavone formononetin was believed to be a pharmacologically important constituent of the herb; however, testing of numerous samples has failed to detect it in any sample, including the commercial products Remifemin (Schaper & Brummer GmbH & Co. KG, Salzgitter, Germany) and CimiPure (Kennelly et al 2002).

**MAIN ACTIONS****Hormone modulation**

The hormonal effects of black cohosh are believed to be the result of complex synergistic actions of several components, particularly the triterpene glycosides. Experimental and clinical evidence confirms that black cohosh does not contain natural oestrogens and does not exert significant oestrogenic activity, although some components may exert selective oestrogen receptor modulation. This has

been confirmed in studies involving women where no oestrogenic effects on mammary glands or the endometrium were observed (Wuttke et al 2014).

Preclinical studies to determine how black cohosh works have yielded conflicting results, but several hypotheses have been proposed. It acts either (1) as a selective oestrogen receptor modulator (SERM); (2) through serotonergic pathways; (3) as an antioxidant; or (4) on inflammatory pathways (Ruhlen et al 2008). There is evidence to support all these actions.

One study suggests that black cohosh works as a SERM, augmented by central nervous effects (Viereck et al 2005). Results from studies found that it has SERM activity with a lower potency but comparable efficacy to that of 17 beta-oestradiol (Bolle et al 2007). It has no action in the uterus, but beneficial effects in the hypothalamopituitary unit and in bone (Seidlova-Wuttke et al 2003). This has been confirmed in a double-blind, randomised, multicentre study (Wuttke et al 2003). In that study, the standardised black cohosh extract BNO 1055 was equipotent with conjugated oestrogens in reducing menopausal symptoms, had beneficial effects on bone metabolism and significantly increased vaginal superficial cells; however, it did not exert uterotrophic activity. Most recently, a 2013 systematic review concluded that black cohosh does not appear to influence circulating levels of oestradiol, FSH or LH, nor to exert oestrogenic effects on breast, endometrial or vaginal tissues. However, it does appear to display oestrogenic activity on bone by stimulating bone formation and inhibiting bone breakdown (Fritz et al 2013). This validates the understanding of black cohosh as a SERM.

Overall, it is generally agreed that black cohosh reduces LH secretion in menopausal women. This has been confirmed in a human study and is believed to be the result of at least three different active constituents acting synergistically (Duker et al 1991). Reductions in LH have also been demonstrated in PCOS patients experiencing infertility (Kamel 2013).

**Anti-inflammatory**

Animal studies have identified some anti-inflammatory activity (Hirabayashi et al 1995). More recently, black cohosh extracts have demonstrated *in vitro* anti-inflammatory activity by inhibiting IL-6 and TNF- $\alpha$ , IFN- $\gamma$  (Schmid et al 2009a) and nitric oxide (Schmid et al 2009b).

**Serotonergic**

*In vitro* tests identified compounds in a black cohosh methanol extract that were capable of strong binding to the 5-HT<sub>1A</sub>, 5-HT<sub>1D</sub>, and 5-HT<sub>7</sub> receptor subtypes (Burdette et al 2003). Further investigation by these authors found that the components functioned as a partial agonist of the 5-HT<sub>7</sub> receptor. Further investigation has identified triterpenoids and phenolic acids which bind weakly to the 5-HT<sub>7</sub> receptor and a new constituent, *N* $\omega$ -methylserotonin, which demonstrates strong 5-HT<sub>7</sub> receptor binding

affinity, together with induction of cAMP and inhibition of serotonin re-uptake (Powell et al 2008). As 5-HT<sub>7</sub> receptors are present in the hypothalamus, it has been speculated that serotonergic activity in the hypothalamic thermoregulatory centres may be responsible for the reduction of hot flushes, although the precise mechanism of action remains unclear.

### Dopaminergic

It is suggested that the effects of *A. racemosa* may be due to dopaminergic activity, because black cohosh extract BNO 1055 displayed dopaminergic activity with a D<sub>2</sub>-receptor assay (Jarry et al 2003). Considering that dopaminergic drugs reduce some symptoms (e.g. hot flushes) associated with menopause, this theory is feasible; however, further studies are required to explain why black cohosh is devoid of the typical side effects associated with dopaminergic drugs (Borrelli & Ernst 2008).

### Cytochromes and P-glycoprotein

Clinical studies have found no indication that Black cohosh affects CYP 3A, 1A2, 2E1 or 2D6 (Gurley et al 2005, 2006a, 2006b, 2008, 2012, Izzo 2012, Pang et al 2011).

Extremely high doses of black cohosh (1090 mg equivalent to 0.2% triterpene glycosides, twice daily for 28 days) demonstrated a minor inhibitory effect on CYP2D6; however, these results are unlikely to be clinically significant due to the high doses and negligible effect. Other studies have demonstrated that recommended doses (40 mg and 80 mg) did not modulate P-gp or CYP3A activity (Borrelli & Ernst 2008, Gurley et al 2006b, Shord et al 2009).

### OTHER ACTIONS

Black cohosh serves as an agonist and competitive ligand for the mu-opioid receptor (Rhyu et al 2006), which provides some rationale for the herb's traditional reputation as a treatment for painful conditions such as dysmenorrhoea and arthritis.

A dose-dependent antihypertensive effect was identified for a triterpene found in black cohosh (actein) in animal tests. The clinical significance of this finding for humans using black cohosh root is unknown (Genazzani & Sorrentino 1962). *In vitro* research has demonstrated endothelium-independent vasorelaxation probably due to calcium channel activity (Kim et al 2011), suggesting possible benefit for vascular conditions.

Black cohosh is traditionally thought to act as a tonic and nervous system restorative medicine and to exert antispasmodic and anti-inflammatory activity.

### CLINICAL USE

Most clinical research has investigated the use of various black cohosh preparations as either stand-alone treatments or in combination with other herbal medicines, notably St John's wort in the treatment of menopausal symptoms. More recently, investigation has begun to determine whether black cohosh has a role in female infertility.

### Menopausal symptoms

Most clinical research on black cohosh has focused on its potential to prevent or decrease the severity of various menopausal symptoms. It can be described as the non-oestrogenic alternative treatment used for menopausal symptoms. Most trials test the commercial preparation of black cohosh known as Remifemin, which is standardised to contain triterpene glycosides (0.8–1.2 mg/tablet), and the extract BNO 1055, an aqueous ethanolic extract (58% vol/vol), sold as Klimadynon and Menofem (Bionorica AG, Neumarkt, Germany). There has also been some investigation with other black cohosh preparations, mainly in the United States. Overall, results from clinical studies have been positive for reducing the frequency of hot flushes, most consistently with the German/Swiss preparations and less consistently with US American black cohosh products. This is likely to be due to great variations in test dose, with lower doses appearing more effective, and differences in herbal extract quality and chemical profile. It may also be because the identity of many American black cohosh preparations is often unknown and they are on the market as food supplements. It was previously shown that many of them contain Asian *Cimicifuga* species, for which no clinical data are available. Importantly, the HPLC profiles of these Asian species look quite different from those of the species that grew originally in America, whereas the German/Swiss products contain extracts of original black cohosh rhizomes that stem from field-planted crops grown under rigidly controlled conditions (Wuttke et al 2014). Unlike hormone replacement therapy, the effect on menopausal symptoms is due to the presence of dopaminergic, adrenergic and serotonergic compounds and not oestrogen.

### Systematic reviews and meta-analyses

Given the number of clinical trials conducted with black cohosh in alleviating menopausal symptoms, there have been a number of systematic reviews and meta-analyses of the evidence.

One of the early reviews was published in 1998 which discussed eight clinical trials and concluded that black cohosh (Remifemin) was a safe and effective alternative to HRT for menopausal patients in whom HRT is contraindicated (Lieberman 1998). Symptoms responding to treatment with black cohosh included hot flushes, vaginal thinning and drying, night sweats, sleep disturbances, anxiety and depression. In 2005, a systematic review, including randomised, controlled trials, open trials and comparison group studies, found that the evidence to date suggests that black cohosh is safe and effective for reducing menopausal symptoms, primarily hot flushes and possibly mood disorders (Geller & Studee 2005). Later reviews by the same research team showed that black cohosh significantly reduced depression and anxiety in all studies reviewed (Geller & Studee 2007). Another more recent systematic review identified seven randomised controlled trials of black cohosh and concluded that it may be

beneficial in the treatment of menopausal vasomotor symptoms in some women (Cheema et al 2007).

A 2008 update of a previous systematic review evaluated the clinical evidence for or against the efficacy of black cohosh in alleviating menopausal symptoms. Seventy-two clinical trials were identified, but only six of these, with a total of 1163 peri- and postmenopausal women, met the inclusion criteria. With one exception, the results for each of these trials were positive; yet the authors concluded that the efficacy of black cohosh in reducing menopausal symptoms is currently not supported by full conclusive evidence, citing small sample size as a limitation in establishing statistical significance (Borrelli & Ernst 2008). Similarly, a review of 16 eligible studies suggested that there were methodological flaws in many studies making a definitive conclusion difficult. Methodological issues included: lack of uniformity of the drug preparation used, variable outcome measures and lack of a placebo group (Palacio et al 2009).

A 2010 systematic review examined nine RCTs and compared black cohosh preparations to placebo in perimenopausal and postmenopausal women (excluding those with a history of breast cancer) for the frequency of vasomotor symptoms. Seven of these trials demonstrated a significant decrease in frequency of vasomotor symptoms in the treatment group and the combined improvement in these symptoms was 24% (95% CI) in the black cohosh group compared to placebo. Again, this review noted the significant heterogeneity of the trials. Black cohosh was found to be more efficacious in treating menopausal symptoms when given in combination with other botanicals such as St John's wort compared with black cohosh alone (Shams et al 2010). In contrast, a 2012 Cochrane review concluded that stand alone treatment with black cohosh was not superior to placebo for reducing the frequency of hot flushes in peri- and postmenopausal women. The authors analysed results of 16 RCTs involving 2027 women, but cautioned that a definitive conclusion could not be made due to the high level of heterogeneity between the studies. Additionally, due to insufficient data they were unable to pool the results for other menopause-related conditions, such as night sweats, bone health, vulvo-vaginal symptoms, quality of life and sexuality (Leach & Moore 2012).

A review by Wuttke et al (2014) makes the point that most placebo-controlled clinical trials have demonstrated amelioration of climacteric complaints, particularly hot flushes, and these positive effects have been seen mainly with German/Swiss preparations, whereas three out of four placebo controlled trials using US supplements have produced negative results (Geller et al 2009, Newton et al 2006, Pockaj et al 2006). A difference in dosage is one likely reason as the German/Swiss medications contained  $2 \times 20$  mg CR (*Cimicifuga racemosa*) drug (4–8 mg extract), whereas two negative US American studies administered 15–25-fold the amounts

used in the European trials and the third, a more moderate over-dosage. In contrast, the positive American trial used a preparation with a standardised amount of triterpenes (2.5%) which yielded a significant reduction of menopausal symptoms not seen when a triterpene-free extract was given.

There is also concern about the quality and herbal authenticity of US CR products as it has previously been shown that many contain Asian *Cimicifuga* species which have quite different constituent profiles (based on HPLC comparisons) compared to the CR species that originally grew in America. This is particularly of concern when products are not manufactured in countries that enforce strict GMP conditions.

Interestingly, since then another positive study has been published which used a European black cohosh extract (Ze450) in 442 unselected ambulatory female outpatients with menopausal complaints under daily practice conditions (Drewe et al 2013). For the first 3 months, doctors were advised to treat patients with 13 mg/day (high dose, HD) and to continue over additional 6 months either with this treatment or to switch to 6.5 mg/day CR (low dose, LD). The choice of treatment and its dose, however, was fully at the discretion of the doctor. After 3 months treatment with HD, symptom severity (Kupperman Menopause Index, KMI) decreased significantly ( $p < 0.001$ ) from baseline values. Continuation of treatment with HD or LD decreased total KMI and its sub-item scores further (HD, LD:  $p < 0.001$ ). However, more patients (84.9%) responded to HD than to LD (78.4%) and showed an improvement of symptoms ( $p = 0.011$ ).

#### IN COMBINATION

A number of studies have been conducted investigating the combination of black cohosh and St John's wort for the treatment of symptoms of menopause with mood symptoms. One double-blind, randomised study of 301 women found that 16 weeks of herbal treatment produced a significant 50% reduction in the Menopause Rating Scale score compared with 20% for placebo and a significant 42% reduction in the Hamilton Depression Rating Scale compared with only 13% in the placebo group (Uebelhack et al 2006). Another large-scale ( $n = 6141$ ), prospective, controlled open-label observational study supports the effectiveness and tolerability of black cohosh combined with St John's wort for alleviating menopausal mood symptoms (Briese et al 2007). In another double-blind, randomised, placebo-controlled, multicentre study, 89 peri- or postmenopausal women experiencing menopause symptoms were treated with a combination of St John's wort and black cohosh extract (Gynoplus) or a matched placebo. Hot flushes were significantly lower and HDL levels increased in the Gynoplus group (Chung et al 2007).

It is therefore no surprise that two systematic reviews have concluded that black cohosh is more efficacious in treating menopausal symptoms when given in combination with St John's wort, compared to black cohosh alone (Shams et al 2010, Laakmann et al 2012).

### Comparison studies

Numerous comparison studies have been conducted utilising various pharmaceutical agents. One pilot study demonstrated that BNO 1055 is able to reduce oestrogen deficiency symptoms to the same degree as conjugated oestrogens (Wuttke et al 2006b). A randomised, double-blind, controlled 3-month study to investigate the efficacy–safety balance of black cohosh (Remifemin) in comparison with tibolone in 244 symptomatic menopausal Chinese women gave remarkable results. The efficacy of both treatments was similar and statistically significant. The safety for both groups was also good. However, the tolerability profile was greatly in favour of the herbal treatment with a significantly lower incidence of adverse events (Bai et al 2007).

An RCT of 120 healthy women with menopausal symptoms found, when compared with fluoxetine, black cohosh was more effective for treating hot flushes and night sweats by the third month, whereas fluoxetine was more effective for reducing mood change according to the Beck's Depression Scale (Beck et al 2003). Monthly scores for hot flushes and night sweats decreased significantly in both groups; however, black cohosh reduced monthly scores for hot flushes and night sweats to a greater extent than did fluoxetine. At the end of the sixth month of treatment, black cohosh reduced the hot flush score by 85%, compared with a 62% result for fluoxetine (Oktem et al 2007).

Wuttke et al (2003) conducted a double-blind, randomised, multicentre study which compared the effects of BNO 1055 (40 mg/day) to conjugated oestrogens (0.6 mg/day) and placebo on climacteric complaints, bone metabolism and endometrium (Wuttke et al 2003). The study involved 62 postmenopausal women who took their allocated treatment for 3 months. BNO 1055 proved to be equipotent to conjugated oestrogens and superior to a placebo in reducing climacteric symptoms, and both active treatments produced beneficial effects on bone metabolism. Vaginal superficial cells increased with both active treatments; however, BNO 1055 had no effect on endometrial thickness, which was significantly increased by conjugated oestrogens.

Commission E has approved the use of this herb as a treatment for menopausal symptoms (Blumenthal et al 2000). Similarly, the World Health Organization (WHO) recognises its use for the 'treatment of climacteric symptoms such as hot flushes, profuse sweating, sleeping disorders and nervous irritability'. The North American Menopause Society recommends black cohosh, in conjunction with lifestyle approaches, as a treatment option for women with mild menopause-related symptoms (North American Menopause Society 2004). In herbal practice generally, menopausal symptoms are usually addressed using a combination of herbs, supplements and dietary and lifestyle advice.

### Weight gain

Rat models demonstrate that BNO 1055 black cohosh extract decreases enhanced pituitary LH secretion, attenuates body weight gain and intra-abdominal fat accumulation, lowers fasting plasma insulin and has no effects on uterine mass. The effects on plasma lipids are complex and are characterised by an increase of LDL cholesterol and decrease of triglyceride levels, which is in contrast to the effects of oestrogen (Rachon et al 2008). There has been no investigation of these effects in human trials.

### Osteoporosis prevention

Black cohosh demonstrates osteoprotective effects comparable to oestrogen, although through a different mechanism of increasing osteoblast activity (Wuttke et al 2006a), mediated via an oestrogen receptor-dependent mechanism (Chan et al 2008). One experimental study has shown that a triterpenoid glycoside isolated from black cohosh (25-acetyl-cimigenol xylopyranoside) both blocks the osteoclastogenesis enhanced by cytokines in vitro and attenuates TNF-alpha-induced bone loss in vivo (Qiu et al 2007). These results demonstrate that black cohosh can offer effective prevention of post-menopausal bone loss.

### Breast cancer protection

A number of in vitro studies on black cohosh show that it is cytotoxic to human breast cancer cells and inhibits the conversion of oestrone sulphate to active oestradiol in breast cancer cells (Rice et al 2007), and suppresses tumour cell invasion without affecting cell viability (Hostanska et al 2007). One in vitro study found that black cohosh enhances the action of some chemotherapy agents, most notably tamoxifen (Al-Akoum et al 2007). The triterpene glycoside, actein, induced a stress response and apoptosis in human breast cancer cells (Einbond et al 2006, 2007, 2008). A recent in vitro study suggests that a herbal combination, Avlimil (which includes black cohosh, licorice, red raspberry, red clover and kudzu), exhibits both stimulatory and inhibitory effects on the growth of oestrogen-dependent breast tumour (MCF-7) cells. This casts doubt on the safety of Avlimil for women with oestrogen-dependent breast cancer (Ju et al 2008).

A randomised study (Hernandez & Pluchino 2003) was performed with 136 young premenopausal breast cancer survivors experiencing hot flushes as a result of tamoxifen therapy. When BNO 1055 (Menofem/Klimadynon, corresponding to 20 mg of herbal drug) was used together with tamoxifen for 12 months, the number and severity of hot flushes were reduced, with almost 50% of subjects becoming free of hot flushes, and severe hot flushes were reported by only 24% compared with 74% for those using tamoxifen alone.

In contrast, a previous double-blind, placebo-controlled study ( $n = 85$ ) failed to detect significant

improvements with black cohosh for hot flush frequency or severity when used by patients with breast cancer for 2 months who were also taking tamoxifen (Jacobson et al 2001). Unfortunately, the authors of that study did not specify which black cohosh product was used or the dosage, making a comparison with the previous study difficult.

A 2013 systematic review on the efficacy of black cohosh in breast cancer found that black cohosh does not appear to influence circulating levels of oestradiol, FSH or LH, nor to exert oestrogenic effects on breast, endometrial or vaginal tissues. However, it does appear to display oestrogenic activity on bone by stimulating bone formation and inhibiting bone breakdown (Fritz et al 2013).

### Premenstrual syndrome and dysmenorrhoea

Commission E has approved the use of black cohosh as a treatment in these conditions (Blumenthal et al 2000). Randomised clinical studies are still required to confirm efficacy in these conditions.

### Menstrual migraine

#### IN COMBINATION

An RCT of 49 women with menstrual migraines tested placebo against a herbal combination consisting of 60 mg soy isoflavones, 100 mg dong quai and 50 mg black cohosh, with each component standardised to its primary alkaloid (Burke et al 2002). Over the course of the study, the average frequency of menstrually associated migraine episodes was significantly reduced in the active treatment group.

### Primary and secondary infertility

Several RCTs have been conducted in the last few years investigating the use of a commercial black cohosh preparation (Klimadynon) as an adjunctive treatment for women with unexplained infertility, both producing promising results (Shahin et al 2008, 2009). One RCT has also been conducted with women diagnosed with polycystic ovarian syndrome (PCOS) and primary or secondary infertility.

*Cimicifuga racemosa* in conjunction with clomiphene citrate was investigated in a 2008 RCT ( $n = 119$ ) in women under 35 years with primary or secondary unexplained infertility who were previously unsuccessful in achieving pregnancy after clomiphene citrate cycles. Both groups received clomiphene citrate (150 mg/day from days 3 to 7) and the treatment group also received *Cimicifuga racemosa* (Klimadynon 120 mg/day from days 1 to 12). In the treatment group, there were higher levels of oestradiol ( $274.5 \pm 48.5$  vs.  $254.6 \pm 20.6$ , NS) and LH concentrations, although these were considered non-significant. There was however a statistically significant increase in endometrial thickness ( $8.9 \pm 1.4$  mm vs.  $7.5 \pm 1.3$  mm,  $P < 0.001$ ), serum progesterone ( $13.3 \pm 3.1$  ng/mL vs.  $9.3 \pm 2.0$  ng/mL,  $P < 0.01$ ) and clinical pregnancy rate (36.7% vs. 13.6%,  $P < 0.01$ ) (Shahin et al 2008).

A follow-up trial in the same population group ( $n = 134$ ) compared *Cimicifuga racemosa* (CR) (Klimadynon 120 mg/day from days 1 to 12) to ethinyl oestradiol (EO) (100 mcg/day from days 1 to 12) in conjunction with clomiphene citrate (150 mg/day from day 3 to 7) (Shahin et al 2009). Although changes to clinical pregnancy rates did not reach statistical significance, these were higher in the black cohosh group (21.1% CR vs. 14.0% EO). The treatment group needed significantly fewer days for follicular maturation ( $13.55 \pm 0.99$  vs.  $11.65 \pm 0.98$ ,  $P < 0.001$ ), had a thicker endometrium ( $7.66 \pm 0.68$  vs.  $8.08 \pm 0.59$ ,  $P < 0.001$ ), higher luteal-phase serum progesterone ( $10.52 \pm 0.89$  vs.  $12.15 \pm 1.99$ ,  $P < 0.001$ ) and higher oestradiol concentration at the time of human chorionic gonadotrophin injection ( $245.10 \pm 15.24$  vs.  $277.0 \pm 27.73$ ,  $P < 0.001$ ).

A 2012 prospective RCT compared *Cimicifuga racemosa* as a stand-alone treatment to clomiphene citrate in 100 women aged 21–27 with polycystic ovarian syndrome (PCOS) and primary or secondary infertility (Kamel 2013). Both groups received black cohosh (Klimadynon 20 mg/day for 10 days) or clomiphene citrate (100 mg/day for 5 days) from the second day of the cycle for three consecutive cycles. Again, although the change in pregnancy rate was not statistically significant, more women taking *Cimicifuga racemosa* became pregnant (7 vs. 4 pregnancies;  $P = 0.1$ ). Remarkable hormonal differences were noted in the black cohosh group, particularly in LH level and FSH/LH ratio, with a marked reduction in the LH level (first cycle  $8.5 \pm 0.28$  vs.  $8.9 \pm 0.55$ ;  $P = 0.0001$ ) which was significant in all three treatment cycles. This confirms the understanding of black cohosh as a hypothalamic-pituitary-ovarian axis modulator. Progesterone was also statistically higher in the Klimadynon group, especially in the first cycle ( $10.12 \pm 0.14$  vs.  $9.54 \pm 0.15$  ng/mL,  $P = 0.0001$ ) along with endometrial thickness (first cycle:  $8.34$  vs.  $6.89$  mm; second cycle:  $9.67$  vs.  $6.34$  mm; third cycle:  $9.11$  vs.  $7.32$  mm;  $P = 0.0004$ ). This study suggests that black cohosh has potential as an alternative to clomiphene citrate for ovulation induction in women with PCOS-related infertility.

### Prostate cancer

Two in vitro studies suggest that black cohosh may have theoretical usefulness in the treatment of prostate cancer (Hostanska et al 2005, Jarry et al 2005, Seidlova-Wuttke et al 2006). Further research is now required to determine whether black cohosh may play a role in the prevention or treatment of prostate cancer.

### OTHER USES

Black cohosh has been used traditionally to treat a variety of other female reproductive disorders and inflammatory disorders, especially menopausal arthritis and diarrhoea. It has also been used to promote menstruation. The British Herbal

Pharmacopoeia states it is indicated in ovarian dysfunction and ovarian insufficiency.

## SAFETY

Evidence now confirms that black cohosh does not pose a risk in women with breast cancer, nor increase its incidence or recurrence. Four hundred postmenopausal women with symptoms related to oestrogen deficiency were enrolled into a prospective, open-label, multinational, multicentre study to investigate endometrial safety and the tolerability and efficacy of the black cohosh extract, BNO 1055. Low dose treatment (40 mg) for 52 weeks showed no case of hyperplasia or more serious adverse endometrial outcome occurred (Raus et al 2006). This finding is supported by the HALT study (Reed et al 2008).

A population-based case-control study consisting of 949 breast cancer cases and 1524 controls was used to evaluate the relationship between phyto-oestrogens and breast cancer risk. Use of black cohosh was found to have a significant breast cancer protective effect. This association was similar among women who reported use of either black cohosh or Remifemin (Rebeck et al 2007). Another smaller trial demonstrated that Remifemin does not cause adverse effects on breast tissue. A total of 65 healthy, naturally postmenopausal women completed a trial with 40 mg black cohosh daily. Mammograms were performed, and breast cells were collected by percutaneous fine needle aspiration biopsies at baseline and after 6 months (Hirschberg et al 2007). A systematic review was conducted about the safety and efficacy of black cohosh in patients with cancer. There is laboratory evidence of antiproliferative properties but no confirmation from clinical studies for a protective role in cancer prevention. Black cohosh appears to be safe in breast cancer patients (Walji et al 2007).

A pharmacoepidemiological, observational, retrospective cohort study examined breast cancer patients to investigate the influence of Remifemin on recurrence-free survival after breast cancer, including oestrogen-dependent tumours. Remifemin was not found to be associated with an increase in the risk of recurrence but was associated with prolonged disease-free survival. After 2 years following initial diagnosis, 14% of the control group had developed a recurrence, while the Remifemin group reached this proportion after 6.5 years, demonstrating a protractive effect of black cohosh on the rate of recurrence of breast cancer for women with a history of breast cancer who had used Remifemin, compared to women who had not (Zepelin et al 2007).

In regards to safety, a 2013 systematic review of black cohosh in breast cancer found that the current evidence does not demonstrate an increased risk or recurrence of breast cancer in women with or without a history. Of the four studies investigating risk, two found no significant association with the use of black cohosh and two reported reduced risk,

including a study that combined black cohosh with tamoxifen. When considering hormones, black cohosh does not appear to influence circulating levels of oestradiol, FSH or LH, nor to exert oestrogenic effects on breast, endometrial or vaginal tissues (Fritz et al 2013).

## DOSAGE RANGE

- Decoction or powdered root: 0.3–2 g three times daily.
- Tincture (1:10): 2–4 mL three times daily.
- Fluid extract (1:1) (g/mL): 0.3–2 mL three times daily.
- Perimenopausal symptoms: 40–160 mg per day.
- Infertility: 20–120 mg per day.

Many practitioners have used black cohosh long term without safety concerns.

## TOXICITY

Overdose has produced nausea and vomiting, vertigo and visual disturbances.

### Idiosyncratic hepatic reactions

Rare, spontaneous hepatotoxicity has been reported in at least 42 case reports worldwide with treatment by *Cimicifugae racemosae rhizoma* (Levitsky et al 2005, Nisbet & O'Connor 2007, Teschke & Schwarzenboeck 2009, Whiting et al 2002). As a result, several safety reviews have been conducted to evaluate the available data and determine what risk exists with the use of this herb. A 2008 safety review of black cohosh products was conducted by the Dietary Supplement Information Expert Committee of the US Pharmacopoeia's Council of Experts. All the reports of liver damage were assigned possible causality, and none were probable or certain causality. The clinical pharmacokinetic and animal toxicological information did not reveal unfavourable information about black cohosh. The Expert Committee determined that in the United States black cohosh products should be labelled to include a cautionary statement, a change from their decision of 2002, which required no such statement (Mahady et al 2008).

Assessment of the 42 cases by European Medicines Agency (EMA) has shown a possible or probable causality in only four out of 42 patients. A diagnostic algorithm has been applied in the four patients with suspected BC (black cohosh) hepatotoxicity using several methods to allow objective assessment, scoring and scaling of the probability in each case. Due to incomplete data, the case of one patient was not assessable. For the remaining three patients, quantitative evaluation showed no causality for BC in any patient regarding the observed severe liver disease (Teschke & Schwarzenboeck 2009).

In Australia in February 2006, the TGA announced that based on the appraisal of case reports, a causal association between black cohosh and serious hepatitis exists; however, the incidence is very low considering its widespread use. As a result, products available in Australia containing

black cohosh have to carry label warnings informing consumers of the risk. The conclusion made by the TGA is considered controversial by some experts because numerous confounding factors were present in many of the case reports, such as the use of multiple ingredient preparations, concurrent use of at least one pharmaceutical medicine and the presence of other medical conditions.

A 2008 study evaluated the effects of black cohosh extract on liver morphology and on levels of various hepatic function indices in an experimental model finding that at high doses, well above the recommended dosage, black cohosh appears quite safe (Mazzanti et al 2008).

More recently, Teschke (2010) investigated data from 69 spontaneous or published case reports of suspected black cohosh-induced hepatotoxicity and found confounding variables such as uncertainty about the quality and authenticity of the black cohosh product, dose or insufficient adverse event description, missing or inadequate evaluation of a clear temporal association, the possible presence of other medications or comorbidities and lack of de-challenge or re-exposure. A clear causal relationship between black cohosh and hepatotoxicity was not found.

A 2011 meta-analysis investigated the potential hepatotoxicity of black cohosh (Remifemin) from published RCTs in peri- and postmenopausal women. Liver function data (AST, ALT and  $\gamma$ -GT) from 1020 women was compared at baseline and after taking black cohosh (40–128 mg/day) for 3 to 6 months. No significant difference between the treatment and reference groups was found (Naser et al 2011).

## ADVERSE REACTIONS

Black cohosh is a well tolerated treatment. A 2012 Cochrane systematic review of 16 RCTs involving 2027 women found no significant difference in incidence of adverse effects between black cohosh and placebo groups (Leach & Moore 2012). The adverse effects associated with black cohosh tend to be rare, mild and reversible. The most common adverse effects reported are gastrointestinal symptoms, musculoskeletal and connective tissue disorders such as rashes (Borrelli & Ernst 2008). According to data from clinical studies and spontaneous reporting programs, large doses can cause headache, tremors or giddiness in some people (Huntley & Ernst 2003).

A few rare but serious adverse events, including hepatic and circulatory conditions, have been reported, but without a clear causality relationship in most instances (see above).

## SIGNIFICANT INTERACTIONS

### Cisplatin

Black cohosh decreased the cytotoxicity of cisplatin in an experimental breast cancer model — while the clinical significance of this finding is unknown, it is

recommended that patients taking cisplatin should avoid black cohosh until safety can be confirmed.

### Clomiphene citrate

RCTs in women with infertility have demonstrated improved pregnancy rates, hormone profiles, follicular maturation and endometrial thickness when taking black cohosh in conjunction with clomid treatment when used during the follicular phase (Shahin et al 2008, Shahin et al 2009). Beneficial interaction possible under professional supervision.

### Doxorubicin

Black cohosh increased the cytotoxicity of doxorubicin in an experimental breast cancer model — while the clinical significance of this finding is unknown, it is recommended patients taking doxorubicin avoid black cohosh until safety can be confirmed.

### Docetaxel

A trial used mouse breast cancer cell line to test whether black cohosh altered the response of cancer cells to radiation and to four drugs commonly used in cancer therapy. The black cohosh extracts increased the cytotoxicity of doxorubicin and docetaxel and decreased the cytotoxicity of cisplatin, but did not alter the effects of radiation or 4-hydroperoxycyclophosphamide (4-HC), an analogue of cyclophosphamide which is active in cell culture. This evidence may be applicable to humans, so it is advisable that patients undergoing cancer therapy should be made aware that use of black cohosh could alter their response to the agents commonly used to treat breast cancer (Rockwell et al 2005).

## ❓ CONTRAINDICATIONS AND PRECAUTIONS

There is some controversy over the use of black cohosh in women with a history of breast cancer. Results from a 2002 study testing the safety of black cohosh in an in vitro model for oestrogen-dependent breast tumours found that the herbal extract significantly inhibited tumour cell proliferation, oestrogen-induced proliferation and enhanced the antiproliferative effects of tamoxifen (Bodinet & Freudenstein 2002). This finding is supported in a more recent in vitro study that showed black cohosh having a cytotoxic effect on both oestrogen-sensitive and oestrogen-insensitive breast cancer cells and a synergism with tamoxifen for inhibition of cancerous cell growth (Al-Akoum et al 2007). A 2013 systematic review of black cohosh in breast cancer found that the current evidence does not demonstrate an increased risk or recurrence of breast cancer in women with or without a history (Fritz et al 2013). As with all medicines, a risk-versus-benefit conversation should take place with patients.

**Practice points/Patient counselling**

- In general, clinical trials support the use of black cohosh for relieving menopausal symptoms, with most consistent benefits reported for the European extracts.
- It appears that 4–12 weeks continuous treatment are required for adequate menopausal symptom relief and it can be used successfully with St John's wort.
- Black cohosh is also used in the treatment of premenstrual syndrome and dysmenorrhoea and is Commission E-approved for these uses; however, controlled studies are not available to confirm its efficacy.
- Black cohosh has many different actions, including selective oestrogen receptor modulator activity, serotonergic, dopaminergic, anti-inflammatory and analgesic activity.
- Black cohosh should be used only under professional supervision by people with oestrogen-dependent tumours, or during pregnancy.
- Black cohosh is well tolerated with few side effects; however, rare case reports of idiosyncratic hepatic reactions have been described. Until safety can be confirmed, avoid prescribing black cohosh in conjunction with medications that are potentially hepatotoxic or in patients with liver disease.

**PREGNANCY USE**

Although it has been used to assist in childbirth, black cohosh is not traditionally recommended in pregnancy, particularly during the first trimester although it has been used in the final weeks of pregnancy to aid in delivery. Safety in lactation remains to be confirmed; however, it is usually avoided because of its hormonal effects (Dugoua et al 2006).

**PATIENTS' FAQs****What will this herb do for me?**

Black cohosh may be an effective treatment for menopausal symptoms in most women, especially those with mild to moderate symptoms. The European extracts give the most consistently positive results for reducing the frequency of hot flushes. Effects are also good when combined with the herb St John's wort. It may also be useful in the treatment of premenstrual syndrome and prevention of period cramping. Black cohosh can also be considered in women with unexplained or PCOS-related infertility.

**When will it start to work?**

Studies suggest that benefits are seen within 4–12 weeks for the treatment of menopausal symptoms.

**Are there any safety issues?**

Black cohosh is well tolerated with few side effects. It should only be used under professional

supervision by people undergoing chemotherapy, receiving treatment for oestrogen-dependent tumours or during pregnancy.

Due to rare case reports of idiosyncratic hepatic reactions, avoid prescribing black cohosh in conjunction with medications that are potentially hepatotoxic or in patients with liver disease, until safety can be confirmed.

## Brahmi

**HISTORICAL NOTE** Brahmi is the Sanskrit name for the herb *Bacopa monniera* and has been used in Ayurvedic medicine as a nerve tonic since time immemorial. Under this system, *B. monniera* is classified under ‘Medhya rasayana’, that is, medicinal plants rejuvenating intellect and memory, and has been used in India for almost 3000 years. The ancient classical Ayurvedic treatises recommend it for the promotion of memory, intelligence and general performance. Over time, it has earned a reputation as an important brain tonic (Williamson 2002).

### COMMON NAME

Brahmi

### OTHER NAMES

Bacopa, herb of grace, herpestis herb, Indian pennywort, jalamimba, jalnaveri, sambrani chettu, thyme-leave gratiola, keenmind, Nira-Brahmi, Sambrani Chettu

*Centella asiatica* (gotu kola) and *Merremia gangetica* have also been referred to by the name brahmi, but most authorities associate brahmi with *Bacopa monniera*. The name brahmi is derived from the word ‘Brama’, the mythical ‘creator’ in the Hindu pantheon. Because the brain is the centre for creative activity, any compound that improves brain health is called brahmi (Russo & Borrelli 2005).

### BOTANICAL NAME/FAMILY

*Bacopa monniera* (family Scrophulariaceae)

### PLANT PARTS USED

Dried whole plant or herb, mainly leaves and stems (aerial parts)

### CHEMICAL COMPONENTS

Dammarene-type saponins (bacosides [A, B, C] and bacosaponines [D, E, F], based on the bacogenins A1–A5, are considered the most important) and alkaloids (brahmine, herpestine), flavonoids (luteolin-7-glucoside, glucuronyl-7-apigenin and glucuronyl-7-luteolin), phytosterols (Chakravarty et al 2003) and luteolin, phenylethanoid glycosides,

monnierasides I–III and plantainoside B have been isolated (Adams et al 2007).

Standardised extract BacoMind has been shown to contain bacoside A<sub>3</sub>, bacoside I, bacoside II, jujubogenin isomer of bacosapponin C, bacosine, luteolin, apigenin and β-sitosterol D-glucoside (Dutta et al 2008).

The commercial extract KeenMind is standardised for bacosides A and B (no less than 55% of combined bacosides). Each capsule contains 150 mg *B. monniera* extract (20:1), equivalent to 3 g dried herb.

### MAIN ACTIONS

Information about the mechanisms of action of brahmi chiefly comes from in vitro and animal tests using various experimental models, although an increasing number of clinical trials are now available. Some studies have investigated the effects of an Ayurvedic herbal combination known as brahmi rasayan, which consists of 10 parts bacopa, two parts cloves, one part cardamom, one part *Piper longum* and 40 parts sucrose.

### Antioxidant

Brahmi has potent antioxidant activity, which appears to be a result of both direct free radical scavenging activity and increasing the activity of endogenous antioxidant systems (Bhattacharya et al 2000, Tripathi et al 1996). Administration of bacoside A reduced the effects of cigarette smoke in an animal model by increasing lactate

dehydrogenase and its isoenzymes (Anbarasi et al 2005a). Bacoside A has also been shown to reduce creatine kinase in brain and cardiac tissue (Anbarasi et al 2005b), and prevent expression of hsp70 and neuronal apoptosis (Anbarasi et al 2006), thus preventing smoke-induced damage. An extract of brahmi provided protection against DNA damage in both animal cells (Russo et al 2003a) and human cells (Russo et al 2003b) in vitro. Dose-related increases in superoxide dismutase, catalase and glutathione peroxidase activities in several important regions of the brain have been demonstrated in animal models (Bhattacharya et al 2000) and it has been shown to induce the activity of superoxide dismutase and catalase in the liver (Kar et al 2002). Additionally, brahmi enhances antioxidant activity to protect against reactive oxygen species-induced damage in diabetic rats (Kapoor et al 2009).

### Neuroprotective

Bacopa has demonstrated neuroprotective activity in a number of animal models, chiefly mediated by an antioxidant mechanism (Saini et al 2012). In particular, antioxidant effects have been observed for bacopa in areas of the brain that are key memory areas, such as hippocampus, frontal cortex and striatum (Bhattacharya et al 2000).

In one study, bacopa significantly protected lipids and proteins from oxidative stress-induced damage caused by aluminium. The protective antioxidant effect was described as similar to L-deprenyl (Jyoti et al 2007). In another experiment, bacopa improved memory functions in hypobaric conditions which induce hypoxia, most likely due to neuroprotective activity, antioxidant and mitochondria-stabilising effects (Hota et al 2009). Antioxidant activity and attenuation of oxidative damage were further confirmed for an oral bacopa extract in a study using a colchicine-induced dementia model (Saini et al 2012).

Administration of bacoside A prevented the structural and functional impairment of mitochondria upon exposure to cigarette smoke in vivo (Anbarasi et al 2005c). From the results, it was suggested that chronic cigarette smoke exposure induces damage to the mitochondria and that bacoside A protects the brain from this damage by maintaining the structural and functional integrity of the mitochondrial membrane.

In an Alzheimer's dementia model, bacopa extract significantly reduced beta-amyloid levels when administered prior to beta-amyloid deposition (Dhanasekaran et al 2004). The neuroprotective effect was specific for beta amyloid-induced cell death but not glutamate-induced excitotoxicity (Limpeanchob et al 2008). Bacopa extracts contain polyphenols and sulfhydryl compounds that demonstrate dose-dependent antioxidant activity, which reduces divalent metals, decreases the formation of lipid peroxides and inhibits lipoxygenase activity (Dhanasekaran et al 2007).

### Cognitive or nootropic effects — multiple mechanisms

Cognitive and nootropic effects are not merely due to antioxidant activity and neuroprotection, as demonstrated in an experimental model of Alzheimer's dementia whereby the cognitive-enhancing effect of *Bacopa monniera* was not well correlated with its neuroprotection (Uabundit et al 2010).

Evidence shows that cognitive activation is due to a combination of mechanisms, which include serotonergic and cholinergic systems together with antioxidant and mitochondrial stabilisation activities. Further research with experimental models indicates that bacopa enhances synaptic plasticity (Preethi et al 2012). The saponins bacoside A and B are considered to be the most important active constituents responsible for enhancing cognitive function (Russo & Borelli 2005, Singh & Dhawan 1982).

Effects on the cholinergic system include the modulation of acetylcholine release, choline acetylase activity and muscarinic cholinergic receptor binding (Das et al 2002). Results from a double-blind, placebo-controlled trial using brahmi (300 mg/day) support this view, as one of the major effects seen was on speed of early information processing, a function predominantly modulated by the cholinergic system (Stough et al 2001). *Bacopa monniera* (120 mg/kg oral) significantly reversed diazepam-induced (1.75 mg/kg intraperitoneal) amnesia in an animal study (Saraf et al 2008), thereby confirming previous reports of cholinergic activity (Dhanasekaran et al 2007).

Research in animal models provides evidence of activation of the serotonergic system (Charles et al 2011). In one study, the level of serotonin (5-HT) increased in rat brains while dopamine decreased significantly. Based on this observation, the learning and memory enhancement effects are likely to be due to upregulation of serotonin-synthesising enzyme tryptophan hydroxylase-2 expression which could enhance 5-HT synthesis and also upregulated SERT (serotonin transporter) expression, which would enhance transportation of 5-HT and subsequent activation of the 5-HT<sub>3A</sub> receptor during hippocampus-dependent learning. The characterised *Bacopa monniera* leaf extract used in this study contained 31.27% bacosides, i.e. bacoside I (0.9%), bacoside A3 (9.47%), bacoside II (17.15%), jujubogenin of bacosaponin C (0.38%) and bacosaponin C (3.37%). High-performance liquid chromatography analysis confirmed the presence of bioactive compounds in the serum of treated rats.

### Antidepressant activity

A rodent model of depression found that an extract of brahmi produced significant antidepressant activity comparable to that of imipramine after 5 days of oral administration (Sairam et al 2002).

Serotonergic activity identified in animal models provides a mechanistic basis for the antidepressant activity.

**Clinical note — what is a nootropic agent?**

Giurgen first coined the phrase when describing a proposed class of pharmacologically active substances that improve cognition or intelligence without side effects and which should protect the brain from damage (Stough et al 2011). This is in contrast to pharmaceutical cognitive activators such as amphetamine or modafinil that only improve cognition and are accompanied by side effects and therefore cannot be described as true nootropic agents. Bacopa is a good example of a nootropic agent due to its cognitive-enhancing and neuroprotective activities and excellent safety profile.

**Antiulcer effects**

Significant antiulcer activity for the fresh juice from the whole plant of *Bacopa monniera* has been demonstrated in an animal model of aspirin-induced gastric ulceration (Rao et al 2000). The study found that brahmi had a beneficial influence on the natural mucosal defensive factors, such as enhanced mucin secretion, mucosal glycoprotein production and decreased cell shedding, thereby reducing ulceration (Rao et al 2000). A follow-up in vivo study in various gastric ulcer models further confirmed brahmi's ability to increase the body's natural defence factors and showed that *B. monniera* is effective for both the prophylaxis and the treatment of gastric ulcers (Sairam et al 2001). In addition, brahmi was shown to reduce lipid peroxidation. An in vitro study demonstrated that *B. monniera* significantly inhibited *Helicobacter pylori*, and the effect was comparable to that of bismuth subcitrate, a known *H. pylori* growth inhibitor (Goel et al 2003).

**Anti-inflammatory effects**

Several different mechanisms are responsible for the observed anti-inflammatory activity of brahmi. Inhibition of cyclooxygenase-2, 5-lipoxygenase (5-LOX) and 15-LOX and downregulation of tumour necrosis factor- $\alpha$  were demonstrated in one study testing a methanolic extract of *B. monniera*. The activity was found for both ethyl acetate and bacoside fractions (Viji & Helen 2008). Channa et al (2006) also identified anti-inflammatory activity but reported that this was mediated by prostaglandin E<sub>2</sub> inhibition, inhibition of histamine, serotonin and bradykinin release (Channa et al 2006).

The anti-inflammatory activity of bacopa was found to be comparable to indomethacin without causing an associated gastric irritation (Jain et al 1994). Several constituents are thought to be responsible for the anti-inflammatory action, chiefly the triterpene, betulinic acid, saponins and flavonoids.

**OTHER ACTIONS****Adaptogen**

A standardised extract of *B. monniera* possesses adaptogenic effects in an animal model, which were found to be comparable to *Panax quinquefolium* (Rai et al 2003). The neuropharmacological adaptogenic activity of brahmi was identified by significant normalisation of stress-induced changes in plasma corticosterone, and monoamine levels and dopamine in cortex and hippocampus regions of the brain (Sheikh et al 2007).

**Antinociceptive activity**

Previously, brahmi rasayan (an Ayurvedic herbal combination containing brahmi) demonstrated antinociceptive activity in animal experiments (Shukla et al 1987). An interaction with the GABAergic system is believed to be involved. More recent research confirms antinociceptive activity specifically for *Bacopa monniera* (Bhaskar & Jagtap 2011). Research using an aqueous extract in an experimental model indicates that the endogenous adrenergic, serotonergic and opioidergic systems are involved in the analgesic mechanism of action of the herb.

**Mast cell stabilisation**

The methanolic fraction of brahmi exhibits potent mast cell-stabilising activity in vitro, which was found to be comparable to that of disodium cromoglycate (Samiulla et al 2001).

**Increased thyroid hormone levels**

Results from animal experiments have found that brahmi increases thyroxine concentrations by 41% without enhancing hepatic lipid peroxidation (Kar et al 2002).

**Antispasmodic effect on smooth muscle**

A spasmolytic effect on smooth muscle has been demonstrated in vivo, and is predominantly due to inhibition of calcium influx into the cell (Dar & Channa 1999). Bronchodilatory effects have also been demonstrated, most likely due to the same mechanism (Channa et al 2003).

**Anticlastogenic effect**

An in vitro study identified significant anticlastogenic effects of the standardised extract of Baco-Mind on human lymphocytes due to the herb's antioxidant activity (Dutta et al 2008).

**Hepatoprotective**

Bacoside A was hepatoprotective against D-galactosamine-induced liver injury in rat studies. Researchers found that bacoside A reduced alanine transaminase, aspartate transaminase, alkaline phosphatase, gamma-glutamyl transpeptidase, lactate dehydrogenase and 5'ND enzyme levels and restored the decreased levels of vitamins C and E reduced

by D-galactosamine in both liver and plasma (Sumathi & Nongbri 2008).

### Cholesterol-lowering activity

According to a study using an experimental model of hypercholesterolaemia, feeding test animals an ethanolic extract of whole plant material (*Bacopa monniera*) for 45 days resulted in a significant reduction in levels of total cholesterol (TC), triglycerides, low-density lipoproteins (LDL), very-low-density lipoprotein (VLDL), atherogenic index, LDL:high-density lipoprotein (HDL) ratio and TC:HDL ratio and significantly increased the level of HDL (Kamesh & Sumathi 2012).

### Anticonvulsant activity

Using an experimental epileptic model, Matthew et al (2012) demonstrated that *Bacopa monniera* and bacoside A treatment reverses epilepsy-associated changes to near controls. The effect appears to be mediated via GABA-A receptors and attributed to the bacoside A constituent (Mathew et al 2010, 2011).

#### **Clinical note — Scientific investigation of Ayurvedic medicines in India**

Modern-day interest in many Ayurvedic herbs, such as brahmi, really started in 1951 when the then Prime Minister of India set up the Central Drug Research centre in Lucknow. The goal of this initiative was to encourage scientists to investigate many of the traditional Ayurvedic herbs in a scientific way, and to determine their potential as contemporary drugs or as potential sources for newer drugs.

### CLINICAL USE

Brahmi has been subject to many in vitro and animal studies, which indicate that the herb and several of its key constituents have significant pharmacological activity. Increasingly, clinical studies are being published which provide a scientific basis for its use in practice. Most clinical research has been conducted with standardised bacopa extracts and focused on its effects on memory and learning, overall supporting its traditional reputation as a 'brain tonic'.

#### **Improving cognitive function — learning, memory, intelligence**

In Ayurvedic medicine, bacopa is used to improve cognitive function and increase intelligence. Over time, it has developed an excellent reputation, prompting scientific researchers to investigate the activity of bacopa more closely.

The evidence available from clinical studies indicates a significant effect on various aspects of memory and learning when bacopa extract is taken long-term. Less is known about the acute neuro-cognitive effects as there is less research to draw on

and the two available clinical trials have produced inconsistent results (Downey et al 2013, Nathan et al 2001).

The bacopa extract known as KeenMind has been the subject of most studies, although there is evidence that other extracts, including BacoMind, also have significant effects.

### Healthy adults

A double-blind, placebo-controlled trial using a dose of 300 mg bacopa (KeenMind) over 12 weeks in 46 healthy volunteers aged between 18 and 60 years found that it significantly improved the speed of visual information processing, learning rate and memory consolidation and that it has a significant anxiolytic effect (Stough et al 2001).

Another study of the same design tested brahmi (KeenMind) in 76 adults aged 45–60 years taken for over 3 months (Roodenrys et al 2002); significant improvements in a test for new information retention was observed, but there were no changes in the rate of learning.

More recently, a 90-day double-blind placebo-controlled study demonstrated that bacopa (300 mg/day; KeenMind) produced significantly improved performance on the 'working memory' factor, more specifically spatial working memory accuracy and accuracy in the rapid visual information processing task compared to placebo (Stough et al 2008). Additionally, those receiving active treatment reported significantly greater incidence of increased energy. The only significant increase in side effects was for incidence of diarrhoea and reduction in the number of dreams. While 107 people were originally enrolled in the study, there were 45 withdrawals, a similar amount from both groups (23 and 22), so only 62 people were considered sufficiently compliant with treatment and included in the final analysis.

### Older adults

In 2008, Calabrese et al demonstrated that whole-plant standardised dry extract of *Bacopa monniera* (300 mg/day) safely enhanced cognitive performance in the aged in a double-blind, randomised, placebo-controlled study. The trial involved 54 volunteers aged 65 years or older, without clinical signs of dementia, who received placebo or herbal treatment for 12 weeks. The group receiving active herbal treatment also experienced a reduction in anxiety, whereas anxiety increased in the placebo group.

A double-blind, placebo-controlled randomised study was conducted in India involving 40 volunteers aged over 55 years and complaining of memory impairment (Ranghavi et al 2008). The subjects received either 125 mg of an ethanolic standardised bacopa extract (containing 55% bacosides) or placebo twice a day for a period of 12 weeks followed by a placebo period of another 4 weeks (total duration of the trial 16 weeks). Active treatment produced a significant improvement in calculating

ability, logical memory and paired associate learning compared to the placebo group.

Calculating ability was significantly improved by the end of week 8 and became highly significant at the end of week 12 and was maintained for a further 4 weeks after treatment withdrawal. Logical memory and recall of story improved by the end of week 4 onwards with active treatment and, once again, remained for 4 weeks after treatment ceased. Paired associate learning improved by week 8.

In 2010, results from a 12-week, randomised, double-blind, placebo-controlled trial using a brahmi extract known as BacoMind (300 mg/day: Natural Remedies) were published (Morgan & Stevens 2010). The study involved 81 healthy participants aged over 55 years of age. This comprehensive study measured audioverbal and visual memory performance together with subjective memory performance using a battery of validated measures. Treatment with bacopa significantly improved memory acquisition and retention in healthy older people — specifically verbal learning, memory acquisition and delayed recall — when compared to controls.

### Acute effects in healthy people

Whether bacopa has acute effects is uncertain as current clinical trials have produced inconsistent results. Nathan et al (2001) found no significant change in cognitive function 2 hours after ingesting 300 mg of a bacopa extract (standardised to 55% combined bacosides A and B). The double-blind, placebo-controlled trial of 38 healthy volunteers (ages 18–60) found no effects on working and short-term memory, memory consolidation, information processing, executive processes, problem solving or motor responsiveness.

In contrast, acute neurocognitive effects were identified in a double-blind, placebo-controlled, crossover study utilising bacopa extract (KeenMind) and involving 24 healthy participants (Downey et al 2013). Two doses of bacopa (320 mg and 640 mg) were compared to each other and placebo for effects on participants' performance on six repetitions of the Cognitive Demand Battery (CDB). The standard treatment dose of 320 mg improved performance on the first, second and fourth repetition of the CDB but had no effects on cardiovascular parameters, task-induced rating of stress or fatigue.

### Children

Less research has been conducted with children; however the available evidence is promising. A single-blind open clinical study reported memory- and learning-enhancing effects and improved reaction time in children after 12 weeks of treatment (Sharma et al 1987). In this study children were given bacopa syrup three times daily (350 mg/dose) over 3 months. A small, randomised, double-blind trial of 36 children diagnosed with attention-deficit hyperactivity disorder (ADHD) showed that 12

weeks' treatment with fresh whole-plant extract of bacopa (50 mg twice daily) improved logical memory impairment (Negi et al 2000).

An Israeli study utilising a patented herbal and nutritional combination produced significant improvements to attention, cognition and impulse control in a larger double-blind, placebo-controlled study of 120 children with newly diagnosed ADHD (Katz et al 2010). After 4 months of treatment, the group showed substantial, statistically significant improvement in the four subscales and overall test of variables of attention scores, compared with no improvement in the control group, which persisted in an intention-to-treat analysis. The treatment being evaluated consisted of a patented blend of nutritive, food-grade herbs, prepared as a highly stable, dilute ethanol extract called Nurture & Clarity. Bacopa was one of the main herbal ingredients, but not the sole ingredient. Others in the treatment included *Paconiae alba*, *Withania somnifera*, *Centella asiatica*, *Spirulina platensis* and *Mellissa officinalis*, together with a range of vitamins.

### Anxiety

Bacopa has traditionally been used in Ayurvedic medicine to treat anxiety, and preliminary evidence is promising.

A placebo-controlled, randomised study of healthy subjects found that 300 mg of brahmi (KeenMind) daily reduced the anxiety compared with placebo, an effect most pronounced after 12 weeks compared to 5 weeks of treatment (Stough et al 2001). A reduction in anxiety was also reported by Calabrese et al (2008) in a double-blind, randomised, placebo-controlled study which tested whole-plant standardised dry extract of *Bacopa monniera* (300 mg/day) over 12 weeks. The trial of 54 volunteers aged 65 years or older, without clinical signs of dementia, found that active treatment reduced anxiety whereas anxiety increased in the placebo group.

## OTHER USES

### Traditional uses

Bacopa has been traditionally used as a brain tonic and is commonly recommended to improve memory and heighten learning capacity. It is also used as a nerve tonic to treat anxiety, nervous exhaustion or debility and is prescribed to enhance rehabilitation after any injury causing nervous deficit, such as stroke. Other traditional uses include promoting longevity, and treating diarrhoea and asthma. It is used as an anti-inflammatory, analgesic, anxiolytic and antiepileptic agent, with some support for these uses provided by in vitro and in vivo studies.

### Irritable bowel syndrome

An Ayurvedic herbal combination consisting of *Aegle marmelos correa* and *Bacopa monniera* successfully treated 65% of patients with irritable bowel

syndrome under double-blind, randomised conditions (Yadav et al 1989). Herbal treatment was particularly useful in the diarrhoea-predominant form of irritable bowel syndrome, compared with the placebo. Follow-up reviews 6 months after the trial found that relapse rates were the same among all test subjects. Although encouraging, it is not certain to what extent brahmi was responsible for these results.

### DOSAGE RANGE

- Dried aerial parts of herb: 5–10 g/day.
- Fluid extract (1:2) or equivalent oral dose form: 5–13 mL/day in divided doses.
- Standardised extract (BacoMind or KeenMind) 300 mg/day.

For children aged 6 years and older: 350 mg of dried plant extract in a syrup form was administered three times daily.

### According to clinical studies

- Cognitive activator effects: 300 mg/day.

Positive results obtained in one controlled study have found that 5–12 weeks' use is required before clinical effects are observed (Stough et al 2001).

### TOXICITY

The LD<sub>50</sub> data for an ethanolic extract of bacopa is 17 g/kg (oral) (Mills & Bone 2005).

Animal studies indicate that LD<sub>50</sub> of standardised extract (BacoMind) is 2400 mg/kg body weight with no observed adverse effect limit of 500 mg/kg body weight after 90 days (Allan et al 2007).

### ADVERSE REACTIONS

The most common side effects are minor gastrointestinal disturbances, nausea, abdominal cramps, increased stool frequency and diarrhoea (Morgan & Stevens 2010, Pravina et al 2007). Less frequent side effects include sleepiness, headache, palpitations, dry mouth, thirst and fatigue, insomnia and vivid dreams or lack of dreams.

### SIGNIFICANT INTERACTIONS

Controlled studies are not available, so interactions are based on evidence of activity and are largely theoretical and speculative.

#### Cholinergic drugs

Cholinergic activity has been identified for brahmi, therefore increased drug activity is theoretically possible — observe patient, although a beneficial interaction is possible under professional supervision.

#### Serotonergic drugs

Serotonergic activity has been identified for bacopa extracts, therefore there is a theoretical increased risk of serotonin syndrome when bacopa is used together with selective serotonin reuptake inhibitor and serotonin-noradrenaline reuptake inhibitor medicines — the clinical significance of the

interaction is unclear. Caution until further investigation can confirm.

### Practice points/Patient counselling

- Brahmi is an Ayurvedic herb that has been used for several thousand years as a brain tonic, to enhance intellect, treat psychiatric illness, epilepsy and insomnia and as a mild sedative.
- There is now good evidence that bacopa exerts cognitive and nootropic activity via multiple mechanisms, including activation of the serotonergic and cholinergic systems, antioxidant and mitochondrial stabilisation activities and enhancement of synaptic plasticity.
- Human studies have shown that brahmi (KeenMind, BacoMind, whole-plant extract) has a significant effect on various aspects of learning and memory when used long-term; effects with short-term use or single doses are less well investigated. There is also evidence of anxiolytic activity according to clinical studies.
- Brahmi has potent antioxidant activity, which appears to be a result of both direct free radical scavenging activity and increasing endogenous antioxidant systems in the brain and liver.
- Anticholinesterase, antidepressant, antiulcer, antispasmodic, anti-inflammatory, antihistamine, neuroprotective, antinociceptive activities and lipid-lowering actions have been demonstrated in animal studies. Elevated thyroxine levels have also been observed.

### CONTRAINDICATIONS AND PRECAUTIONS

Caution is advised in hyperthyroidism, as bacopa has been shown to significantly elevate thyroxine levels in vivo. The clinical significance of this finding is unknown.

Brahmi may cause gastrointestinal symptoms in people with coeliac disease, fat malabsorption syndrome, vitamins A, D, E or K deficiency, dyspepsia or pre-existing cholestasis due to the high saponins content of the herb (Mills & Bone 2005).

### PREGNANCY USE

Brahmi is recommended as a tonic for anxiety in pregnancy according to traditional Ayurvedic medicine; however, insufficient information is available to confirm safety during pregnancy.

### PATIENTS' FAQs

#### What will this herb do for me?

Brahmi has a long history of use as a brain tonic. Results from scientific studies demonstrate that it will enhance aspects of learning, memory and cognitive function with long-term use and is also likely to reduce anxiety,

### When will it start to work?

Studies indicate that 5–12 weeks' continual use is required for benefits on cognitive function to become apparent. Acute effects may also be possible, but there is less evidence to be certain.

### Are there any safety issues?

Information from traditional sources suggests that brahmi is well tolerated at the usual therapeutic doses and the most common side effects relate to gastrointestinal disturbances which are mild and reversible, such as nausea, frequent bowel motions and abdominal cramping. Clinical studies have not confirmed drug interactions so cautions are theoretical.

## Calcium

### BACKGROUND AND RELEVANT PHARMACOKINETICS

In the context of both biosphere and biology (plant and animal) calcium plays a leading role. Its abundance in the environment (e.g. limestone, marble, coral) is reflected, in part, in the human body, with calcium being the most abundant mineral in the body. Calcium homeostasis reflects a balancing act between requirements for proper function and the organism's need to protect against excess cellular calcium levels and associated toxicity. This balance has ramifications not only for our own physiology, but also in terms of levels and bioavailability of dietary calcium.

Three hormones regulate calcium status in the body — calcitriol (active vitamin D), parathyroid hormone (PTH) and calcitonin. Calcitriol increases intestinal absorption of dietary calcium when blood levels are low. In addition, PTH signals the kidneys to reduce calcium loss, produce more calcitriol and also activate osteoclasts that release bone calcium. Calcitonin is secreted by the thyroid gland when calcium levels become too high and opposes the action of PTH, thereby returning calcium levels back to normal.

Calcium, found in the diet or supplements, exists in salt form, from which it must be released for absorption to occur. Adequate hydrochloric acid levels are required to solubilise the majority of these calcium ions, failing which calcium salts entering the higher pH environment of the small intestine are more likely to precipitate and be rendered insoluble (Wahlqvist 2002). Low or moderate calcium intakes ( $\leq 400$  mg/day) are absorbed via active transport mechanisms that are influenced by vitamin D. When intake is high, active transport mechanisms become saturated, leading to greater passive absorption. Although most absorption occurs in the small intestine, the large intestine may also be responsible for up to 4% of absorption and provides compensatory mechanisms for those individuals

with compromised small intestine absorption (Groff & Gropper 2009).

Calcium's bioavailability from both food and supplements shows substantial variation, and may be influenced by other foods present in the gastrointestinal tract. Phytates (in wholegrains, nuts and seeds), oxalates, all types of fibres, unabsorbed dietary fatty acids and other divalent minerals all potentially compromise its absorption, while lactose (especially in children) and other sugars, as well as protein and the presence of vitamin D, all enhance uptake (Groff & Gropper 2009).

Calcium salts differ in the amount of elemental calcium, which may have clinical implications and affect dose selection. Calcium carbonate contains the highest amount of elemental calcium by weight (40%), calcium citrate (21%), calcium lactate (14%) and calcium gluconate (9%) (Kopic & Geibel 2013). In addition to having variable calcium fractions, the different calcium salts have widely divergent water solubility, which may also affect absorption and bioavailability. For example, calcium citrate dissolves 17 times more readily than calcium carbonate in water. However, 86% of calcium carbonate will still dissolve in a slightly more acidic environment (pH 5.5), which is higher than a normal maximum stomach pH of 4.5. Researchers in this area have not reached consensus as to whether the difference in water solubility is clinically relevant, provided the stomach pH is sufficiently acidic to dissolve the calcium supplement and allow for absorption (Kopic & Geibel 2013).

Besides the variation in absorption due to gastric pH, other dietary components and type of calcium salt, there are differences between individuals in their calcium absorption efficiency which can be up to 60% variance; the underlying mechanisms, although unclear, may be linked to vitamin D receptor (VDR) polymorphisms (Heaney & Weaver 2003). Consistent with this, our understanding of the magnitude of vitamin D's influence upon

calcium absorption continues to broaden, including the life-stage-dependent bioavailability of this mineral. The age-associated decline in calcium absorption (children absorb ≈75% compared with ≤30% in adults) (Groff & Gropper 2009) has now been linked to vitamin D via reduced available calcitriol and decreased intestinal VDR levels, producing vitamin D resistance (Groff & Gropper 2009, Pattanaungkul et al 2000). Similarly, the decreasing bioavailability associated with (peri)menopause and the increased absorption evident early in pregnancy (Prentice 2003) are attributed largely to vitamin D-mediated effects. Calcium absorption, however, is described as being generally inefficient, with a substantial amount of calcium remaining unabsorbed in the lumen (Heaney & Weaver 2003).

Distribution results in 99% of absorbed calcium being deposited in bones. The remainder of the absorbed calcium is present in teeth and the intracellular or extracellular fluids. Calcium is excreted in faeces, sweat and urine.

### FOOD SOURCES

Good dietary sources of calcium include dairy products, fortified soy products, fish with bones (especially salmon and sardines), tofu, broccoli, collard greens, mustard greens, bok choy, clams and black strap molasses. Certain brands of soy milk, fruit juice, breakfast cereal and bread are also fortified with calcium, which provides an alternative for people who don't eat dairy products. People with limited dairy intake may still need to consider supplementation to ensure they meet RDI levels.

### DEFICIENCY SIGNS AND SYMPTOMS

Optimal calcium intake is essential during every stage of life and insufficient intake in childhood years can have ramifications later in life.

While there is little information available about the prevalence of deficiency across the general Australian population, a Melbourne study of 1045 women aged 20–92 years in 2000 revealed that approximately 76% of women consumed calcium at levels less than the recommended daily intake (RDI), and an additional 14% demonstrated a grossly inadequate intake of less than 300 mg/day (Pasco et al 2000). Dietary calcium intake has been found to be inadequate and below Estimated Average Requirement (EAR) in the majority of elderly Australian women (Meng et al 2010). These figures are similar to those obtained by larger studies in the United States (Groff & Gropper 2009). Calculating the prevalence of calcium deficiency is partly hampered by physiological preservation of 'non-osseous' calcium for critical roles in exchange for the 'expendable' reserves in bone and, therefore, the slow development of overt deficiency features. Consequently, calcium deficiency is insidious in its early stages and potentially irreversible in the latter, making preventive optimisation the only successful pathway in all patients perceived to be at an increased risk. In addition to this, long-term

suboptimal calcium has been linked to an increased risk of a range of other morbidities, including pre-eclampsia and colorectal cancer.

Deficiency signs and symptoms include:

- tetany: muscle pain, spasms and paraesthesias
- rickets
- osteomalacia
- increased neuromuscular irritability
- altered heart rate
- ambulatory developmental delays in children
- osteoporosis and increased risk of fractures
- bone pain and deformity
- tooth discolouration and increased decay
- hypertension
- increased risk of preeclampsia
- increased risk of colon cancer (controversial).

There are many situations and conditions in which the risk of hypocalcaemia may be increased.

### Primary deficiency

Primary deficiency occurs as a result of inadequate dietary intake, with greatest risk seen in populations with increased calcium requirements e.g. children, adolescents, pregnant and lactating women, postmenopausal women (particularly those taking hormone replacement therapy [HRT] [Wahlqvist 2002]), people experiencing rapid weight loss or patients receiving total parenteral nutrition (TPN).

### Secondary deficiency

Calcium absorption is impaired in achlorhydria (more common in the elderly), intestinal inflammation and any malabsorptive disorder accompanied by steatorrhoea (Wilson et al 1991). Increased faecal calcium loss occurs with higher intakes of fibre and in fat malabsorption, while renal excretion has been shown in some studies to be increased in those patients ingesting a high protein diet (Kerstetter et al 1998).

Factors that compromise vitamin D status or activity will also affect calcium status), e.g. oral and inhaled corticosteroids (Beers & Berkow 2003, Pattanaungkul et al 2000, Prince et al 1997, Rossi et al 2005).

Other conditions that can predispose to hypocalcaemia include hypoparathyroidism (a deficiency or absence of PTH), idiopathic hypoparathyroidism (an uncommon condition in which the parathyroid glands are absent or atrophied), pseudohypoparathyroidism (characterised not by deficiency of PTH, but by target organ resistance to its action), magnesium depletion, renal tubular disease, renal failure, acute pancreatitis, hypoproteinaemia, septic shock or the use of certain medicines such as anticonvulsants (phenytoin, phenobarbitone) and rifampicin, and corticosteroids (Beers & Berkow 2003, Rossi et al 2005).

### MAIN ACTIONS

Calcium is an essential mineral required for the proper functioning of numerous intracellular and

extracellular processes, including muscle contraction, nerve conduction, beating of the heart, hormone release, blood coagulation, energy production and maintenance of immune function. It also plays a role in intracellular signalling and is involved in the regulation of many enzymes.

### **Bone and teeth mineralisation**

Calcium is found in bone where it is mainly complexed with other ions in the form of hydroxyapatite crystals. Approximately 1% of calcium in bone can be freely exchanged into the extracellular fluid in order to buffer changes in calcium balance.

### **Muscle contraction**

Calcium plays a major role in muscle contraction. Ionised serum calcium helps to initiate both smooth and skeletal muscle contraction and in particular, the regulation of rhythmic contraction of the heart muscle in combination with sodium and potassium. During exercise, one cause of muscle fatigue is the impaired activity of calcium in muscle cells (Insel et al 2013).

### **Blood clotting**

Calcium is required in order for blood to clot. It is involved in several steps of the blood clotting cascade and is required for the production of fibrin, the protein that gives structure to blood clots (Insel et al 2013).

### **Nerve conduction**

Calcium is required for nerve cells to transmit signals. The strength of the signal is proportional to the number of calcium ions crossing the nerve cell membrane (Insel et al 2013).

### **Altered membrane functions**

Calcium fluxes across membranes, both within the cell and across the plasma membrane, and acts as a vehicle for the signal transduction necessary for neurotransmitter and hormone function. It also selectively alters cell wall permeability to regulate passage of fluids in and out of cells.

### **OTHER ACTIONS**

Regulates various enzyme systems responsible for muscle contraction, fat digestion and protein metabolism.

### **CLINICAL USE**

Many of the indications for calcium supplements are conditions thought to arise from a gross or marginal deficiency; however, some are based on the concept of 'beyond-repletion' calcium therapy.

### **Calcium deficiency**

Traditionally, calcium supplementation has been used to treat deficiency or prevent deficiency in high-risk conditions or people with increased calcium requirements such as pregnant and lactating

women. Acute severe hypocalcaemic states are treated initially with intravenous infusion of calcium salts. In chronic cases, oral calcium supplements are often combined with vitamin D supplements to improve absorption and utilisation.

### **Rickets and osteomalacia**

A deficiency of either calcium or vitamin D can produce these bone disorders. (See *Vitamin D* monograph for further information.)

### **Infants**

The percentage and type of fats within an infant formula and their ability to bind calcium salts and increase excretion has been shown to influence the bone mineral content (BMC) of infants. One hundred 8-week-old infants given formulas considered to be more similar to breastmilk and less likely to form calcium soaps in the gut showed increased BMC after only 1 month's treatment compared with those infants on standard formula (Kennedy et al 1999).

### **Bone mineral density (BMD), osteoporosis prophylaxis and reducing fracture risk**

Calcium supplements are prescribed widely to promote bone health, including the treatment and prevention of osteoporosis, a major cause of morbidity and mortality in older people (Hennekens & Barice 2011). RCTs assessing BMD generally show a beneficial effect of calcium treatment in both men and women (typically a 1%–2% absolute difference between the treatment and control groups over 2–3 years), which results in a sustained reduction in bone loss of 50%–60%. The effect appears to be greatest for people whose baseline dietary calcium intake is low (Sanders et al 2009).

Adequate calcium intake is particularly important to consider in at-risk populations because osteoporosis-related fractures can lead to early disability and death. Ensuring adequate calcium intake alone is not sufficient and vitamin D status is also important as both contribute to bone density and associated protective effects. Sufficient trace minerals such as manganese, zinc and copper and weight-bearing exercise is also suggested and the use of anti-resorptive drugs together with mineral supplementation may be required in high risk groups or those with preexisting osteoporosis.

The lifetime risk of fracture is highest in white women, and decreases successively among Hispanic, Asian and African-American people. For white women, it occurs 20% for the spine, 15% for the wrist and 18% for the hip, with an exponential increase in risk beyond the age of 50 years. Within 12 months after a hip fracture, approximately 13% of people die, with most survivors losing their previous independence. Calcium supplementation, together with vitamin D, may reduce vertebral and non-vertebral fractures (Vestergaard et al 2011). This is supported by a 2010 meta-analysis of seven randomised studies of vitamin D or calcium and

vitamin D which included 68,517 participants (mean age 69.9 years, range 47–107 years, 14.7% men) (Abrahamsen 2010). The study found that calcium and vitamin D given together significantly reduced hip fractures and total fractures, and probably vertebral fractures, irrespective of age, sex or previous fractures. The protective effect is modest for combined therapy, whereas no significant effects were seen for vitamin D alone in doses of 10–20 microg/day for preventing fractures. Recently, a question has arisen as to whether calcium supplementation may in fact increase hip fracture risk; however, the issue has not been resolved and deserves further investigation.

Based on these findings, calcium could be considered a low potency anti-resorptive agent which should be taken in sufficient doses together with adequate vitamin D to produce any benefits.

The position statement from Osteoporosis Australia, the Endocrine Society of Australia and the Australian and New Zealand Bone and Mineral Society states that the balance of evidence remains in favour of combined calcium and vitamin D supplementation in elderly men and women for the prevention of fractures and calcium is regarded as an integral component of anti-resorptive regimens (Sanders et al 2009).

### Children and adolescents

Most, but not all, RCTs involving children and adolescents using either dairy-supplemented foods or calcium supplementation have demonstrated some benefit at one or more of the BMD sites measured (Sanders et al 2009). However, a meta-analysis of 19 RCTs showed that there was no effect on BMD in children at the femoral neck or lumbar spine, and only a small benefit on total body BMD and upper limb BMD that was unlikely to substantially reduce adult fracture risk (Winzenberg et al 2006). The upper limb was the only site where a sustained BMD benefit was demonstrated after cessation of calcium supplementation. More studies are required in children with low calcium intakes and in peripubertal children.

The benefits of long-term supplementation may be greatest in children with pre-existing deficiency according to a meta-analysis of 21 RCTs (Huncharek et al 2008b). This study found no effect for calcium supplementation in individuals with (near) adequate calcium intake at baseline but found a significantly increased BMC (35–49 g) in individuals with a preexisting deficiency taking long-term treatment.

The same year, Lambert et al (2008) undertook an 18-month study of calcium-deficient adolescent girls (average age 12 years), increasing their mean daily intake by 555 mg in the treatment group which yielded a significantly increased BMC and BMD and reduced bone turnover markers in the treatment group compared with a placebo (Lambert et al 2008).

A more recent meta-analysis investigating whether weight-bearing exercises done by prepubertal children improves BMC found that the effect was strongest when done alongside a high calcium intake and only weak otherwise (Behringer et al 2014). Numerous studies, including one by Stear et al in 2003 of 144 pubertal girls, have confirmed a synergistic relationship between mechanical load through physical activity, calcium status and bone calcium accumulation; however, it is important to note that physical activity has a positive effect on BMD only at high calcium intakes, with no effect at calcium intakes of less than 1000 mg/day (Harkness & Bonny 2005).

The results of one long-term study has suggested that skeletal stature may be a determinant in whether long-term benefits are more likely with supplementation during puberty. The placebo-controlled study ( $n = 354$  pubertal girls) used calcium supplements (670 mg/day) over a 7-year period and reported significant increases in BMD during growth spurts in the supplemented group; however, these gains did not uniformly persist into late adolescence and only girls of tall stature received long-lasting benefits. Interestingly, the placebo group exhibited a 'catch-up' in bone mineral accretion subsequent to the pubertal growth spurt (Matkovic et al 2005).

A second study introduces other issues regarding the impact of variable calcium status in adolescents. This RCT of 144 prepubertal girls used 850 mg/day of calcium over 1 year. After follow-up some 7 years later, in addition to positive effects on BMD outcomes, an inverse relationship became apparent between calcium supplementation and age of menarche. The authors speculate that higher calcium intake prior to menarche may favourably impact on long-term BMD through this dual mechanism (Chevalley et al 2005).

### Postmenopausal women

Bone mass remains relatively stable during early adulthood but changes dramatically after menopause. For about the first 5 years after menopause, women lose bone at the rate of about 2%–3% per year and then continue to lose about 1% of bone mass per year to the end of life. During this time, there is a decline in intestinal calcium absorption and an increase in urinary calcium excretion (Sanders et al 2009).

Numerous studies have confirmed a role for calcium in bolstering BMD in late postmenopausal women where results are more consistent than for perimenopausal women (Sanders et al 2009). Clinical studies have assessed its efficacy as a sole agent against placebo, in comparison with steroid hormones, antiresorptive drugs and as part of combination therapy. While increased calcium intake provides some benefits it should be accompanied by sufficient vitamin D status for optimal results. In addition, a protein rich-diet together with weight-bearing exercise are considered the key pillars for osteoporosis prevention among postmenopausal

women (Bischoff-Ferrari 2012). Adequate levels of trace minerals such as zinc, copper and manganese are also recommended (Strause et al 1994).

The efficacy of supplementation with calcium is not only dependent on vitamin D status but also baseline calcium levels as women with poor dietary intakes tend to achieve significant improvements over placebo, with more modest or no effect evident in groups with higher intakes at baseline (Daniele et al 2004, Fardellone et al 1998).

In a recent RCT trial of 159 postmenopausal women, calcium 1200 mg daily was shown to reduce the parathyroid hormone and bone turnover markers (cross-linked C-telopeptide and procollagen type 1 N-terminal propeptide) after 6 months (Aloia et al 2013). This provides some rationale for the long-term use of calcium supplements for osteoporosis prevention.

### Men

While bone mineral density remains stable throughout adulthood, men start to lose bone density about the age of 50 years, although at a slower rate than women. By the age of 60 years, the rate of bone loss is similar for men and women as calcium absorption decreases over time (Sanders et al 2009).

The overwhelming majority of calcium studies for bone health have been conducted in postmenopausal women and often their results have simply been extrapolated to produce clinical protocols for men regarding osteoporosis prevention and management. The few studies conducted in male populations have produced inconsistent results, possibly due to differences in dosage and also vitamin D status of participants. For example, one study showed no benefit at 600 mg/day, while yielding BMD improvements secondary to higher doses (1200 mg/day) comparable with postmenopausal women (Reid et al 2008).

### The elderly

A number of large studies have investigated the preventive effect of calcium alone or in combination with vitamin D in the elderly. Studies by Chapuy et al (1992, 1994, 2002), Dawson-Hughes et al (1997) and Larsen et al (2004) demonstrate a significant reduction in fracture risk ( $\leq 16\%$ ), while a meta-analysis of 29 RCTs conducted in 63,897 individuals 50 years of age or older over an average of 3.5 years also concluded that calcium alone ( $\geq 1200$  mg/day) or in combination with vitamin D ( $\geq 800$  IU/day) reduced the risk of fracture by 12–24% and reduced bone loss by 0.54% at the hip and 1.19% at the spine (Tang et al 2007).

More recently, a meta-analysis of over 68,000 participants (mean age 69.9 years) concluded that calcium combined with vitamin D significantly but modestly reduced hip fractures and total fractures, and probably vertebral fractures, irrespective of age, sex or previous fractures (2010).

In general, the greatest improvements are noted specifically in the elderly, institutionalised, underweight and calcium deficient.

### Glucocorticoid (GC)-induced osteoporosis

Glucocorticoid-induced osteoporosis is the leading cause of osteoporosis in young adults and the most common cause of secondary osteoporosis. GCs induce rapid bone loss and increase the risk of fracture; however, the fracture risk is higher than expected based on bone mineral density values suggesting excess bone fragility is multifactorial (Soen 2013). GCs have a negative impact on bone through direct effects on bone cells and indirect effects on calcium absorption (Warriner & Saag 2013).

The use of GCs is widespread in medicine as they are used in almost all medical specialties. They are also used long-term by various patient groups such as those with severe asthma or rheumatological disease. In regards to rheumatological disease, morbidity secondary to the use of GCs represents an important aspect of the management as the incidences of vertebral and non-vertebral fractures are elevated, ranging from 30% to 50% of the individuals on GC for over 3 months (Pereira et al 2012). The risk of fracture is also elevated among asthmatics receiving inhaled and/or systemic glucocorticoids, with one report indicating approximately one in six people with asthma developed fractures over 5 years. The interaction with calcium plays a small role in this process, with GCs directly inhibiting vitamin D-mediated intestinal absorption of calcium. High vitamin D doses (50,000 IU twice weekly) in combination with 1.5 g calcium daily can overcome this interference (Wilson et al 1991), whereas treatment with calcium alone or in combination with etidronate may not be effective (Campbell et al 2004).

### Supplementation during pregnancy and lactation

The NHMRC nutrient reference value recommendations for calcium intakes for pregnant women (ages 14–18 years) are 1300 mg/day and 1000 mg/day for older women (19–50 years). If the woman avoids dairy in her usual diet (e.g. lactose intolerant) and does not consume alternative high calcium food (e.g. calcium enriched soya milk), calcium supplementation is recommended at 1000 mg/day. Sufficient calcium intake is important as deficiency is associated with preeclampsia and intrauterine growth restriction. Supplementation may reduce both the risk of low birth weight and the severity of preeclampsia (Hovdenak & Haram 2012).

Evidence from 1997 found that approximately 40% of primiparous Australian women failed to meet the RDI for calcium. Considered a critical nutrient during pregnancy with at least a two-fold increase in requirements observed, its metabolism during gestation significantly changes from as early as 12 weeks, with doubling of both absorption and

excretion, followed by additional losses through lactation, which can account for reductions in maternal bone mineral content of 3–10% (Prentice 2003).

### Prevention of hypertension and preeclampsia

Gestational hypertensive disorders are the second leading cause of maternal deaths worldwide. Both epidemiological and clinical studies have shown that an inverse relationship exists between calcium intake and development of hypertension in pregnancy (Imdad & Bhutta 2012).

A 2012 systematic review analysing results from 15 RCTs confirmed that calcium supplementation during pregnancy is associated with a significant reduction in risk of gestational hypertensive disorders and pre-term birth and an increase in birth-weight (85 gm) without any associated increased risk of kidney stones. Pooled analysis showed that calcium supplementation during pregnancy reduced risk of preeclampsia by 52% and that of severe preeclampsia by 25%. There was no effect on incidence of eclampsia. Importantly, there was a significant reduction for risk of maternal mortality/severe morbidity by 20% and a 24% reduction in risk of pre-term birth with calcium supplementation during pregnancy (Imdad & Bhutta 2012).

Trials that included a 1996 meta-analysis of studies involving calcium and hypertension in pregnancy have shown a substantial mean reduction in both systolic blood pressure (SBP) and diastolic blood pressure (DBP), which was also confirmed by more recent reviews (Atallah et al 2002, Bucher et al 1996).

Further reviews of studies involving over 15,000 women, however, have supported calcium's preventive role with researchers demonstrating significant risk reduction in both low-risk (RR 0.48) and high-risk women (RR 0.22), hence concluding calcium supplementation should be recommended for those women with a low calcium intake who are at risk of developing gestational hypertension (Crowther et al 1999, Hofmeyr et al 2003, 2006, 2007).

There is currently no unanimous explanation for calcium's protective effect (Villar et al 2003). While the antagonistic relationship between calcium and lead has been previously hypothesised to be involved (Sowers et al 2002), recent evidence of calcium's lack of effect on platelet count, plasma urate and proteinuria, in spite of reducing preeclamptic incidence, implies that high-dose calcium effectively lowers blood pressure without influencing the condition's underlying pathology (Hofmeyr et al 2008).

A small number of studies have investigated the effects of calcium in combination with other nutrients, including antioxidant and omega-3 oils in this population. One randomised, placebo-controlled, double-blind study involving a sample of 48 primigravidas, using a combination of 600 mg/day calcium and 450 mg/day of conjugated linoleic acid (CLA) from weeks 18–22 until delivery, resulted in a significantly reduced incidence of

pregnancy-induced hypertension (8% vs 42% of the control group) (Herrera et al 2005). Further studies are warranted to elicit the individual impact of both nutrients and to determine the superiority of sole or combination treatment.

### Leg cramps

Calcium supplements are commonly prescribed in pregnancy when leg cramps are a problem. A Cochrane review of five trials involving 352 women taking various supplements for the treatment of leg cramps in pregnancy included only one placebo-controlled trial of calcium. From this, researchers concluded that any improvement in cramps in those groups treated solely with calcium was likely to be due to a placebo effect, with significant findings limited to the groups taking other nutrients (Young & Jewell 2013).

### Lead toxicity

Increased blood lead levels may occur during pregnancy and lactation as a result of bone resorption to accommodate the calcium needs of the developing fetus or nursing infant. Lead exposure is considered a potential risk to fetal and infant health and may affect fetal neurodevelopment and growth. Ninety-five per cent of lead is stored in the bone and, if mobilised, can be transferred to the fetus and infant via cord blood and breast milk (Ettinger et al 2007). Several studies suggest a low placental barrier to lead, with 79% of the mobilised lead from maternal bone passed to the infant (Dorea & Donangelo 2005). While a number of studies have indicated lead levels in the breast milk of Australian women appear to be well within a safe range, recent data from a study conducted by Ettinger et al (2004) revealed that even low lead content in human milk appears to be highly influential on the lead levels of infants in their first month of life. A separate review published in 2005 discussed additional related trends, such as increased lead concentrations in cord blood during winter months, because of lower vitamin D status (Dorea 2004).

Dietary calcium supplementation of 1200 mg/day commencing in the first trimester was associated with modest reductions in blood lead during pregnancy and may reduce risk of fetal exposure, according to the findings of a RCT of 670 pregnant women (Ettinger et al 2009).

A RCT of 617 lactating women supplemented with high-dose calcium carbonate found that the women in the calcium group showed significant reductions in blood lead levels. Those subjects who showed improved compliance and also had baseline higher bone lead content produced an overall reduction of 16.4% (Hernandez-Avila et al 2003). Similar positive findings came from a study in Mexico of 367 lactating women; however, the maximal reduction in lead concentrations reached only 10% (Ettinger et al 2006). When considered together, these results suggest that calcium supplementation may represent an important

interventional strategy, albeit with a modest effect, for reducing infant lead exposure.

### Neonatal benefits

Calcium supplementation during pregnancy has been postulated to have prolonged benefits in the offspring, as indicated in a study of nearly 600 children aged 5–9 years whose mothers had previously participated in a calcium trial during their pregnancy. The children demonstrated reduced SBP, compared with the children whose mothers had taken placebo, with significance reached particularly for those in the upper BMI bracket (Belizan et al 1997). More recent reviews, while still demonstrating some association between gestational calcium supplementation and reduced blood pressure and incidence of hypertension in the offspring (particularly older children e.g. 7 years), highlight the weakness of the evidence to date, including small sample sizes, methodological issues and the fact that most of the studies have been conducted in developed countries where calcium intake is more likely to be adequate (Bergel & Barros 2007, Hiller et al 2007).

### Dyspepsia

A first-line over-the-counter (OTC) treatment for heartburn, indigestion and dyspepsia has often been an antacid, based on calcium carbonate in combination with magnesium and aluminium salts. Calcium, alone or in combination with the other ingredients, neutralises stomach acid allowing for immediate short-term symptomatic relief (Kopic & Giebel 2013, Sulz et al 2007). There have been case-reports of milk-alkali syndrome associated with excessive prolonged use of calcium carbonate products, especially for dyspepsia, however the incidence appears rare (Kopic & Giebel 2013, Bailey et al 2008, Picolos et al 2004, Nabhan et al 2004, Beall & Scofield 1995). Long-term use of calcium carbonate as an antacid has largely been superseded by use of H<sub>2</sub>-antagonists or proton pump inhibitors, thus the milk-alkali risk is possibly also of less clinical relevance than it was several years ago.

### Prevention of cancer

Interest in a relationship between dairy consumption and cancer incidence continues to grow, with evidence of both protective and contributory effects dependent upon both cancer type and timing of exposure. The consumption of dairy products, however, represents a mix of numerous variables and biological pathways that potentially convey these underlying actions, from which calcium's role is difficult to extricate (van der Pols et al 2007). An interventional study of calcium (1400–1500 mg/day), alone or with vitamin D<sub>3</sub> (1100 IU/day) compared to placebo over 4 years, offers more specific information regarding calcium's role in cancer (Lappe et al 2007). The study, conducted in 1179 women of more than 55 years, was primarily designed to assess effects on fracture incidence; however, upon further analysis also demonstrated

significant risk reduction (RR 0.40) for all cancer incidence among the calcium and vitamin D group. When the analysis was restricted to only those cancers diagnosed after the first year of treatment, the RR became 0.23. While the group receiving calcium alone also demonstrated a reduced risk, the researchers speculate that this may not be robust and conclude that vitamin D is the key variable in reduced incidence of all cancer.

### Prevention of colorectal cancer and recurrence of adenomatous polyps

Currently, the gold standard for measuring risk reduction by an intervention in colorectal cancer investigates the incidence of recurrence of adenomatous polyps following removal of all colonic polyps by polypectomy; further analyses evaluate reduction of total adenomatous polyps and reduction of advanced polyps as defined by size and the presence of severe dysplasia.

Low calcium intake has been associated with a higher risk of colorectal cancer (Kim et al 2013). A meta-analysis of 10 cohort studies showed a reduction in risk of colorectal cancer in those with a higher calcium intake (Cho et al 2004). Reasonably consistent evidence suggests that calcium supplementation of 1200 mg/day reduces total adenomas by approximately 20% and advanced adenomas by about 45% (Holt 2008). Calcium supplementation may also significantly prevent risk of recurrence of adenomas 3–4 years after initial removal, according to findings of a meta-analysis of three trials ( $n = 1485$ ) (Shaikat et al 2005). Further to this, a 2008 Cochrane review examining the effect of supplementary calcium on the incidence of colorectal cancer and the incidence or recurrence of adenomatous polyps included two double-blind, placebo-controlled trials with a pooled population of 1346 subjects. Doses of supplementary elemental calcium used were 1200–2000 mg/day for 3–4 years. Reviewers concluded that, while the evidence to date appears promising and suggests a moderate degree of prevention against colorectal adenomatous polyps, more research with similar findings is required before this can be translated into any preventive protocol (Weingarten et al 2008).

Interestingly, some studies show that calcium's protective effect against recurrent adenomas is largely restricted to individuals with baseline serum 25-hydroxy vitamin D above the median ( $\approx 29$  ng/mL). These data, together with other research findings, strongly point to the importance of both calcium and vitamin D for reducing colorectal cancer risk and altering adenoma recurrence (Mizoue et al 2008, Grau et al 2003, Holt 2008, Oh et al 2007).

Interactions between calcium and other variables in colorectal carcinogenesis have also been explored, revealing gender-specific results; protective in males but not in females in most (Ishihara et al 2008, Jacobs et al 2007, Ryan-Harshman & Aldoori 2007), but not all, studies. Further research, including

re-analysis of the Women's Health Initiative (WHI) findings pertaining to colorectal cancer incidence, has elucidated oestrogen's critical modifying effect upon calcium, whereby the higher oestrogen levels of both menstruating and postmenopausal women taking HRT negate calcium's otherwise protective effect (Ding et al 2008). Explanations for this phenomenon include oestrogen's influence upon calcium distribution: removing it from circulation for bone deposition and competition for binding evident between vitamin D and oestrogen (Ding et al 2008, Oh et al 2007).

Early hypotheses regarding calcium's general protective effects focused on its ability to bind bowel-irritating substances secreted into bile. This notion is further supported by a number of studies demonstrating enhanced chemoprotection when high doses of calcium have been combined with dietary factors such as reduced fat and increased carbohydrate, fibre and fluid intakes (Hyman et al 1998, Rozen et al 2001, Schatzkin & Peters 2004).

One significant development in our understanding has been the discovery of human parathyroid calcium-sensing receptors in the human colon epithelium, which function to regulate epithelial proliferation and differentiation. New *in vitro* studies suggest that expression of these receptors may be induced by the presence of extracellular calcium and vitamin D, therefore promoting greater differentiation of the epithelial cells (Chakrabarty et al 2005, Holt 2008) and inducing apoptosis (Miller et al 2005). The effect of the calcium-sensing receptor (CASR) gene on development of colorectal cancer has also been investigated, with *in vitro* studies suggesting that CASR may mediate the pro-cell proliferative effects of low intestinal calcium concentration. Results from a recent case-controlled study involving 1235 participants showed that low calcium intake was associated with an increase in colorectal cancer risk; however, this did not appear to relate directly to CASR polymorphism (Kim et al 2013).

Clear parameters for dosing are not yet available, with some studies showing no further benefit above 700–800 mg/day of total calcium, while other studies suggest an ongoing inverse dose-dependent relationship without cutoff (Schatzkin & Peters 2004). Current evidence for a combined protective role of calcium, either dietary or supplemental, and vitamin D, particularly in men and postmenopausal women not taking HRT, is strong and further elucidation of the independent and combined effects of these nutrients will assist in the development of preventive protocols.

### Other cancers

Ongoing research regarding calcium's potential role in a range of other cancers suggests a possible protective effect against breast and ovarian cancers (Genkinger et al 2006, McCullough et al 2005, 2008); however, the research remains preliminary and largely of epidemiological design. A greater

body of evidence has developed regarding the interplay between calcium and prostate cancer, with initial findings touting a positive association between dairy product consumption, total dietary calcium intake (especially >1500 mg/day) and risk. The results of ongoing extensive, prospective epidemiological research involving hundreds of thousands of men, however, have been conflicting, both confirming (Ahn et al 2008, Gao et al 2005) and negating (Huncharek et al 2008a, Park et al 2007a, 2007b) earlier evidence. Two important details have recently emerged regarding the potential interaction between calcium and prostate cancer risk with several studies consistently demonstrating that calcium derived from supplements does not convey a greater risk (Ahn et al 2008, Baron et al 2005, Park et al 2007a) and limiting calcium as a risk factor only when consumed as dairy products, while greater non-dairy calcium intake appears to lower the risk (Allen et al 2008, Park et al 2007b). A prospective study of serum calcium adds to the riddle, revealing that results in the highest tertile typically more than 9 years prior to diagnosis were strongly associated with increased risk of fatal prostate cancer (Skinner & Schwartz 2008); however, such results may be indicative of calcium dysregulation rather than high intakes.

### Hypertension

Ongoing broad-scale international epidemiological data, including prospective studies, link low dietary calcium intake with a slightly increased risk of hypertension (Alonso et al 2005, Elliott et al 2008, Geleijnse et al 2005, Wang et al 2008), in particular raised systolic blood pressure. Conversely, increased dietary calcium, typically in the form of low-fat dairy products, has been shown to be independently protective (RR 0.87 for highest quintile of calcium intake) (Alonso et al 2005, Wang et al 2008). One study identified that high dietary calcium was associated with SBP/DBP reductions of  $-2.42/-1.48$  mmHg, after controlling for other known risk factors (Elliott et al 2008). This effect was more pronounced when accompanied by increased magnesium and phosphorus consumption. Interestingly, neither high-fat dairy products nor calcium supplements convey protection (Wang et al 2008).

Additional findings attracting attention include epidemiological links between markers of low calcium status or calcium metabolism abnormalities, hypertension and insulin resistance. Supporting the possible link between these phenomena are the results of a Japanese study of 34 non-diabetic hypertensive and 34 non-diabetic normotensive women. Multiple group assessments revealed statistically significant increased urinary calcium, lower BMD, depressed serum calcium and elevated circulating PTH in the hypertensive sample (Gotoh et al 2005).

Underlying mechanisms for calcium's protective effect are speculated to involve reduced calcium influx into cells, inhibiting vascular smooth muscle cell constriction, reduced activity of the

renin-angiotensin system and improved Na/K balance (Wang et al 2008).

A 2006 Cochrane review of 13 RCTs involving 485 volunteers found that calcium supplementation significantly reduced SBP (mean difference:  $-2.5$  mmHg), but not DBP (mean difference:  $-0.8$  mmHg) compared with controls (Dickinson et al 2006). The authors temper their conclusion, stating that the quality of included trials was poor and the heterogeneity between trials means there is a tendency to overestimate treatment effects. Earlier, an extensive systematic review, updated in 1999 to include 42 randomised comparative trials, showed modest reductions in both SBP and DBP ( $-2$  mmHg and  $-1$  mmHg, respectively) with 1–2 g/day calcium over a 4–14-week intervention (Griffith et al 1999). Dietary calcium appeared to have a larger effect than supplementation, a finding reiterated in more recent studies (Wang et al 2008). The clinical significance of these small effects has been questioned and the recommendation of calcium as a therapy for all types of hypertension appears premature (Kawano et al 1998), particularly in light of more recent negative findings from the WHI, which investigated the effects of 1 g of calcium together with 400 IU of vitamin D over a median follow-up period of 7 years in postmenopausal women (Margolis et al 2008). Some studies have proposed that it is only a particular hypertensive subset that is calcium responsive. A number of researchers, for example, have hypothesised a physiological correlation between ‘salt sensitive’ hypertension and responsiveness to calcium treatment (Coruzzi & Mossini 1997, Resnick 1999). The link may be that sodium excess encourages calcium losses. This theory is further supported by an epidemiological study demonstrating that, while blood pressure was inversely correlated with dietary calcium, further analysis revealed sodium intake to be the primary influence, increasing pressures while concomitantly reducing BMD (Woo et al 2008).

### Premenstrual syndrome

Of all the vitamins and minerals used in the treatment of premenstrual syndrome (PMS), calcium supplements show overwhelmingly positive results.

One of the earliest trials to show that calcium supplementation can alleviate symptoms in PMS was conducted in 1989 (Thys-Jacobs et al 1989). A randomised, double-blind, crossover trial involving 33 women with confirmed PMS compared the effects of daily 1000 mg calcium carbonate with placebo over 6 months. Results showed that 73% of women reported improved symptoms while taking calcium supplementation, whereas 15% preferred placebo. The premenstrual symptoms responding significantly to calcium supplementation were mood changes, water retention and premenstrual pain. Menstrual pain was also significantly alleviated.

In 1993, the *American Journal of Obstetrics and Gynecology* published a study that compared the effects of calcium (587 mg or 1336 mg) and manganese

(1.0 mg or 5.6 mg) on menstrual symptoms. Ten women with normal menstrual cycles were observed over four 39-day periods during the trial (Penland & Johnson 1993). The researchers found that increasing calcium intake reduced mood, concentration and behavioural symptoms generally and reduced water retention during the premenstrual phase. Additionally, menstrual pain was reduced.

A more recent large, double-blind, placebo-controlled, randomised parallel-group study was conducted in the United States and supports the previous findings (Thys-Jacobs et al 1998). Four hundred and sixty-six premenopausal women with confirmed moderate to severe PMS were randomly assigned to receive either 1200 mg elemental calcium (from calcium carbonate) or placebo for three menstrual cycles. Symptoms were documented daily by the subjects based on 17 core symptoms and four symptom factors (negative affect, water retention, food cravings and pain). Additionally, adverse effects and compliance were monitored daily. During the luteal phases of both the second and the third treatment cycles, a significantly lower mean symptom score was observed in the calcium group. By the third treatment cycle, calcium treatment resulted in a 48% reduction in total symptom score compared with baseline, whereas placebo achieved a 30% reduction. Furthermore, all four symptom factors responded in the calcium-treated group.

A 1999 review of multiple trials investigating calcium supplementation as an effective therapy for PMS has found overwhelming positive results (Ward & Holimon 1999).

The only RCT to be conducted in recent years was published in 2009 and once again produced positive results. The double-blind RCT compared 500 mg of calcium carbonate twice daily to placebo taken for 3 months by young female college students (mean age  $21.4 \pm 3.6$  years) with diagnosed PMS. Active treatment resulted in significant improvements to early tiredness, appetite changes and depressive symptoms compared to placebo (Ghanbari et al 2009).

Some researchers in this area have hypothesised that part of the PMS aetiology lies in calcium dysregulation in the luteal phase and have highlighted the dramatic similarities between symptoms of PMS and hypocalcaemia (Thys-Jacobs 2000). Recent data from the Nurses’ Health Study II support this theory, with evidence of low calcium and vitamin D levels in PMS populations when compared to controls (Bertone-Johnson et al 2005).

### Weight loss

Evidence suggests that higher calcium intake may be associated with a lower body weight. This has been seen in several epidemiological studies and also some, but not all, studies using calcium supplementation (Onakpoya et al 2011, Tremblay & Gilbert 2011, Christensen et al 2009, Barba & Russo 2006, Garcia-Lorad et al 2007, Bueno et al 2008, Zhu et al 2013).

A relationship between low calcium intake and obesity was observed in an epidemiological study involving 1459 adults in Brazil, where the prevalence of participants that were overweight was higher in those with a low calcium intake, especially when less than 398.5 mg/day (Bueno et al 2008). Similarly, a negative relationship between calcium intake and BMI was reported in a study of 647 Spanish men and women (Garcia-Lorad et al 2007).

A meta-analysis of seven RCTs reported that calcium supplementation in overweight and obese individuals results in a small, but significant reduction in body weight (0.74 kg) and body fat (0.93 kg) compared to placebo. This review excluded studies that had been conducted for less than 6 months or that included subjects that were of a normal weight (Onakpoya et al 2011).

A prolific researcher in this area is Zemel (2004, Zemel et al 2004, 2005a, 2005b), having published three small trials investigating the effects of dietary and supplemental calcium in patients for weight maintenance or weight loss. These trials have consistently yielded positive results, demonstrating that in addition to enhanced weight loss on isocaloric and identical macronutrient profiles, with or without energy restriction, a diet providing high calcium levels of 1100–1200 mg/day results in central fat loss and corresponding improvements in blood pressure, insulin sensitivity and retention of lean tissue. Australian researchers Bowen and colleagues have also demonstrated similar results (Bowen et al 2004). Zemel et al conclude that dietary calcium and, in particular, dairy-based foods are the most effective form of calcium for weight loss and that results are significant within 12 weeks. An early review by Teegarden (2003), bringing together trials dating back 10 years to the first rat studies and updated in 2005, while acknowledging the promising data in relation to increased consumption of dairy products and weight management which had emerged over the intervening 2 years, noted the limitations of the current body of evidence that required addressing to elucidate the full extent of calcium's effect on weight. A more recent meta-analysis of 13 RCTs investigating calcium interventions ranging between 610 mg and 2400 mg/day over a period of 12 weeks–36 months failed to demonstrate a positive effect on weight loss for either calcium supplements or dairy products; however, once again methodological concerns were raised (Trowman et al 2006). In particular, this meta-analysis included RCTs designed to investigate the effects of calcium on bone health and only one of the included RCTs was specifically designed and powered to see if calcium supplementation altered fat loss. As Astrup (2008) notes in an editorial piece, this point is highly relevant, because a body fat loss of  $\approx 1$  kg/year may be extremely important in the prevention of weight gain and obesity, but large study groups are required in a randomised trial to obtain the statistical power necessary to detect such an effect (Astrup 2008).

In spite of this, studies have continued to emerge yielding positive findings in postmenopausal women as part of the WHI study (calcium and vitamin D treatment reducing risk of weight gain by 11%) (Caan et al 2007) and in overweight and obese type 2 diabetic patients (>8% more weight loss in those consuming calcium in the highest compared with the lowest tertile) (Shahar et al 2007). Additionally, one small study demonstrated an augmenting effect of calcium (1200 mg together with 400 IU vitamin D/day) over 15 weeks on weight loss-induced beneficial changes to blood lipids and lipoproteins (Major et al 2007). Most recently, an RCT involving 53 subjects showed that calcium (600 mg elemental/day) plus vitamin D<sub>3</sub> (125 IU/day) supplementation for 12 weeks promoted loss of body fat and visceral fat (Zhu et al 2013).

Although the underlying mechanism of action remains unclear, there is general acceptance that high calcium intake, particularly in the form of dairy products, and more recently calcium-fortified soy (Lukaszuk et al 2007), depresses PTH levels and 1,25(OH)<sub>2</sub>D, which in turn decreases intracellular calcium, thereby potentially inhibiting lipogenesis and stimulating lipolysis (Major et al 2007, McCarty & Thomas 2003, Schrager 2005, Zemel et al 2004). Additional proposed actions include promoting faecal fat loss and fat oxidation (Christensen et al 2009, Gonzalez et al 2012, Tremblay & Gilbert 2011), as well as by decreasing energy intake and facilitating appetite control (Tremblay & Gilbert 2011) and promoting satiety (Kabrnova-Hlavata et al 2008).

Christensen et al (2009) performed a meta-analysis of 15 RCTs that assessed the effect of calcium on faecal fat loss. The authors concluded that an increase in dietary calcium by about 1240 mg/day has the potential to increase faecal fat excretion by about 5.2 g/day, which is enough to be relevant for prevention of weight gain, or re-gain (Christensen et al 2009). Another meta-analysis investigating mechanisms by which calcium intake may affect weight reported that a high calcium intake appears to increase rate of fat oxidation, however the magnitude of effect appears relatively weak (Gonzalez et al 2012).

### Nephrolithiasis

In spite of previous concerns regarding a causal relationship between dietary or supplemental calcium intake and the recurrence of oxalate stones, recent studies demonstrate that this fear appears unfounded. Collectively, the evidence points more towards a protective effect for increased dietary calcium, in relation to both urinary oxalate concentrations (Taylor & Curhan 2004) and reduced stone formation (Goldfarb 2009). The current view is that, rather than being a contributing factor for oxalate stones, dietary calcium, through its binding of oxalate in the gut, can minimise recurrence, as substantiated by other studies (Curhan et al 1997, Liebman & Chai 1997).

One study comprised 120 men with recurrent calcium oxalate stones due to idiopathic hypercalcaemia and who were randomly assigned to either a low-calcium diet or low-animal protein, low-salt normal-calcium diet and assessed for changes in frequency of stone formation. Results clearly showed reduced oxalate excretion in those on a normal calcium intake, as well as a greater decrease in calcium oxalate saturation (Borghi et al 2002). In another study of 14 healthy men, assessment of the influence of dietary calcium on the given amount of oxalate demonstrated that with the inclusion of additional calcium (1121 mg) urinary oxalate levels increased in the control but not in the treatment group (Hess et al 1998).

## OTHER USES

### Hyperlipidaemia

Only a very few studies investigating calcium intake and serum lipids in postmenopausal women have been described and these showed significant increases in high-density lipoprotein and high-density lipoprotein to low-density lipoprotein ratio (Challoumas et al 2013).

For example, a randomised, placebo-controlled crossover trial of 56 patients with mild-moderate hypercholesterolaemia on a controlled low-cholesterol diet, calcium carbonate supplementation was shown to significantly reduce LDL levels by 4.4%, with additional 4.1% increases in HDL levels. No other effects on other blood lipids or blood pressure were observed (Bell et al 1992). Another small study demonstrated an augmenting effect of calcium (1200 mg together with 400 IU vitamin D/day) over 15 weeks on weight loss-induced beneficial changes to blood lipids and lipoproteins, with significantly greater reductions in total HDL, LDL:HDL and LDL levels (Major et al 2007).

### Dry eye

A controlled double-masked study of petrolatum ointment containing 10% w/w calcium carbonate applied on the lower lid twice daily for 3 months resulted in significant improvements in all criteria assessed. However, significance over placebo was only found in ocular surface staining, therefore determination of the action of petrolatum needs to be established and controlled in future studies to identify the therapeutic value of calcium (Tsubota et al 1999).

### Fluorosis

Calcium has been shown to reduce the clinical manifestations of fluorosis in children exposed to contaminated water (Gupta et al 1996).

## DOSAGE RANGE

### Australian RDIs

- Infants
  - 1–3 years: 500 mg/day.
  - 4–8 years: 700 mg/day.

- Children
  - 9–11 years: 1000 mg/day.
  - 12–18 years: 1300 mg/day.
- Adults
  - <70 years: 1000 mg/day.
  - >70 years: 1300 mg/day.
- Pregnancy: 1000–1300 mg/day.
- Lactation: 1000–1300 mg/day.

## According to clinical studies

- Osteoporosis prophylaxis: 1500 mg/day in combination with vitamin D and accessory nutrients (e.g. zinc, manganese, copper and fluoride) and/or antiresorptive agents
- Premenstrual syndrome: 1200–1600 mg/day; however, 500 mg calcium carbonate twice daily for 3 months is also effective
- Prevention of preeclampsia: 2000 mg/day.
- Increased BMD in children with low intake: 100 mg/day.
- Supplementation during pregnancy to increase mineral accretion in fetus: 2000 mg/day for last trimester.
- Allergic rhinitis: 100 mg/day.
- Hyperacidity: 500–1500 mg/day as required.
- Hyperlipidaemia: 400 mg three times daily.
- Hypertension: 1000–2000 mg/day.
- Dry eye: 10% w/w calcium carbonate in petrolatum base applied twice daily.
- Fluorosis in children: 250 mg/day.
- Prevention of colorectal cancer: 1200 mg/day.
- Weight loss: 1000–1200 mg/day long term.

## ADVERSE REACTIONS

Oral administration of calcium supplements may cause gastrointestinal discomfort, nausea, constipation and flatulence.

### Hypercalcaemia

Increased serum calcium may be associated with anorexia, nausea and vomiting, constipation, hypotonia, depression and occasionally lethargy and coma. Prolonged hypercalcaemic states, especially if associated with normal or elevated serum phosphate, can precipitate ectopic calcification of blood vessels, connective tissues around joints, gastric mucosa, cornea and renal tissue (Wilson et al 1991).

## SIGNIFICANT INTERACTIONS

Calcium carbonate when taken as an antacid alters the absorption and excretion of a wide range of drugs. Please refer to a drug interaction guide for specific concerns. Only those interactions encountered with oral administration of calcium supplements will be included in this section.

### Antacids, including H<sub>2</sub> antagonists and proton pump inhibitors

Use of drugs that raise gastric pH may reduce calcium absorption, especially that of calcium carbonate or calcium phosphate as these salts require an acidic environment for solubilisation before

**Clinical note — Is calcium supplementation a risk for increased vascular events?**

Recently, concern has emerged regarding a potential increase in cardiovascular events associated with long-term high-dose calcium supplementation. This was largely triggered by the results of a New Zealand RCT investigating the effect of calcium supplements (1000 mg/day elemental calcium as calcium citrate) administered to 1471 postmenopausal women, with an average age 74 years, over 5 years. Concomitant vitamin D supplements were not given to participants in this trial (Bolland et al 2008). The primary outcome of this study was bone density; however, the researchers also hypothesised that a secondary effect of the treatment would be a reduction in cardiovascular (CV) events, based on existing observational studies highlighting calcium's positive effect on blood lipids and blood pressure (Nainggolan 2008). However, secondary analysis of the data revealed that the women taking calcium supplements experienced an increase in CV events rather than the expected decrease in CV event. In the calcium-treated group, there was a statistically significant higher rate of verified myocardial infarction (MI) ( $P = 0.05$ ), and a non-significant increase in all vascular events ( $P = 0.08$ ) and stroke ( $P = 0.21$ ), compared to those taking placebo. While the authors concluded that their study does not unequivocally demonstrate causality, it did suggest that high calcium intakes may have an adverse effect on vascular health (Bolland et al 2008).

The same authors subsequently conducted a meta-analysis of 15 RCT of calcium  $\geq 500$  mg vs placebo, concluding that in the absence of vitamin D, calcium supplements were associated with a significant increase in MI ( $P = 0.035$ ) and non-significant increase in composite end point of MI, stroke or sudden death ( $P = 0.057$ ) or death ( $P = 0.18$ ) (Bolland et al 2010). In addition, this research group conducted a re-analysis of data from a sub-group in the Women's Health Initiative Calcium Vitamin D study (WHI CaD) and concluded that calcium, with or without vitamin D, modestly increased risk of CV events, especially for MI (Bolland et al 2011).

While these findings have caused substantial alarm and led to much speculation, the evidence suggesting cardiovascular harm needs to be balanced against the body of opposing evidence that reports that calcium does not significantly increase cardiovascular event risk.

Daily supplementation with calcium carbonate 1000 mg plus vitamin D 400 IU for 7 years showed neither an increase nor a decrease in coronary or cerebrovascular events in a large-scale study (WHI CaD) involving 36,282 postmenopausal women aged 50–79 years (Hsia et al 2007). Another prospective study (EPIC-Heidelberg) that involved almost 24 000 participants with an 11-year follow-up found no significant association between calcium intake and risk of stroke or cardiovascular mortality. Interestingly, a trend towards a decrease in MI risk was observed in those with a moderately high dairy calcium intake (mean = 820 mg/

day), especially in women. By contrast, a statistically significant increase in MI was found in the group taking supplemental calcium in the absence of vitamin D; however, this may not be clinically meaningful as it translated to only 20 cases of MI in the calcium users, out of 24,000 participants (Li et al 2012). Results from the NHANES III study ( $n = 20,024$ ) reported that there was no clear association for CVD death and intake of dietary or supplemental calcium (van Hemelrijk et al 2013). Another large prospective study involving 388,229 men and women aged 50–71 years, with a 12-year follow-up, reported that supplemental calcium intake was not associated with increased CVD or cerebrovascular death in women, although an increase CV risk was observed in men taking supplemental calcium ( $>1000$  mg/day), who were also smokers (Xiao et al 2013).

Further to this, a 5-year study of 1460 older women suggested that supplementation with calcium carbonate (1200 mg/day) may reduce risk of hospitalisation and mortality in patients with pre-existing atherosclerotic CVD (Lewis et al 2011). It has been proposed that high calcium intake may increase risk of vascular calcification, or carotid atherosclerosis, although this effect was not demonstrated in recent studies (Lewis et al 2013, Kim et al 2012). In addition, there is some evidence that calcium may have a beneficial role in terms of cardiovascular disease by modestly reducing blood pressure and improving serum lipid profiles (Guessous et al 2011). In addition, a review of studies involving over 70,000 people concluded that mortality was reduced with vitamin D plus calcium (odds ratio, 0.94; 95% CI, 0.88–0.99), but not with vitamin D alone (odds ratio, 0.98; 95% CI, 0.91–1.06) (Rejnmark et al 2012).

While it is difficult at this stage to either confirm or refute the association between calcium supplementation and cardiovascular disease, there are a few factors for consideration:

- No RCTs have been conducted to specifically examine the effects of calcium supplementation on CVD morbidity and mortality; concerns have been raised due to secondary data analysis
- Current data does not support an association between dietary or supplemental calcium intake and an increased risk of stroke, cerebrovascular disease, cardiovascular disease or cardiovascular death
- Increased dietary intake of calcium has not been associated with an increase in risk of myocardial infarction
- Supplemental calcium may possibly be associated with an increased risk of myocardial infarction, but this appears to be limited to calcium given alone, without vitamin D.
- Known benefits of combined calcium and vitamin D therapy for reducing risk of osteoporotic fractures needs to be balanced against unproven risk of MI when making treatment decisions for an individual patient, and research now indicates that calcium and vitamin D reduce mortality in the elderly.

calcium can be absorbed. Aluminium- and magnesium-containing antacids may increase urinary excretion of calcium.

### **Bisphosphonates**

Bisphosphonates (e.g. alendronate) are indicated for the treatment of osteoporosis; however, they commonly cause hypocalcaemia as an adverse effect, which reduces drug effectiveness in maintaining bone mineral density. Adequate intake of both calcium and vitamin D is essential for those taking bisphosphonates, however the drug must be taken on an empty stomach, at least 30 minutes before calcium supplementation.

### **Caffeine**

Caffeine increases urinary excretion of calcium and may affect calcium absorption — ensure adequate calcium intake and monitor for signs and symptoms of deficiency in those with high caffeine intake.

### **Calcium channel blockers**

Calcium supplements can have an antagonistic effect on the desired action of calcium channel blockers that could precipitate the re-emergence of arrhythmias — avoid high-dose supplements unless under professional supervision.

### **Cardiac glycosides (e.g. digoxin)**

Administered concurrently, high-dose calcium may potentiate digoxin toxicity — use this combination with caution unless under medical supervision.

### **Corticosteroids**

Long-term use of corticosteroids, especially oral formulations, may lead to reduced intestinal calcium absorption, increased calcium excretion and inhibition of osteoblasts, leading to drug-induced osteoporosis — ensure adequate calcium intake and monitor for signs and symptoms of deficiency. Consider supplementation with long-term drug therapy.

### **Excess dietary fat**

This increases urinary excretion of calcium — ensure adequate calcium intake and monitor for signs and symptoms of deficiency.

### **Excess fibre, including guar gum**

May simply delay or decrease absorption of calcium — separate doses by at least 2 hours.

### **Iron**

Concurrent administration of calcium with iron may reduce absorption of both minerals. Separate supplemental or dietary intake of minerals by at least 2 hours.

### **Levothyroxine**

Calcium administered concurrently may reduce drug absorption, while levothyroxine may block absorption of calcium, e.g. calcium carbonate — separate doses by at least 4 hours.

### **Lysine**

Additive effects may occur as lysine enhances intestinal absorption and reduces renal excretion of calcium — potentially beneficial interaction.

### **Magnesium**

Magnesium decreases calcium absorption as they compete for the same absorption pathway, however it is unclear if this mineral interaction is clinically significant — it is advisable to separate doses by at least 2 hours.

### **Oestrogen and progesterone**

Calcium supplementation in combination with these hormones will have an additive effect on minimising bone resorption in postmenopausal women — potential beneficial interaction, so consider increasing intake.

### **Phosphorus**

Excess intake (soft drinks, meat consumption) can increase urinary excretion of calcium — ensure adequate calcium intake and monitor for signs and symptoms of deficiency.

### **Quinolone antibiotics**

Drug bioavailability may be reduced by concurrent administration with calcium supplements, reducing drug efficacy and increasing risk of developing bacterial resistance — quinolones should be taken either 2 hours before or 4–6 hours after calcium.

### **Tetracyclines**

Calcium supplements form complexes with these antibiotics and render 50% or more insoluble, therefore reducing the efficacy of the drug and absorption of calcium — separate doses by at least 2 hours.

### **Thiazide diuretics**

These diuretics decrease urinary excretion of calcium. Monitor serum calcium and look for signs of hypercalcaemia, such as anorexia, polydipsia, polyuria, constipation and muscle hypertonias when using high-dose calcium supplements. Contributing risk factors are the presence of hyperparathyroidism or concurrent use of vitamin D.

### **Zinc**

Concurrent administration of calcium and zinc may reduce absorption of both minerals, however it is unclear if this is clinically significant. Calcium supplementation has been shown in some studies to increase faecal losses of zinc (McKenna et al 1997) — ensure adequate zinc intake and monitor for signs and symptoms of deficiency.

## CONTRAINDICATIONS AND PRECAUTIONS

People with hyperparathyroidism, chronic renal impairment or kidney disease, sarcoidosis or other granulomatous diseases should only take calcium supplements under medical supervision. Calcium supplementation is contraindicated in hypercalcaemia.

## PREGNANCY USE

The safety of calcium supplementation during pregnancy in doses up to 2000 mg elemental calcium per day is well established in clinical trials.

## Practice points/Patient counselling

- Calcium is an essential mineral required for the proper functioning of numerous intracellular and extracellular processes, including muscle contraction, nerve conduction, beating of the heart, hormone release, blood coagulation, energy production and maintenance of immune function.
- Low-calcium states are associated with several serious diseases such as colorectal cancer, osteoporosis types I and II, hypertension, preeclampsia and eclampsia.
- Although supplementation is traditionally used to correct or avoid deficiency states, research has also shown a role in the prevention of osteoporosis, preeclampsia and management of numerous disease states and research now indicates that calcium and vitamin D reduces mortality in the elderly.
- Clinical studies show that calcium supplementation has benefits in symptomatic relief in premenstrual syndrome, reducing the risk of fracture (when combined with vitamin D), reducing the risk of preeclampsia and improving birthweight, weight loss and reducing incidence of some cancers.
- Calcium can interact with numerous drugs and should be used with caution by people with renal disease or hyperparathyroid conditions.

## PATIENTS' FAQs

### What will this supplement do for me?

Calcium is essential for health and wellbeing. Although used to prevent or treat deficiency states, and primarily associated with BMD, it is also beneficial in a wide range of conditions such as prevention of preeclampsia, premenstrual syndrome, reducing the risk of bone fractures (with vitamin D), aiding in weight loss, maintenance of fetal growth, treatment of lead toxicity. It is considered to be a critical nutrient in pregnancy, and may actually reduce mortality in the elderly when taken with vitamin D.

### When will it start to work?

This will depend on the indication it is being used to treat; however, in most instances long-term administration is required (i.e. months to years).

## Are there any safety issues?

In very high doses, calcium supplements can cause some side effects, including constipation, but generally calcium is considered safe and has a wide therapeutic range. High-dose supplements should not be used by people taking some medications. Caution should also be exercised with high doses in individuals with preexisting cardiovascular disease. (See *Significant interactions* above for specific information.)

## Calendula

**HISTORICAL NOTE** Calendula is indigenous to Eastern Europe and the Mediterranean, where its medicinal value has been respected since ancient times. Calendula was popular in Ancient Greece and in earlier Indian and Arabic cultures. It has been a common garden plant since the 12th century and it is mentioned in several older herbals. The name calendula comes from the Latin *calends*, meaning the first day of the month, referring to the plant's near-continual flowering habit.

### COMMON NAME

Marigold

### OTHER NAMES

Pot or garden marigold, gold-bloom, holligold.

Field marigold (*Calendula arvensis*) is also used medicinally for the same indications because it has similar constituents. Take care not to confuse with *Tagetes erecta* (Mexican marigold).

### BOTANICAL NAME/FAMILY

*Calendula officinalis* (family Asteraceae [Compositae or Daisy])

### PLANT PARTS USED

The flowers are primarily used, but the stems, younger leaves, seeds and roots all have medicinal properties.

### CHEMICAL COMPONENTS

The major constituents are triterpene saponins (2–10%) based on oleanolic acid and flavonols,

including astragalin, hyperoside, isoquercitrin and rutin, as well as the carotenoids flavoxanthin and auroxanthin (Bako et al 2002). The triterpene diol esters faradiol laurate, faradiol myristate and faradiol palmitate have been identified as the major active compounds, which are also used as marker compounds for standardisation of calendula extracts (Hamburger et al 2003, Zitterl-Eglseer et al 2001).

Additional constituents include other phenolic compounds, steroids and other terpenoids, tocopherols, quinines, carotenes and resins (Re et al 2009), polysaccharides (WHO 2003), as well as minerals such as calcium, sodium, potassium, magnesium, iron, copper and manganese (Ahmed et al 2003).

### MAIN ACTIONS

#### Antimicrobial and antiparasitic

Hydroalcoholic extracts have been shown to have antibacterial, antiparasitic, antiviral and antifungal activities.

The *in vitro* antibacterial activity of a hydroethanolic extract of calendula flower has been demonstrated against *Campylobacter jejenum* (Cwikla et al 2010) and an isolated oleanolic acid (triterpene) aglycone from calendula demonstrated the ability to affect morphology of Gram-positive bacteria *in vitro* (Szakiel et al 2008).

Glycosidic fractions of oleanolic acid isolated from calendula demonstrated antiparasitic activity against *Heligmosomoides bakeri* (Doligalska et al 2011) and a flower extract has been shown to inhibit the parasite *Trichomonas*. The oxygenated terpenes are thought to be the main active compounds (Gracza & Szasz 1968, Samochowiec et al 1979).

The *in vitro* antifungal activity of calendula flower extracts has been investigated against *Aspergillus niger*, *Rhizopus japonicum*, *Candida albicans*, *C. tropicalis* and *Rhodotorula glutinis*, *C. krusei*, *C. glabrata*, *C. parapsilosis*, *Aspergillus flavus*, *A. fumigatus* and *Exophiala dermatitidis*. Calendula extract showed a high degree of activity against all fungi and the inhibitory effect was comparable to that of standard antifungals (Efstratiou et al 2012, Kasiram et al 2000).

A 70% hydroalcoholic extract demonstrated virucidal activity against influenza virus and suppressed the growth of herpes simplex virus (Bogdanova et al 1970). Calendula flower extract has also been shown to possess anti-HIV and anti-Epstein-Barr virus activity *in vitro* (Kalvatchev et al 1997, Ukiya et al 2006).

### Promotes wound healing

An ointment containing 5% calendula flower extract, as well as an ointment containing two different fractions of calendula extract combined with allantoin, has been shown to stimulate physiological regeneration and epithelialisation in experimentally-induced surgical wounds. The effect is thought to be due to more intensive metabolism of glycoproteins, nucleoproteins and collagen proteins during regeneration of the tissues (Klouchek-Popova et al 1982). A similar finding was reported *in vivo* for skin puncture wound healing, where collagen production was increased by application of a hydroethanolic extract of calendula flowers. The same study demonstrated increased angiogenic activity, suggesting that an increased blood supply may be involved (Parente et al 2012). Both a 5% and a 10% calendula gel showed accelerated healing in 5-fluorouracil-induced oral mucositis *in vivo* (Tanideh et al 2013). Hexane and ethanolic extracts of calendula stimulated both proliferation and migration of fibroblasts in an *in vitro* scratch assay. The triterpene esters faradiol myristate and palmitate contributed partially to this effect (Fronza et al 2009).

### Anti-inflammatory

Anti-inflammatory activity has been demonstrated in several animal models for multiple chemical constituents found in calendula. Pretreatment with an 80% hydroalcoholic extract reduced carrageenan-

induced rat paw oedema at a dose of 100 mg extract/kg. Indomethacin 5 mg/kg was shown to be fourfold more potent in the same experiment (Mascolo et al 1987). Application of a hydroethanolic extract to wounds decreased the presence of fibrin and hyperaemia *in vivo*, thus directly altering the inflammatory process (Parente et al 2012). Both a 70% hydroalcoholic extract and a CO<sub>2</sub> extract have been shown to inhibit experimentally induced inflammation and oedema. The triterpenoids faradiol, amidiol and calenduladiol demonstrate anti-inflammatory activity (Neukirch et al 2005), with the faradiol monoester appearing to be the most relevant compound due to its quantitative prevalence (Della et al 1994). A freeze-dried extract of calendula was found to suppress both the inflammatory effect and leucocyte infiltration in an inflammatory model induced by the simultaneous injection of carrageenan and prostaglandin E<sub>1</sub> (Shipochliev et al 1981).

Ten triterpenoid glycosides (including four new compounds) were isolated from calendula and tested for anti-inflammatory activity. Of these, nine were found to be effective against 12-O-tetradecanoylphorbol-13-acetate-induced inflammation in mice (Ukiya et al 2006).

## OTHER ACTIONS

### Reduces oedema

Oral administration of a triterpene-containing fraction prevented the development of ascites and increased survival time compared with controls in mice inoculated with a carcinoma (Boucaud-Maitre et al 1988). The main triterpendiol esters of calendula, the faradiol esters, have been shown to possess antioedema activity by inhibiting croton oil-induced oedema of the mouse ear (Zitterl-Eglseer et al 1997).

### Immunomodulation

Isolated polysaccharides have been shown to stimulate phagocytosis of human granulocytes (Varljen et al 1989, Wagner et al 1985). A 70% ethanol extract of calendula was shown to completely inhibit the proliferation of lymphocytes in the presence of phytohaemagglutinin *in vitro* (Amirghofran et al 2000).

### Antioxidant

Calendula has free radical scavenging and antioxidant activity, with aqueous extracts having greater activity than methanolic extracts. Antioxidant activity is related to the total phenolic and flavonoid content (Cetkovic et al 2004, Matic et al 2012).

The butanolic fraction of a calendula extract reduces superoxide and hydroxyl radicals, suggesting a free radical scavenging effect. Lipid peroxidation in liver microsomes is also reduced (Cordova et al 2002). Isorhamnetin glycosides isolated from calendula have been shown to inhibit the activity of lipo-oxygenase (Bezakova et al 1996).

Research with animal models also shows various antioxidant effects. A propylene glycol extract of calendula petals administered orally to rats on a high-polyunsaturated fatty acid diet protected lymphocyte DNA from oxidative damage and was comparable with vitamin E supplementation in preventing lipid peroxidation (Frankič *et al* 2009). Similarly, a dose-dependent protective effect against ultraviolet B-induced glutathione depletion was seen with an oral solution of a hydroethanolic extract of calendula *in vivo* (Fonseca *et al* 2010).

### Antispasmodic activity

Calendula has demonstrated antispasmodic activity in isolated gut preparations (Bashir *et al* 2006). These effects appeared to be due to calcium channel blocking and cholinergic activity.

### Hypoglycaemic activity

A methanolic extract and its butanol-soluble fraction have been found to have hypoglycaemic and gastroprotective effects and to slow gastric emptying. From the butanol-soluble fraction, four new triterpene oligoglycosides, calendasaponins A, B, C and D, were isolated, together with eight known saponins, seven known flavonol glycosides and a known sesquiterpene glucoside. Their structures were elucidated on the basis of chemical and physicochemical evidence. The principal saponin constituents, glycosides A, B, C, D and F, exhibited potent inhibitory effects on an increase in serum glucose levels in glucose-loaded rats, gastric emptying in mice and ethanol- and indomethacin-induced gastric lesions in rats (Yoshikawa *et al* 2001).

### Hypolipidaemic activity

Oral administration of an isolated saponin fraction has been shown to reduce serum lipid levels in hyperlipidaemic rats (ESCOP 1996).

### Hepatoprotective

Calendula extracts have been shown to have hepatoprotective effects on rat hepatocytes both *in vitro* and *in vivo* (Barajas-Farias *et al* 2006, Rusu *et al* 2005), with cytotoxic and genotoxic effects being evident at very high doses (Barajas-Farias *et al* 2006, Perez-Carreón *et al* 2002).

## CLINICAL USE

Calendula is generally used in the treatment of inflammatory skin disorders or inflammation of the mucosa and as an aid to wound healing (Blumenthal *et al* 2000, ESCOP 1996). It is used both internally and topically for a variety of indications.

### Wounds and burns

Historically, calendula flower preparations have been used to accelerate the healing of wounds, burns, bruises, grazes and minor skin infections. In recent times, it has been investigated for its effects on wound healing and burns in a variety of experimental models and clinical studies as either a

stand-alone topical treatment or in combination with other ingredients. Generally, studies investigate various topical preparations; however, an oral mouthwash has also been tested for effects.

Calendula ointment (8%, 1:10 tincture in 70% alcohol) is a useful adjuvant treatment during cosmetic surgery, according to a study of 19 cleft-lip patients with discoloured scar tissue. Pretreatment with the calendula ointment under a gauze dressing every evening for 1 month improved the results of dermatography, a refined tattooing technique used to improve the appearance of scars (Van der Velden & Van der Dussen 1995).

In another controlled trial involving 34 patients with venous leg ulcers, a calendula extract applied twice daily for 3 weeks was found to produce a significant acceleration in healing compared to a saline solution (Duran *et al* 2005). Another clinical study used a mixture of chlorhexidine acetate and a 2% calendula extract as a haemostatic aerosol, producing good results (Garg & Sharma 1992).

A larger, open, randomised parallel study of 156 patients in four burn centres in France compared the effects of three different topical ointments (calendula, a proteolytic ointment and Vaseline) on the management of second- and third-degree burns. A thick layer of the test ointment was applied daily under a closed dressing until grafting or spontaneous healing occurred and effectiveness was evaluated between the eighth and 12th day of treatment. Failure was defined as the presence of an eschar, local infection, premature treatment discontinuation or failure to complete the study. A marginally significant difference in favour of calendula over Vaseline was observed and calendula was significantly better tolerated than the other treatments (Lievre *et al* 1992).

Prophylactic treatment with calendula ointment has also been used successfully to reduce the incidence and severity of bedsores in an open multicentre study. In other studies, positive results have been demonstrated in the treatment of poor venous return associated with ulcers, thrombophlebitis and other cutaneous changes, such as inflammation, cracks and eczema (Issac 1992).

### Adjunct to radiation therapy

In a randomised controlled trial (RCT) involving 254 patients treated with adjuvant radiotherapy for breast cancer, topical treatment with calendula to the irradiated skin was found to be significantly more effective than trolamine in reducing acute dermatitis, with patients receiving calendula having less frequent interruption of radiotherapy and significantly reduced radiation-induced pain (Pommier *et al* 2004).

A 2012 RCT compared calendula cream to a standard aqueous cream to determine whether application would reduce the risk of severe acute radiation skin reactions in 411 patients undergoing radiation therapy for breast cancer. The study found no significant statistical difference between the two

groups. The calendula application was reported as being more poorly absorbed than placebo, which may have been a factor; however, this remains to be tested further (Sharp et al 2012).

In contrast, a 2% calendula mouthwash decreased the intensity of radiation-induced oropharyngeal mucositis compared to placebo mouthwash in an RCT involving 40 patients with head and neck cancers. Patients were instructed to use 5 mL of mouthwash twice daily (placebo or calendula) over a period of 7 weeks during concurrent radiotherapy treatment. The severity of oropharyngeal mucositis was assessed by two doctors using the Oral Mucositis Assessment Scale (Babaee et al 2013).

#### IN COMBINATION

In practice, calendula is often combined with other herbs, such as St John's wort, to provide stronger effects. The combination of *Calendula arvensis* (field marigold) and *Hypericum perforatum* oils has been shown to improve the epithelial reconstruction of surgical wounds in childbirth with caesarean section (Lavagna et al 2001).

In a prospective, non-randomised study, 25 patients with venous ulcers were treated with an ointment containing calendula oil, *Hypericum perforatum* and *Allium sativa*. There was an average 99.1% improvement in epithelialisation by the end of the 7 weeks without any adverse effects (Kundakovic et al 2012).

A combination of calendula, *Arctium lappa* and *Geranium robertianum* has also been shown to improve healing of ulceration in 52 patients suffering herpetic keratitis compared with treatment with aciclovir alone (Corina et al 1999).

Commission E approves the external use of calendula for poorly healing wounds and leg ulcers (Blumenthal et al 2000).

#### Gastrointestinal inflammatory disorders

In practice, calendula is often combined with other herbs to provide stronger effects, a fact often reflected in the research.

#### IN COMBINATION

An oral mixture of *Symphytum officinalis* (comfrey) and calendula was beneficial in the treatment of duodenal ulcers and gastroduodenitis according to a study involving 170 patients. Of these, 137 were treated with the herbal combination and 33 also received an antacid. A dramatic 90% of treated patients became painfree and 85% had a reduction in dyspeptic complaints. Gastric acidity showed a statistically insignificant tendency to decrease in both groups. Gastroscopy later revealed that the ulcers had healed in 90% of patients (Chakurski et al 1981). Interestingly, a smaller study conducted by the same researchers involving only 32 patients with the same condition failed to detect a beneficial effect (Matev et al 1981).

A further study by the same authors found another mixture containing calendula to be beneficial in the treatment of chronic colitis. A combination of *Taraxacum officinale*, *Hypericum perforatum*, *Melissa officinalis*,

*Calendula officinalis* and *Foeniculum vulgare* was shown to relieve the spontaneous and palpable pains along the large intestine in over 95% of the patients ( $n = 24$ ) by day 15 of treatment. Defecation was normalised in patients with diarrhoea and constipated patients were successfully treated with the addition of *Rhamnus frangula*, *Citrus aurantium* and *Carum carvi*. The pathological admixtures in faeces disappeared (Chakurski et al 1981).

Although encouraging, the role of calendula as a stand-alone treatment is difficult to determine from these studies. Additionally, the oral ingestion of comfrey is not recommended due to potential hepatotoxic effects.

#### Gingivitis

Calendula has been shown in an open clinical study to be beneficial in the treatment of chronic catarrhal gingivitis (Krazhan & Garazha 2001). Interestingly, calendula extract failed to show any significant activity in vitro against common oral microorganisms in a second study that tested it against the saliva and dental plaque from 20 infants (Modesto et al 2000); however, a homeopathic preparation of calendula has been found to inhibit *Streptococcus mutans* (Giorgi et al 2004).

Commission E approves the internal and topical use of calendula flowers for inflammation of the oral and pharyngeal mucosa (Blumenthal et al 2000).

#### Nappy rash

In a postmarketing surveillance study (Guala et al 2007), 82 infants aged between 3 days and 48 months were randomised to receive either calendula cream (Weleda) or Babygella for treatment of their nappy rash. Both preparations were judged by doctors and mothers as useful; however mothers tended to describe the calendula cream more frequently than Babygella as very good rather than satisfactory. The calendula cream also contained other anti-inflammatory and healing ingredients, such as chamomile and zinc, making the contribution of calendula hard to judge.

In a double-blind RCT, 66 children suffering from diaper dermatitis ('nappy rash') were treated with either *Aloe vera* (syn. *Aloe barbadensis*) cream or calendula ointment. The treatment was applied three times a day over a period of 10 days and, while an improvement was observed in both treatment groups, there was a significantly greater reduction in rash severity with calendula treatment (Panahi et al 2012).

#### OTHER USES

The British Herbal Pharmacopoeia recommends calendula for gastric and duodenal ulcers, amenorrhoea, dysmenorrhoea and epistaxis (BHMA 1983). Typically it is recommended for leg ulcers, varicose veins, haemorrhoids, eczema and proctitis. The specific indications are for enlarged or inflamed lymphatic nodes, sebaceous cysts, duodenal ulcers and acute and chronic inflammatory skin conditions. Its styptic activity makes it a popular topical treatment for bleeding.

**Practice points/Patient counselling**

- Calendula has antimicrobial and anti-inflammatory activity and promotes wound healing.
- European textbooks recommend calendula for inflammation of the skin, poorly healing wounds, bruises, boils, rashes, bed sores, dermatitis resulting from chilblains, wound healing after amputations, cracked nipples during pregnancy and lactation, acne, sunburns, burns and nappy rashes. Calendula is also indicated for pharyngitis and tonsillitis (Bisset 1994, Bruneton 1999, Evans 2002, Issac 1992).
- There is some evidence from clinical trials that calendula may be beneficial in the treatment of burns, wounds and gastrointestinal inflammation and ulceration.
- People who are sensitive or allergic to foods or plants from the Asteraceae (previously Compositae) family should use calendula with caution.

**DOSAGE RANGE**

- Dried herb: 1–2 g as an infusion daily in divided doses.
- Liquid extract (1:2): 15–30 mL/week for internal use or 1.5–4.5 mL/day in divided doses. Dilute 1:3 for external application.
- Tincture (1:5): 0.3–1.2 mL three times daily.
- Calendula oil can be produced by steeping fresh flowers in vegetable oil for 1 week. Strain before use.

**TOXICITY**

Calendula has low toxicity. No symptoms of toxicity were found after long-term administration of a calendula extract in animal studies (Elias et al 1990, ESCOP 1996). A study evaluating an excessive dose (5 g/kg) in rats found no toxicity; however signs of liver and kidney burden were noted (Silva et al 2007). Similarly, changes to biochemical (alanine aminotransferase, aspartate aminotransferase and alkaline phosphatase) and haematological (haemoglobin, erythrocytes and leucocytes) parameters as well as slight changes to hepatic parenchyma were seen in male rats after subchronic daily administration (250 mg/kg/day and 1000 mg/kg/day) over 90 days (Lagarto et al 2011). Calendula has been found to be neither mutagenic nor carcinogenic (Elias et al 1990).

**ADVERSE REACTIONS**

Irritant dermatitis from calendula has been reported (Paulsen 2002, Reider et al 2001) but is rare. Sesquiterpene lactones are the most important allergens present in Compositae species, but there are also a few cases of sensitisation from a coumarin, a sesquiterpene alcohol and a thiophene (Paulsen 2002).

A study of over 1000 patients randomly chosen from several different patch test clinics identified

only one who reacted to calendula (Bruynzeel et al 1992). Patch test results need to be carefully interpreted because false positives can occur, as the following case shows. A 35-year-old woman with recalcitrant atopic dermatitis, with a positive patch test reaction to Compositae mix, was told she was allergic to calendula. However, it turned out that she followed a self-devised diet consisting largely of food products of the Asteraceae (previously Compositae) family (which includes lettuces and artichoke). On excluding these foods her skin condition improved quickly. This case report underscores the difficulty in determining the relevance of positive patch tests, and shows that thorough analysis of positive patch tests, by both patient and doctor, may reveal unexpected or less common sources of contact allergens (Wintzen et al 2003).

**SIGNIFICANT INTERACTIONS**

Controlled studies are not available to assess the interaction potential of calendula.

**? CONTRAINDICATIONS AND PRECAUTIONS**

Use with caution in patients with confirmed allergy to herbs or foods from the Compositae family.

**! PREGNANCY USE**

Insufficient reliable information available to assess safety.

**! PATIENTS' FAQs****What will this herb do for me?**

Calendula is used for inflammatory skin conditions, including poor wound healing, burns and ulcers, due to its non-irritant, antiseptic and healing properties. Internally it is used for inflammation and ulceration of the digestive tract.

**When will it start to work?**

Topical effects are quickly established and should improve with continuous use. Internal use may take longer.

**Are there any safety issues?**

Although there have been some reports of allergic reactions to calendula, these are very rare. Calendula is generally well tolerated by children and adults.

## Carnitine

### BACKGROUND AND RELEVANT PHARMACOKINETICS

Carnitine was discovered in 1905, although its role in metabolism was only described in the mid-1950s and deficiency symptoms outlined in 1972. It is a trimethylated amino acid, roughly similar in structure to choline, that is ingested in the diet and also synthesised from lysine and methionine in the body. To do this, a large number of cofactors are required, such as *S*-adenosyl methionine, methionine, magnesium, vitamins C, B<sub>6</sub>, B<sub>2</sub>, B<sub>3</sub>, iron, alpha-ketoglutarate and oxygen (Kelly 1998). Dietary carnitine is absorbed in the intestine via a combination of active transport and passive diffusion (Li et al 1992). Mucosal absorption is saturated at around 2 g carnitine (Harper et al 1988). The bioavailability of carnitine is difficult to establish as reports vary widely, from 16% to 87% (Harper et al 1988, Rebouche & Chenard 1991). Peak blood levels occur 3.5 hours after digestion and excretion is primarily via the kidneys (Bach et al 1983).

### CHEMICAL COMPONENTS

L-Carnitine is the form most commonly used. As the D form is not biologically active, there is concern that it might interfere with the use of the L isomer by competitive inhibition and thus cause L-carnitine deficiency (Tsoko et al 1995).

### FOOD SOURCES

Red meat is the richest dietary source. Vegetarian sources include avocado and tempeh (Hendler & Rorvik 2001). Human colostrum also contains carnitine (Wahlqvist 2002).

### DEFICIENCY SIGNS AND SYMPTOMS

L-Carnitine deficiency leads to an accumulation of free fatty acids in the cell cytoplasm and of acyl-coenzyme A (CoA) in the mitochondria. This produces a toxic effect and disturbs fatty acid use for

#### **Clinical note — Acetyl-L-carnitine shows promise as a strong therapeutic agent**

Acetyl-L-carnitine, an ester form of L-carnitine, has also been investigated for its use in the treatment of Alzheimer's disease (Brooks et al 1998, Pettegrew et al 1995, Sano et al 1992, Thal et al 1996); depression (Garzya 1990), physical and mental fatigue, cognitive status and physical function in the elderly (Malaguamera et al 2008); diabetic (De Grandis & Minardi 2002), peripheral (Onofj et al 1995) and antiretroviral toxic neuropathy (Youle & Osio 2007) as well as prevention of neuropathy in chemotherapy (Bianchi et al 2005, Maestri et al 2005). It has also been researched for fatigue in multiple sclerosis (Tomassini et al 2004), fibromyalgia syndrome (Rossini et al 2007), Peyronie's disease (Biagiotti & Cavallini 2001), degenerative cerebellar ataxia (Sorbi et al 2000) and cognitive disturbances in chronic alcoholics (Tempesta et al 1990).

#### **Clinical note — Primary carnitine deficiency: an uncommon inherited disorder**

Primary carnitine deficiency is an uncommon inherited disorder, related to a functional defect in plasma membrane carnitine transport in muscle and in the kidneys. These conditions have been classified as either systemic or myopathic (Evangelidou & Vlassopoulos 2003, Matera et al 2003). Systemic carnitine deficiency is reflected by low levels of carnitine in plasma and muscle and may result in cardiomyopathy, skeletal myopathy, hypoglycaemia and hyperammonaemia (Hendler & Rorvik 2001). Myopathic deficiency presents with normal plasma but low muscle carnitine levels and is a defect of carnitine transport across the muscle cell membrane (Winter et al 1987).

energy production (Kletzmayer et al 1999). Elevation of triglycerides may also occur due to the role of carnitine in fatty acid metabolism.

Deficiency symptoms (Kelly 1998) include the following:

- hypoglycaemia
- progressive myasthenia
- hypotonia
- fatigue
- cardiomyopathy
- congestive heart failure
- encephalopathy
- hepatomegaly
- neuromuscular disorders
- failure to thrive in infants
- muscle fatigue and cramps
- myoglobinaemia following exercise.

Elevation of triglycerides may also occur due to the role of carnitine in fatty acid metabolism.

### Primary deficiency

People at risk of primary deficiency are vegetarians, preterm infants and infants receiving a carnitine-free formula, and those with an inherited functional defect.

### Secondary deficiency

Secondary carnitine deficiency is associated with several inborn errors of metabolism and acquired medical or iatrogenic conditions, such as the following (Evangelidou & Vlassopoulos 2003):

- genetic defects of metabolism, including methylmalonic aciduria, cytochrome C oxidase deficiency, fatty acyl-CoA dehydrogenase deficiency
- medications (patients taking valproate and the anti-HIV drug zidovudine are at risk)
- dialysis (carnitine depletion in haemodialysis patients is caused by insufficient carnitine synthesis and particularly by loss through the dialytic membranes. Many studies have shown that L-carnitine supplementation leads to improvements in several complications seen in uraemic patients, including cardiac complications, impaired exercise and functional capacities, muscle symptoms, increased symptomatic intradialytic hypotension and erythropoietin-resistant anaemia, normalising the reduced carnitine palmitoyl transferase activity in red cells [Matera et al 2003])
- liver disease, which impairs the last stage of carnitine synthesis, resulting in deficiencies in cardiac and skeletal muscle
- chronic renal failure and renal tubular disorders, in which excretion of carnitine may be excessive
- intestinal resection
- coeliac disease (a case report exists of a 48-year-old man developing encephalopathy due to carnitine deficiency as a result of coeliac disease [Karakoc et al 2006]. In patients with idiopathic dilated cardiomyopathy associated with coeliac disease, a gluten-free diet has been shown to increase serum carnitine levels [Curione et al 2005])
- preterm neonates (develop carnitine deficiency

due to impaired proximal renal tubule carnitine reabsorption and immature carnitine biosynthesis)

- hypopituitarism (Martindale 1999)
- adrenal insufficiency (Hendler & Rorvik 2001)
- advanced AIDS (Hendler & Rorvik 2001)
- vitamin C deficiency (Hendler & Rorvik 2001)
- other chronic conditions — diabetes mellitus, heart failure, Alzheimer's disease.

### MAIN ACTIONS

Carnitine is involved in a myriad of biochemical processes important for health and wellbeing.

#### Cellular energy production

Carnitine assists the transport of fat across cell membranes in muscle tissue for use as an energy source (Wahlqvist 2002). It is essential for mitochondrial fatty acid oxidation, which is the primary fuel source for the heart and skeletal muscles and therefore required for proper functioning (Evangelidou & Vlassopoulos 2003, Kelly 1998). This process is also required in order to maintain CoA levels. The combination of exercise training and L-carnitine (4 g/day) supplementation does not appear to augment fatty acid-binding protein (FABPc) expression and beta-hydroxyacyl CoA dehydrogenase (beta-HAD) activity in human skeletal muscle, indicating that combined treatment does not exert an additive effect in fat metabolism and would thus be unlikely to enhance exercise performance (Lee et al 2007).

#### Improved blood sugar control

Administration of L-carnitine reduces insulin secretion and improves peripheral glucose use (Grandi et al 1997) and tissue insulin sensitivity (Negro et al 1994).

#### Cellular function and integrity

Carnitine is involved in the protection of membrane structures, stabilising a physiological CoA-sulfate hydrate/acetyl-CoA ratio, and reduction of lactate production (Matera et al 2003).

#### Antioxidant

Carnitine acts as an antioxidant in the cell membrane, preventing protein oxidation and pyruvate and lactate oxidative damage (Peluso et al 2000). In vitro studies suggest a dose-dependent inhibition of lipid peroxidation of linoleic acid emulsion superior to alpha-tocopherol. In addition, L-carnitine may have an effect on superoxide anion radical scavenging, hydrogen peroxide scavenging, total reducing power and metal chelating on ferrous ions (Gulcin 2006).

### OTHER ACTIONS

#### Increases male fertility

Based on the high concentrations of L-carnitine in the epididymis, it has been proposed that spermatozoa, which require beta oxidation for energy, may require L-carnitine for proper maturation (Lenzi

et al 1992). Human trials have found carnitine therapy (2–3 g/day) to be effective in increasing semen quality, sperm concentration and total and forward sperm motility, especially in groups with lower baseline levels (Lenzi et al 2003). One trial also reported that improvements in sperm motility were only observed in the presence of normal mitochondrial function, determined by phospholipid hydroperoxide glutathione peroxidase levels (Garolla et al 2005).

### Prevents apoptosis

In vitro and animal studies show that L-carnitine can prevent apoptosis of skeletal muscle cells (Vescovo et al 2002). In patients with HIV it decreases numbers of CD4<sup>+</sup> and CD8<sup>+</sup> cells undergoing apoptosis, and significantly increases CD4<sup>+</sup> counts (Moretti et al 2002).

### Neuroprotective

Animal studies have demonstrated a reduction in mortality and neuronal degeneration in experimentally-induced neurotoxicity (Binienda et al 2004) and a reduction in hypoglycaemia-induced neuronal damage (Hino et al 2005) in rats that were pre-treated with carnitine. In vitro studies suggest that the antiapoptotic and antioxidant actions of L-carnitine contribute to the neuroprotective effect (Ishii et al 2000, Tastekin et al 2005).

### Lipid lowering

The role of carnitine in fatty acid metabolism suggests a potential role in hyperlipidaemia. Several studies have indicated that oral L-carnitine significantly reduces lipoprotein-a levels; however, effects on other lipids are inconsistent. According to human trials the addition of L-carnitine (2 g/day) to simvastatin therapy (20 mg/day) appears to lower lipoprotein-a serum levels in patients with type 2 diabetes mellitus (Solfrizzi et al 2006). In a separate placebo-controlled, double-blind randomised study L-carnitine (2 g/day) significantly reduced serum lipoprotein-a levels in 77.8% of subjects receiving active treatment after 12 weeks. No significant change was observed in other lipid parameters (Sirtori et al 2000). L-Carnitine (2 g/day) was also shown to significantly lower lipoprotein-a levels at 3 and 6 months in a double-blind placebo-controlled trial of 94 hypercholesterolaemic patients with newly diagnosed type 2 diabetes (Derosa et al 2003). In a trial of children with hyperlipidaemia, lipoprotein-a levels were only reduced in those with type II homozygotes and other lipid parameters worsened (Gunes et al 2005).

L-Carnitine has also been shown to decrease apolipoprotein B levels in paediatric peritoneal dialysis patients (Kosan et al 2003). A study of elderly people taking L-carnitine (2 g twice daily) demonstrated improvements in total serum cholesterol, low-density lipoprotein (LDL)-cholesterol, high-density lipoprotein (HDL)-cholesterol, triglycerides and apoproteins A1 and B at 30 days (Pistone et al

2003). Animal studies have also suggested the potential for carnitine to lower triglyceride levels (Eskandari et al 2004); however, clinical trials using oral doses in type 2 diabetes have indicated an increase in triglycerides (Rahbar et al 2005). Further human trials are required to confirm which population groups may benefit from carnitine supplementation.

### CLINICAL USE

Carnitine supplementation may be administered as intravenous (IV) or oral doses. This review will only focus on oral supplementation as this is the form generally used by the public and available over the counter.

#### Treatment of deficiency

L-Carnitine supplementation is traditionally used to treat or prevent deficiency. It is indicated in primary L-carnitine deficiency and secondary deficiency due to inborn errors of metabolism or haemodialysis. L-Carnitine 50–200 mg/kg/day has been shown to normalise plasma carnitine levels within 10 days (Campos et al 1993).

#### Apnoea of prematurity

Preterm neonates develop carnitine deficiency due to impaired proximal renal tubule carnitine reabsorption and immature carnitine biosynthesis (Evangelidou & Vlassopoulos 2003) and are at risk of developing apnoea of prematurity. Despite a promising preliminary study, a blinded, randomised, placebo-controlled study found that infants who received supplemental carnitine did not demonstrate any reduction in apnoea of prematurity, days requiring ventilator or nasal continuous positive airway pressure, or the need for supplemental oxygen therapy (O'Donnell et al 2002). In a randomised controlled trial (RCT) premature neonates supplemented with carnitine (20 mg/kg/day) gained weight more rapidly and showed improvement in periodic breathing compared to placebo, although other respiratory markers were unaffected (Crill et al 2006). A 2004 Cochrane review was unable to locate studies of significant quality to confirm any effects (Kumar et al 2004a). Further studies are needed to determine the role of this treatment in clinical practice as present evidence does not support its use (Kumar et al 2004b).

#### Cardiovascular disease

L-Carnitine supplementation in doses ranging from 2 g to 4 g/day has been investigated in a number of controlled studies involving subjects with angina, heart failure, cardiogenic shock, cardiomyopathy and post myocardial infarction (MI). Overall, positive results have been obtained and reduced mortality reported for some populations.

In a small study investigating endothelial function in 31 patients receiving haemodialysis, 20 patients received 1500 mg oral L-carnitine (3 × 500 mg/day) on alternate days and 11 patients served as a

control group, receiving placebo for 1 month. At completion of the study there were no significant differences in flow-mediated dilation or in carotid intima media thickness in either group of patients (Sabri et al 2012).

### Chronic stable angina

Controlled studies indicate that L-carnitine supplements increase exercise tolerance and reduce frequency of angina attacks, enabling some patients to reduce nitrate requirements.

One RCT of 47 patients with chronic stable angina found that 2 g L-carnitine taken daily for 3 months moderately improved the duration of exercise and the time taken for ST changes to recover to baseline (Iyer et al 2000). This study confirmed the results of an earlier multicentre, double-blind, randomised, placebo-controlled crossover trial that examined the effects of L-carnitine 1 g twice daily for 4 weeks in 44 men with stable chronic angina (Cherchi et al 1985). This study showed that active treatment resulted in increased exercise tolerance and reduced electrocardiographic indices of ischaemia in stable effort-induced angina. A meta-analysis also highlighted a significant reduction in the number of angina attacks and nitrate requirements with doses of 2 g/day (Fernandez & Proto 1992).

### Post myocardial infarction

L-carnitine supplementation may lead to a reduction in early mortality (assessed at day 5) without affecting the risk of death and heart failure at 6 months in patients with anterior acute MI (Tarantini et al 2006). A dose of 4 g/day L-carnitine over 12 months improved quality of life and increased life expectancy in patients who had suffered an MI, according to a controlled study (Davini et al 1992). This included an improvement in heart rate, systolic arterial pressure, a decrease in anginal attacks and improvement in the lipid profile. Changes were also accompanied by lower mortality in the treated group (1.2% vs 12.5% in the control group).

In a randomised, double-blind placebo-controlled trial, the effects of oral L-carnitine (2 g/day) for 28 days were assessed in patients with suspected acute MI. Total cardiac events, including cardiac deaths and non-fatal infarction, were 15.6% in the carnitine group and 26.0% in the placebo group. Angina pectoris (17.6% vs 36.0%), New York Heart Association class III or IV heart failure plus left ventricular enlargement (23.4% vs 36.0%) and total arrhythmias (13.7% vs 28.0%) were significantly less in the carnitine group compared with placebo (Singh et al 1996).

### Cardiomyopathy

Cardiomyopathy appears to cause leakage of carnitine from heart stores, which may make cardiac tissue vulnerable to damage; however, it is unclear whether carnitine leakage is a cause or effect of cardiomyopathy (Baker et al 2005). Long-term

placebo-controlled studies (10–54 months) using an oral dose of 2 g/day L-carnitine for treatment of heart failure caused by cardiomyopathy found a statistically significant advantage in survival rates with carnitine treatment (Rizos 2000). In patients with idiopathic dilated cardiomyopathy associated with coeliac disease, a gluten-free diet has been shown to increase serum carnitine levels (Curione et al 2005).

### Cardiogenic shock

Several studies confirm the role of L-carnitine in the reversible phase of cardiogenic shock in terms of enzymic protection in the course of cellular oxidative damage. This has been reflected in improved survival rates (Corbucci & Lettieri 1991, Corbucci & Loche 1993).

### Congestive heart failure

In congestive heart failure a specific myopathy secondary to myocyte apoptosis triggered by high levels of circulating tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ) has been described. The role of carnitine in preventing apoptosis in skeletal muscle and reducing TNF- $\alpha$  provides a theoretical basis for its use in the treatment of myopathy associated with congestive heart failure (Vescovo et al 2002).

### Myocarditis resulting from diphtheria

Two studies using D,L-carnitine (100 mg/kg/day in two divided doses orally for 4 days) found a reduction in the incidence of, and mortality from, myocarditis in diphtheria (Ramos et al 1984, 1992).

### Non-ST elevation acute coronary syndrome (NSTEMI)

In an RCT 96 patients with NSTEMI were randomised to treatment or control group. All patients received percutaneous coronary intervention within 24 hours from the onset of chest pain. The treatment group also received L-carnitine (5 g IV bolus followed by 10 g/day IV infusion for 3 days) and demonstrated significantly lower levels of cardiac markers (creatinine kinase-MB and troponin-I) (Xue et al 2007).

### Peripheral vascular disease

Due to its anti-ischaemic activity, L-carnitine supplements have also been used in peripheral vascular disease. A double-blind crossover study supports this use, finding L-carnitine supplements (2 g/day) taken for 3 weeks increased walking time in people with peripheral vascular disease (Brevetti et al 1988). A derivative of L-carnitine, known as propionyl-L-carnitine (PLC), taken for 6 months (2 g/day orally) has also demonstrated significant improvements in walking distance and speed in patients with claudication (Hiatt et al 2001).

A recent systematic review evaluating the effect of L-carnitine or PLC supplementation on walking performance in patients with intermittent claudication concluded that the majority of included studies

(17 articles, with 18 studies of varying duration [4–365 days]; five pretest/posttest studies in which 300–2000 mg PLC was administered orally or intravenously; eight parallel RCT in which PLC was administered orally [600–3000 mg in seven studies and 600 mg/day PLC, intravenously in one study]; five crossover RCTs in which 300–6000 mg L-carnitine or PLC was administered orally in two studies and intravenously in three studies) demonstrated a significant improvement in walking performance, particularly among patients with severe claudication, and also that oral administration was less effective compared to IV administration (Delaney et al 2013).

Likewise, in another recent systematic review and meta-analysis, the effect of PLC administration (daily dose range of 1.0–3.0 g among the included studies) was investigated regarding exercise performance in patients with claudication and it was concluded that oral PLC supplementation resulted in a statistically significant increase in peak walking distance (Brass et al 2013).

### Hypertension

In a small open pilot study the effect of oral acetyl-L-carnitine (2 g/day given as  $2 \times 1$  g/day) supplementation was investigated regarding components of the metabolic syndrome over the course of 24 weeks in non-diabetic subjects who were categorised in one of two groups (glucose disposal rate  $\leq 7.9$  [ $n = 16$ ] or  $>7.9$  [ $n = 16$ ] mg/kg/min) who completed the study. Supplementation of acetyl-L-carnitine significantly reduced the arterial blood pressure and increased plasma adiponectin levels. Acetyl-L-carnitine was also effective in ameliorating insulin resistance and impaired glucose tolerance in patients who were insulin-resistant at the start of the study compared to those with normal or near-normal insulin sensitivity (Ruggenti et al 2009).

However the role of L-carnitine and acylcarnitine derivatives remains to be determined, as a recent study of African ( $n = 101$ ) and Caucasian ( $n = 101$ ) men reported that, independently of ethnicity, higher levels of serum free L-carnitine were significantly associated with elevated blood pressure (Mels et al 2013). The authors of this study considered that increased carnitine biosynthesis may be due to reduced tissue uptake or reduced renal excretion or increased oxidative stress or higher cardiac energy demands due to increases in blood pressure.

### Hyperthyroidism

Considering that this condition is associated with reduced body stores of carnitine and that L-carnitine is a peripheral antagonist of thyroid hormone action in some tissues according to *in vivo* studies, carnitine treatment has been investigated in hyperthyroidism.

One 6-month, randomised, double-blind placebo-controlled trial involving 50 women with induced suppression of thyroid-stimulating hormone

showed that doses of 2 g or 4 g/day oral L-carnitine both reversed and prevented symptoms of the disease and had a beneficial effect on bone mineralisation (Benvenega et al 2001).

### Male fertility

Some studies suggest that a combination of L-carnitine and acetyl-L-carnitine may provide benefit for the treatment of idiopathic asthenospermia and improve semen quality (Cheng & Chen 2008). A placebo-controlled, double-blind crossover trial of 100 infertile males (aged 20–40 years) found that L-carnitine therapy (2 g/day) was effective in increasing semen quality, sperm concentration and total and forward sperm motility, especially in groups with lower baseline levels (Lenzi et al 2003).

The positive effects on sperm motility have also been shown in previous trials using L-carnitine 3 g/day (Costa et al 1994, Vitali et al 1995). In a later trial, improvements in sperm motility were only observed in the presence of normal mitochondrial function, determined by phospholipid hydroperoxide glutathione peroxidase levels (Garolla et al 2005). A meta-analysis comparing L-carnitine and/or acetyl-L-carnitine therapy to placebo found significant improvements in pregnancy rate ( $P < 0.0001$ ), total sperm motility ( $P = 0.04$ ), forward sperm motility ( $P = 0.04$ ) and atypical sperm cells ( $P < 0.00001$ ), but not sperm concentration or semen volume (Zhou et al 2007). One small RCT of 21 men (12 in the treatment group, 9 in the placebo group) with idiopathic asthenospermia showed that a combination of L-carnitine (2000 mg) and L-acetyl-carnitine (1000 mg) taken daily over 24 weeks failed to demonstrate improvements in sperm motility or total motile sperm counts (Sigman et al 2006).

In a 3-month study of patients (aged 22–35 years) with idiopathic infertility, 20 men were randomised to receive L-carnitine (25 mg/day) and 32 men received an antioestrogen clomiphene citrate (2 g/day). There was a significant increase in serum volume in the carnitine group ( $P > 0.001$ ) and clomiphene citrate was reported to result in improved sperm motility and morphology (Moradi et al 2010).

Supplementary carnitine may have a role in assisted reproductive medicine because sperm quality can be adversely affected by cryopreservation. A recent study investigating the cryoprotective effect of L-carnitine on motility, vitality and DNA oxidation on human spermatozoa reported that semen samples from 22 infertile patients, when treated with L-carnitine at a ratio of 1:1 (v/v) (final carnitine concentration per cryovial of 0.5 mg/mL per  $5 \times 10^6$  cell/mL) resulted in improved sperm motility and vitality ( $P > 0.05$ ) compared to control semen samples that were cryopreserved without the addition of L-carnitine. However L-carnitine did not have any effect on sperm DNA oxidation after cryopreservation (Banihani et al 2013).

Decreased carnitine levels as well as low levels of testosterone in male patients on haemodialysis compared to healthy controls have been reported (Sakai et al 2013) and the role of supplementary carnitine remains to be determined in uraemic men on haemodialysis who are at risk of hypogonadism.

### Ergogenic aid

L-Carnitine is a popular supplement amongst athletes in the belief that it will increase performance and recovery. This concept is largely based on the fact that carnitine assists in the transport of fat across cell membranes in muscle tissue and is involved in cellular energy production. However, the combination of exercise training and L-carnitine (4 g/day) supplementation does not appear to augment FABPc expression and beta-HAD activity in human skeletal muscle, suggesting that combined treatment does not exert an additive effect in fat metabolism and would thus be unlikely to enhance exercise performance (Lee et al 2007).

Carnitine reduces insulin secretion and significantly improves peripheral glucose use, when administered with glucose, according to human research (Grandi et al 1997). There is evidence that L-carnitine supplementation may increase maximal oxygen consumption, stimulate lipid metabolism and reduce postexercise plasma lactate (Karlic & Lohninger 2004). One trial reported that acute intake of L-carnitine (2 g) 1 hour prior to exercise did not appear to affect metabolic or blood lactate values of badminton players, although there was a significant difference in exercise maximum heart rate in male participants ( $P < 0.05$ ) (Eroglu et al 2008).

In a placebo-controlled crossover trial using an L-carnitine-L-tartrate (LCLT) supplement (2 g L-carnitine/day) for 3 weeks, researchers suggested that LCLT supplementation was effective in assisting recovery from high-repetition squat exercise (Volek et al 2002). A similar trial of the same dose and duration suggested that recovery from postresistance exercise may be mediated by upregulation of androgen receptor content (Kraemer et al 2006). However, other clinical trials using 2 g L-carnitine twice daily for 3 months found no significant increase in muscle carnitine content, mitochondrial proliferation or physical performance (Wachter et al 2002). Similarly, a study using glycine PLC (1–3 g/day) for 8 weeks in conjunction with aerobic exercise training failed to demonstrate improvement in muscle carnitine content, aerobic or anaerobic exercise performance (Smith et al 2008).

### Ergogenic aid in cardiovascular disease

Trials in subjects with cardiovascular disorders have been more promising. This is supported by the clinical trial discussed earlier involving patients with chronic stable angina (Iyer et al 2000). In addition, a clinical trial using 1 g L-carnitine or placebo three times daily for 120 days has indicated a potential for improved performance and effort tolerance in

patients with cardiac insufficiency (Loster et al 1999).

### Ergogenic aid in chronic obstructive pulmonary disease (COPD)

Compared to placebo, L-carnitine (2 g/day) for 6 weeks can significantly improve inspiratory muscle strength ( $14 \pm 5$  vs  $40 \pm 14$  cm H<sub>2</sub>O) and exercise tolerance (walking test:  $34 \pm 29$  vs  $87 \pm 30$  m,  $P < 0.05$ ) in COPD patients, as well as reducing lactate production ( $2.3 \pm 0.7$  vs  $1.6 \pm 0.7$  mM,  $P < 0.05$ ) (Borghi-Silva et al 2006).

## OTHER USES

### Cancer

Animal studies have reported that L-carnitine can modulate the inflammatory mechanisms via regulation of carnitine palmityl transferase (Liu et al 2011) and human cell line studies have demonstrated inhibition of apoptosis and DNA damage as a result of L-carnitine supplementation (Zaugg et al 2011). As L-carnitine is well known for its role in energy generation by mitochondrial  $\beta$ -oxidation, the utility of supplementary L-carnitine in patients with advanced cancer has been investigated because of L-carnitine deficiency in cancer cachexia and cancer-related fatigue.

In a recent prospective, multicentre, placebo-controlled, randomised and double-blinded study, 72 patients with advanced pancreatic cancer received either 4 g oral L-carnitine or placebo for 12 weeks. At enrolment there were 38 patients in the carnitine-supplemented group and 34 in the control group, and 14 and 12 patients completed the study, respectively and the drop-outs were related to medical issues, not the intervention. The patients in the carnitine-supplemented group were reported to have increased their body mass index by  $3.4 \pm 1.4\%$  compared to the control group, whose body mass index decreased by  $1.5 \pm 1.4\%$  ( $P < 0.05$ ) (Kraft et al 2012). In addition the carnitine-supplemented group was reported to have an improvement in some quality-of-life measures, as determined by European Organisation for Research and Treatment of Cancer (EORTC)-Quality of Life Questionnaire (QLQ)-C30, with a pancreatic cancer-specific module. In addition there was a trend in increased overall survival (median  $519 \pm 50$  days vs  $399 \pm 43$  days) and also reduced hospital stay ( $36 \pm 4$  days vs  $41 \pm 9$  days), although these results were not statistically significant (Kraft et al 2012).

### Neuropathy

The role of acetyl-L-carnitine as a potential neural protective agent has been investigated in cancer treatment-related neuropathy. In a large 24-week placebo-controlled double-blind randomised study of breast cancer, women undergoing adjuvant taxane-based chemotherapy who received acetyl-L-carnitine ( $n = 208$ , 3000 mg/day) were reported to

have a significant increase in chemotherapy-induced peripheral neuropathy by 24 weeks, although there were no differences between the groups at 12 weeks and fatigue levels did not differ either. The study reported that the supplemented group was more likely to have a >5-point decrease in the neurotoxicity component of the FACT-NXT scores (38% vs 28%;  $P = 0.05$ ) (Hershman et al 2013).

In contrast, in a placebo-controlled double-blind RCT of ovarian cancer (OC:  $n = 98$ ) and castration-resistant prostate cancer ( $n = 52$ ) patients receiving sagopilone (16 mg/m<sup>2</sup> intravenously over 3 hours every 3 weeks), the group ( $n = 75$ ) given supplementation of acetyl-L-carnitine (1000 mg every 3 days) reported significantly lower incidence of grade 3 or 4 peripheral neuropathy in the OC group compared to the OC group receiving placebo. However there was no significant difference in duration of neuropathy or overall incidence of peripheral neuropathy (Campone et al 2013).

## Fatigue

### Chronic fatigue syndrome (CFS)

Studies investigating whether people with CFS have lower levels of free L-carnitine have shown contradictory results (Jones et al 2005), and trials using L-carnitine supplementation in CFS have generally produced mixed results (Plioplys & Plioplys 1995, 1997, Soetekouw et al 2000). One RCT did find that 1 g L-carnitine (three times daily) produced a significant clinical improvement, especially between the fourth and eighth week of treatment (Plioplys & Plioplys 1997).

### Fatigue in cancer patients

A number of studies have reported the benefits of oral L-carnitine in patients with chemotherapy-related side effects such as fatigue. In a trial of advanced cancer patients, 76% were found to be carnitine-deficient. In a subset of patients (those whose carnitine levels increase with supplementation) doses up to 3 g/day are deemed to be safe and may reduce fatigue (Cruciani et al 2006).

In a large double-blind, placebo-controlled trial of 376 patients with cancer and fatigue, the change in fatigue was determined in 189 patients who were randomly assigned to 2 g/day of L-carnitine oral supplementation and 187 received a placebo for 4 weeks. The supplemented group resulted in a significant increase in plasma carnitine levels but did not produce a significant change in fatigue levels beyond placebo (L-carnitine:  $-0.96$ , 95% confidence interval [CI]  $-1.32$  to  $-0.60$ ; placebo:  $-1.11$ , 95% CI  $-1.44$  to  $-0.78$ ;  $P = 0.57$ ) (Cruciani et al 2012).

### Fatigue in coeliac disease patients

L-Carnitine blood levels are low in coeliac disease patients most likely due to reduced OCTN2 levels (the specific carnitine transporter). In 60 coeliac disease patients, L-carnitine supplementation (2 g/

day) for 180 days has been shown to be safe and effective in ameliorating fatigue measured by the Scott-Huskisson Visual Analogue Scale for Asthenia compared with placebo ( $P = 0.0021$ ) (Ciacci et al 2007).

### Fatigue in multiple sclerosis

A recent systematic review evaluated the effect of carnitine supplementation on quality of life and symptoms of fatigue in patients with multiple sclerosis-related fatigue; the review included a currently ongoing randomised, placebo-controlled, crossover trial and one completed study which was randomised, active-comparator, crossover in design and conducted over 12 months. In the completed study, 30 patients were exposed to both acetyl-L-carnitine 2 g/day (as two divided doses) and amantadine 200 mg/day (divided as two doses). The effect of carnitine was not clear and therefore it was concluded that at present there is a lack of evidence to support the use of supplemental carnitine for multiple sclerosis-related fatigue (Tejani et al 2012). It is expected that results from ongoing and future studies will provide more data regarding the effects of carnitine supplementation on multiple sclerosis-related symptoms.

### Attention deficit-hyperactivity disorder (ADHD)

In a randomised, double-blind, placebo-controlled double-crossover trial, treatment with L-carnitine (100 mg/kg twice daily, maximum 4 g/day) over 24 weeks significantly decreased attention problems, delinquency and aggressive behaviour in boys with ADHD (Van-Oudheusden & Scholte 2002). At 6-month follow-up 19 of 24 boys had responded to treatment as judged by parents and teachers.

In a 12-month multicentre randomised, double-blind placebo-controlled, parallel study of fragile X syndrome, young boys aged 6–13 years ( $n = 51$ ) with ADHD who were given either L-acetylcarnitine (500 mg twice daily) or a placebo (L-acetylcarnitine supplemented  $n = 24$ ; placebo  $n = 27$ ), improved behaviour was reported in both groups and reduction of hyperactivity. However, improvement of social behaviour was more pronounced in patients treated with L-acetylcarnitine compared with the placebo group (Torrioli et al 2008).

### Diabetes

Only high circulating serum insulin concentrations (90 mU/L) are capable of stimulating skeletal muscle carnitine accumulation (Stephens et al 2007). Carnitine is essential for lipid and carbohydrate metabolism, and correct metabolic control. It has been suggested that some people with diabetes may have reduced levels of total and free carnitine (Mamoulakis et al 2004). Administration of L-carnitine reduces insulin secretion and improves peripheral glucose use (Grandi et al 1997) and tissue insulin sensitivity (Negro et al 1994). Additionally, in type 2 diabetes, L-carnitine (1 g three times daily)

significantly lowers fasting plasma glucose, but may increase fasting triglycerides (Rahbar et al 2005).

In a large 1-year study of obese patients with uncontrolled type 2 diabetes, 258 patients were randomised to receive either orlistat (120 mg, 3 × day) or orlistat (120 mg, 3 × day) with L-carnitine (2 g daily) and the latter group was reported to have improvements in their body weight, blood lipid, inflammatory biomarkers and glycaemic control compared to the group that did not receive L-carnitine (Derosa et al 2011).

In a recent systematic review and meta-analysis evaluating the metabolic effects of L-carnitine supplementation in type 2 diabetes, four trials with 284 patients were included. Oral L-carnitine supplementation was reported to result in improved glycaemia and plasma lipids, although there were no significant changes in triglycerides, lipoprotein-a or HbA<sub>1c</sub> (Vidal-Casariago et al 2013).

### Type 1 diabetes

L-Carnitine (2 g/m<sup>2</sup>/day) in the early stage (stage 1a) of type 1 diabetes may improve nerve conduction velocity, suggesting benefits for the treatment of subclinical neuropathy (Uzun et al 2005).

### Haemodialysis

Carnitine depletion in haemodialysis patients is caused by insufficient carnitine synthesis and excessive loss through the dialytic membranes (Matera et al 2003). Carnitine supplementation has been approved by the US Food and Drug Administration for the treatment and prevention of carnitine depletion in dialysis patients. Supplementation in such patients is said to improve lipid metabolism, protein nutrition, antioxidant status and anaemia, and may reduce the incidence of intradialytic muscle cramps, hypotension, asthenia, muscle weakness and cardiomyopathy (Bellinghieri et al 2003).

In maintenance haemodialysis patients, L-carnitine supplementation (20 mg/kg) has been associated with protein-sparing effects during hyperinsulinaemia (Biolo et al 2008). L-carnitine supplementation (10 mg/kg orally) immediately after haemodialysis sessions three times a week for 12 months induced regression of left ventricular hypertrophy in patients with normal cardiac systolic function undergoing haemodialysis (Sakurabayashi et al 2008).

However, the routine use of L-carnitine in dialysis patients to manage anaemia and refractory dialysis-associated hypotension is contentious and some authors believe that there is insufficient evidence to support this indication (Steinman et al 2003).

In a randomised study of maintenance haemodialysis patients, the effect of L-carnitine supplementation was evaluated in 35 patients regarding lipid parameters, apoproteins (apoprotein A1 and B) and inflammatory (highly sensitive C-reactive protein: hsCRP), and nutritional markers (total protein, albumin). Twenty patients received 1 g/day of L-carnitine supplementation intravenously three

times a week after each session of haemodialysis and 15 patients served as a control group for 6 months. At completion of the study, the carnitine-supplemented group was reported to have a significant decrease in hsCRP levels, with no other significant differences being noted (Suchitra et al 2011).

In a recent study of 30 patients on maintenance haemodialysis, the effect of oral L-carnitine supplementation (750 mg/day; 250 mg tablets three times a day for 8 weeks) was investigated regarding lipid profile and compared with 30 matched patients who served as the control group. At completion of the study period, the carnitine-supplemented group had a significant decrease in total cholesterol (190 ± 36.8 vs 177 ± 31.2 mg/dL), triglyceride (210 ± 64.7 vs 190 ± 54.1 mg/dL) and LDL-cholesterol (117 ± 30.1 vs 106 ± 26.3 mg/dL), although there was no significant change in HDL-cholesterol levels (Naini et al 2012).

A recent systematic review and meta-analysis of 49 RCTs that included 1734 participants investigated the effectiveness of L-carnitine supplementation in adults with end-stage renal disease who required maintenance haemodialysis. This study confirmed the role of carnitine in reducing serum LDL (mean difference: -5.82 mg/dL; 95% CI -11.61 to -0.04 mg/dL) and C-reactive protein (-3.65 mg/L; -6.19 to -1.12 mg/L) levels, but there was no significant change in the required erythropoietin dose or triglyceride, cholesterol and HDL levels. The authors reported the reductions in C-reactive protein and LDL levels to be clinically relevant (Chen et al 2014).

### Hepatitis

A prospective, randomised, open-label study of 69 patients with chronic hepatitis C investigated the effect of supplemental L-carnitine regarding alleviation of anaemia, thrombocytopenia and leucopenia in patients in treatment with interferon-alpha (IFN-α) plus ribavirin. One group of patients (*n* = 35; 30 completed the study) received Peg-IFN-α2b plus ribavirin plus L-carnitine, and the control group (*n* = 34; 27 completed study) received Peg-IFN-α and ribavirin for 12 months. At study completion the L-carnitine-supplemented group demonstrated a significant improvement of sustained virological response in 50% of patients vs 25% of the control group. The study reported a significantly greater decrease in platelets and red and white cells in the Peg-IFN-α plus ribavirin group compared to the Peg-IFN-α plus ribavirin plus L-carnitine group (Malaguarnera et al 2011d).

### Hepatic encephalopathy

Hepatic encephalopathy is a major complication of cirrhosis. A 2008 systematic review suggested that L-acetyl-carnitine is promising as a safe and effective treatment for hepatic encephalopathy (Shores & Keeffe 2008). Human trials have demonstrated a protective effect of L-carnitine (2 g twice daily) in

ammonia-precipitated hepatic encephalopathy in cirrhotic patients at 30 days and, more significantly, at 60 days (Malaguarnera et al 2003).

In a randomised, double-blind, placebo-controlled study the effect of supplementary acetyl-L-carnitine was evaluated in 121 patients with mild ( $n = 61$  total; 31 received 2 g acetyl-L-carnitine and 30 received placebo twice a day for 90 days) and moderate hepatoencephalopathy ( $n = 60$  total; 30 received 2 g acetyl-L-carnitine and 30 received placebo twice a day for 90 days) regarding physical and mental fatigue, fatigue severity and physical activity. The acetyl-L-carnitine-supplemented groups had a significant decrease in mental and physical fatigue, while physical activity levels were also increased (Malaguarnera et al 2011a).

The same authors also reported that acetyl-L-carnitine improves cognitive functions in severe hepatic encephalopathy in a randomised, double-blind, placebo-controlled study of 61 patients with severe hepatic encephalopathy: 31 patients received 2 g acetyl-L-carnitine twice a day for 90 days and 30 patients received a placebo. At completion of the study there was an improvement in electroencephalograms for both patient groups (88% of acetyl-L-carnitine group vs 72% of placebo group), and patients treated with acetyl-L-carnitine were also reported to have significant improvements in cognitive deficits, and a reduction of ammonia compared to the control group (Malaguarnera et al 2011b).

Similarly, in another randomised, double-blind, placebo-controlled study of 67 patients with minimal hepatic encephalopathy, of which 33 were randomly assigned to receive 2 g acetyl-L-carnitine twice a day and 34 patients to receive a placebo for 90 days, the acetyl-L-carnitine group was reported to have a significant improvement in quality-of-life parameters (physical function, role physical, general health, social function, role emotional, mental health), and to be associated with reduction of anxiety and depression (Malaguarnera et al 2011c).

### Inflammatory bowel disease

Short-chain fatty acids (SCFAs) are a major energy source for colonocytes and in ulcerative colitis there is some evidence to indicate that a deficiency of SCFAs may lead to an energy deficit due to impaired beta-oxidation of SCFAs. Studies have reported lower levels of plasma PLC in patients with ulcerative colitis compared to healthy matched controls but similar levels of plasma L-carnitine. It has been proposed that PLC may be serving as a source of L-carnitine and propionyl-coenzyme-A and therefore supplementary PLC may improve cellular energy levels due to the role of L-carnitine in releasing energy as a result of beta-oxidation of fatty acids and propionyl-coenzyme-A as an energy source via the citric acid cycle (Mikhailova et al 2011).

In a recent multicentre, phase II, double-blind, parallel-group study of patients with mild to moderate ulcerative colitis who were receiving stable oral

aminosalicylate or thiopurine therapy, the efficacy of colon release PLC was investigated. Patients ( $n = 121$ ) with disease activity index score 3–10 inclusive were randomised to receive PLC 1 g/day, PLC 2 g/day or placebo. Overall, the majority of patients (57 of 79: 72%) receiving PLC (combined 1 g and 2 g cohort) had a clinical/endoscopic response compared to 50% of patients receiving the placebo (20 of 40) ( $P = 0.02$ ). The PLC doses were similar in their effects, although the 1 g/day dose was the more effective (clinical/endoscopic response in PLC 1 g/day: 30 of 40 [75%];  $P = 0.02$  vs placebo and clinical/endoscopic response in PLC 2 g/day: 27 of 39 [69%];  $P = 0.08$  vs placebo). The rates of remission were greater in the supplemented groups (PLC 1 g/day: 22/40 [55%], PLC 2 g/day: 19/39 [49%], placebo: 14/40 [35%]) (Mikhailova et al 2011).

### Narcolepsy

Narcolepsy patients have been reported to have altered fatty acid beta-oxidation and it has been suggested that supplementary L-carnitine may improve fatty acid oxidation and potentially alleviate symptoms of narcolepsy (Miyagawa et al 2011).

In a randomised, double-blind, crossover, placebo-controlled trial of 16 weeks' duration, 28 narcolepsy patients received 510 mg/day supplemental L-carnitine (as three doses of 170 mg each; two doses were administered in the morning and one dose in the evening) for two 8-week periods; carnitine supplementation resulted in a reduction in excessive daytime sleepiness (Miyagawa et al 2013).

### Rett syndrome

A case is reported of a 17-year-old girl with Rett syndrome whose condition improved while using L-carnitine (50 mg/kg/day). Upon cessation, she relapsed, whereas re-establishing the treatment saw improvements after 1 week. More specifically, alertness increased; she started reaching for objects with both hands, and answered simple questions with one or two words. Interestingly, serum carnitine levels (free and total) were within normal limits before and after L-carnitine treatment (Plioplys & Kasnicka 1993). An 8-week randomised, placebo-controlled, double-blind crossover trial of L-carnitine has since been completed detecting improvements on the Hand Apraxia Scale and in subjects' general wellbeing (Ellaway et al 1999).

### Beta-thalassaemia major

In a small study of regularly transfused and chelated beta-thalassaemia patients ( $n = 40$ ; mean age 17.5  $\pm$  5.0 years) and 10 age-matched controls, L-carnitine levels were assessed. The thalassaemic patients had significantly lower L-carnitine levels (23.71  $\pm$  7.3 microM) as compared to the control group (29.26  $\pm$  2.37 microM) ( $P < 0.0001$ ). Vegetarians also had lower levels compared to non-vegetarians (22.34  $\pm$  6.55 microM vs 26.91  $\pm$  8.4 microM) but the difference was not statistically significant ( $P = 0.072$ ) (Merchant et al 2010).

L-Carnitine appears to be a safe and effective adjunctive therapy in thalassaemia patients, especially younger patients. L-Carnitine therapy (50 mg/kg/day) for 6 months resulted in a significant increase in oxygen consumption, cardiac output and oxygen pulse at maximal exercise ( $P < 0.001$ ,  $P = 0.002$  and  $P < 0.001$ , respectively). There was also a significant increase in the blood transfusion intervals after L-carnitine administration ( $P = 0.008$ ) (El-Beshlawy et al 2007). Additionally L-carnitine (100 mg/kg/day) for 1 month may prevent red blood cell deterioration in beta-thalassaemia major patients (Toptas et al 2006).

### Ageing

In a randomised, double-blind, placebo-controlled trial of 84 elderly subjects (aged 70–92 years) who experienced onset of fatigue after slight physical activity, L-carnitine (2 g twice daily) for 30 days resulted in significant improvements in total fat mass, total muscle mass and lipid profiles, as well as overall improvements in physical and mental fatigue (Pistone et al 2003). Similarly, in a placebo-controlled, randomised, double-blind, two-phase study of 66 centenarians with onset of fatigue even after slight physical activity, L-carnitine (2 g/day)-treated centenarians showed significant improvements compared with the placebo group. Improvements included total fat mass (−1.80 vs 0.6 kg;  $P < 0.01$ ), total muscle mass (3.80 vs 0.8 kg;  $P < 0.01$ ), plasma concentrations of total carnitine (12.60 vs −1.70 micromol;  $P < 0.05$ ), plasma long-chain acylcarnitine (1.50 vs −0.1 micromol;  $P < 0.001$ ), and plasma short-chain acylcarnitine (6.0 vs −1.50 micromol;  $P < 0.001$ ). Significant differences were also found in physical fatigue (−4.10 vs −1.10;  $P < 0.01$ ), mental fatigue (−2.70 vs 0.30;  $P < 0.001$ ), fatigue severity (−23.60 vs 1.90;  $P < 0.001$ ), and Mini-Mental State Examination (4.1 vs 0.6;  $P < 0.001$ ) (Malaguarnera et al 2007).

Animal studies have demonstrated that supplementation of carnitine (300 mg/kg/day) and lipoic acid (100 mg/kg/day) for 30 days protects mitochondria from ageing by raising mitochondrial energy production and reversing the age-associated decline in mitochondrial enzyme activity (Savitha et al 2005). Studies using standard oral doses of L-carnitine in humans are required to confirm these effects.

### Weight loss

Carnitine is a popular supplement for weight loss when combined with an exercise programme. This is based on its biochemical role in the production of energy from fatty acids. Carnitine deficiency impairs fatty acid beta-oxidation and may partly explain weight gain in valproate-treated patients. However, L-carnitine (15 mg/kg/day) for 26 weeks failed to improve weight loss outcomes in valproate-treated bipolar patients consuming an energy-restricted, low-fat diet (Elmslie et al 2006). Currently, one clinical trial that has investigated carnitine

supplementation together with an aerobic training programme failed to detect a significant effect on weight loss (Villani et al 2000).

### DOSAGE RANGE

- Deficiency: L-carnitine 50–200 mg/kg/day.
- Most conditions: L-carnitine 2–4 g/day in divided dose.

Note: Maximum plasma concentration may be achieved at 500 mg. Therefore individual doses exceeding this level may not provide any additional benefits (Bain et al 2006). Larger doses should be divided.

### According to clinical studies

- Cardiovascular disorders: 2 g/day for at least 3 months may improve exercise tolerance and recovery in people with conditions such as chronic stable angina and cardiac insufficiency, and may also reduce lipoprotein-a levels and improve peripheral vascular disease.
- Hyperthyroidism: 2–4 g/day in divided doses.
- Chronic fatigue syndrome: 1 g three times daily.
- Ergogenic aid: 2 g/day.
- Fertility: 2–3 g/day may be useful to increase sperm motility and concentration.
- Peripheral vascular disease: 2 g/day.
- COPD: 2 g/day.
- Thalassaemia (as adjunct): 50 mg/kg/day.
- Ageing (to reduce fatigue): 2 g daily or twice daily.

### ADVERSE REACTIONS

Carnitine is well tolerated at recommended doses. Mild gastrointestinal symptoms including abdominal cramps, diarrhoea, nausea and vomiting, heartburn or gastritis may occur. Mild myasthenia has been reported in uraemic patients using the D,L form (Hendler & Rorvik 2001). Changes in body odour have also been noted (Sigma-Tau Pharmaceuticals 1999, Van-Oudheusden & Scholte 2002).

### SIGNIFICANT INTERACTIONS

#### Anticoagulants

According to one case report, L-carnitine 1 g/day may potentiate the anticoagulant effects of acenocoumarol (also known as nicoumalone or acenocoumarin) (Martinez et al 1993). Use this combination with caution. Monitor bleeding time and signs and symptoms of excessive bleeding.

#### Anticonvulsants (including valproate, phenobarbitone, phenytoin, carbamazepine)

Trials with children and adults have shown a reduction in carnitine levels during anticonvulsant therapy (Hug et al 1991, Rodriguez-Segade et al 1989). A study evaluating carnitine deficiency in children and adolescents with epilepsy found 27.3% taking valproic acid and 14.3% taking carbamazepine showed low free carnitine levels. Polytherapy, female sex, psychomotor or mental retardation and abnormal

neurological examination appeared to increase the risk of hypocarnitinaemia. Patients taking topiramate or lamotrigine or on a ketogenic diet did not appear to be affected (Coppola et al 2006). L-Carnitine deficiency may cause or potentiate valproate toxicity and supplementation is known to reduce the toxicity of valproate, as well as symptoms of fatigue. In a trial using L-carnitine for acute valproate poisoning, no adverse events were noted (LoVecchio et al 2005). Increased carnitine intake may be required with long-term therapy — potentially beneficial interaction under professional supervision.

### Betamethasone

An RCT has shown that a combination of low-dose betamethasone (2 mg/day) and L-carnitine (4 g/5 days) was more effective in the prevention of respiratory distress syndrome (7.3% vs 14.5%) and death (1.8% vs 7.3%) in preterm infants than high-dose betamethasone given alone (8 mg/2 days) (Kurz et al 1993) — beneficial interaction possible under professional supervision.

### Chemotherapy

#### Adriamycin (doxorubicin)

Animal studies suggest long-term carnitine administration may reduce the cardiotoxic side effects of Adriamycin (Kawasaki et al 1996). A small randomised placebo-controlled trial attempted to determine these effects in humans, administering 3 g L-carnitine before each chemotherapy cycle, followed by 1 g L-carnitine/day during the following 21 days to the treatment group. The trial reported no cardiotoxicity in either group and was able to demonstrate stimulation of oxidative metabolism in white blood cells through carnitine uptake (Waldner et al 2006). Increased carnitine intake may be required with long-term therapy — potentially beneficial interaction, only under professional supervision.

#### Carboplatin

Treatment with carboplatin appears to result in marked urinary losses of L-carnitine and acetyl-L-carnitine, most likely due to inhibition of carnitine reabsorption in the kidney (Mancinelli et al 2007).

#### Cisplatin

Research into the use of L-carnitine 4 g/day for 7 days showed a reduction in fatigue resulting from treatment with cisplatin (Graziano et al 2002) — beneficial interaction is possible under professional supervision.

### HIV drugs (zidovudine)

In vitro studies indicate prevention of muscle damage due to carnitine depletion (Dalakas et al 1994, Moretti et al 2002, Semino-Mora et al 1994). Patients with HIV infection undergoing highly active antiretroviral therapy can be carnitine-deficient and supplementation of L-carnitine has

been proposed to ‘increase the number of CD4 cells and reduce lymphocyte apoptosis; improve symptoms of polyneuropathy; prevent cardiovascular damage from wasting and diarrhoea syndromes; decrease serum levels of triglycerides and TNF(alpha)’ (Ilias et al 2004). Beneficial interaction is possible. Increased carnitine intake may be required with long-term therapy — use under professional supervision.

### HMG CoA-reductase inhibitors (statins)

According to human trials the addition of L-carnitine (2 g/day) to simvastatin therapy (20 mg/day) appears to lower lipoprotein-a serum levels in patients with type 2 diabetes mellitus (Solfrizzi et al 2006). Beneficial interaction possible.

### Interferon-alpha

Clinical trials with patients being treated with IFN-alpha for hepatitis C observed reduced fatigue when carnitine 2 g/day was co-administered (Neri et al 2003). L-Carnitine may reduce hepatic steatosis associated with IFN-alpha and ribavirin treatment in patients with hepatitis C (Romano et al 2008). Increased carnitine intake may be required with long-term therapy — potentially beneficial interaction under professional supervision.

### Interleukin-2 immunotherapy

Clinical trials using L-carnitine (1 g/day orally) found that it may be used successfully to prevent

## CONTRAINDICATIONS AND PRECAUTIONS

- Chronic liver disease — may impair metabolism or increase biosynthesis of L-carnitine (Krahenbuhl 1996).
- Seizures — may increase incidence of seizures in those with a pre-existing condition (Sigma-Tau Pharmaceuticals 1999).

## PREGNANCY USE

Insufficient reliable information is available. However, animal studies have revealed no evidence of decreased fertility or harm to the fetus (Hendler & Rorvik 2001). In fact, some research suggests a role for carnitine.

Requirements for carnitine may increase during pregnancy and a small trial found a positive effect in women diagnosed with placental insufficiency taking 1 g L-carnitine twice daily (Genger et al 1988). Due to the role of L-carnitine in the synthesis of surfactant, trials have also been conducted using L-carnitine in combination with low-dose betamethasone in women with imminent premature delivery, with an improvement in respiratory distress syndrome and mortality rates (Kurz et al 1993).

cardiac complications during IL-2 immunotherapy in cancer patients with clinically relevant cardiac disorders (Lissoni et al 1993). Thus a beneficial interaction is possible under professional supervision.

### Practice points/Patient counselling

- Carnitine is an amino acid that is ingested through the diet and also synthesised from lysine and methionine in the body.
- It is involved in numerous biochemical processes and is essential for energy production in the mitochondria of every cell.
- Vegetarians, and preterm infants or those on a carnitine-free formula, are at risk of deficiency. Secondary risk factors include genetic defects of metabolism, liver and renal disease, dialysis, certain medicines and hypopituitarism.
- L-Carnitine 2 g/day for 3 months has been shown to improve exercise tolerance and recovery, especially in people with cardiovascular disorders such as chronic stable angina and cardiac insufficiency. Preliminary evidence also suggests a possible role in hyperthyroidism, male infertility and peripheral vascular diseases such as intermittent claudication.
- Carnitine supplements are also used to promote weight loss and as an ergogenic aid, although large controlled studies are unavailable to assess their effectiveness.

### ! PATIENTS' FAQs

#### What will this supplement do for me?

L-Carnitine supplements improve clinical outcomes in people with cardiovascular disorders by reducing the frequency of angina attacks, and improving outcomes after heart attack, cardiogenic shock and in cardiomyopathy. It may also reduce symptoms in hyperthyroidism, increase male fertility, increase walking distance in people with peripheral vascular disease and reduce the side effects of some medicines.

#### When will it start to work?

People with cardiovascular disorders such as chronic stable angina and cardiac insufficiency should experience benefits within 1–3 months.

#### Are there any safety issues?

Carnitine is well tolerated, but people with chronic liver disease or epilepsy should use it with caution.

## Celery

**HISTORICAL NOTE** Celery is widely used as a food. The ancient Greeks used celery to make a wine called selinites, which was served as an award at athletic games. Dioscorides described celery as an effective remedy for 'heated stomach' and breast lumps and used it as a diuretic for urinary retention and dropsy.

### OTHER NAMES

Smallage, marsh parsley, wild celery

### BOTANICAL NAME/FAMILY

*Apium graveolens* (family Umbelliferae [Apiaceae])

### PLANT PART USED

Fruit (seed)

### CHEMICAL COMPONENTS

Celery is high in minerals, including sodium (Murphy et al 1978), and contains furocoumarins such as psoralen and bergapten (Beier et al 1983). The major constituents of celery seed oil include pinene and D-limonene (Saleh et al 1985). Celery also contains flavonoids, such as apigenin, luteolin and isoquercitrin, and phenolic acids and alkaloids (Fisher & Painter 1996).

### MAIN ACTIONS

#### Anti-inflammatory activity

An ethanol extract of aerial celery parts has been found to have anti-inflammatory activity, with suppression of carrageenan-induced paw oedema observed in rats (Al-Hindawi et al 1989). Several constituents show anti-inflammatory activity, such

as apigenin, eugenol, ferulic acid, luteolin, bergapten and apiin (Duke 2003, Mencherini et al 2007, Ovodova et al 2009, Ziyen et al 2007). Studies in rats suggest that some celery seed extracts are highly effective in suppressing experimental arthritis without exhibiting any gastrotoxicity (Whitehouse et al 1999). Further in vivo studies suggest that celery seed extracts were gastroprotective for non-steroidal anti-inflammatory drug (NSAID) gastropathy and that this effect is mediated through non-prostaglandin mechanisms (Whitehouse et al 2001). Luteolin may also be useful for mitigating neuroinflammation (Jang et al 2008).

#### Cholagogue

Aqueous celery extract has also been found to increase bile acid excretion and lower total serum cholesterol levels in genetically hypercholesterolaemic rats (Tsi & Tan 2000).

#### Chemoprotective

Human in vivo trials imply that apiaceous vegetable intake may be chemopreventive by inhibiting cytochrome P450-mediated carcinogen activation (Peterson et al 2006). Based on in vivo studies in mice, it has been suggested that the phthalide components of celery may be effective chemoprotective agents (Zheng et al 1993). Other studies show that celery consumption, in particular due to its flavones luteolin and apigenin (Lim do et al 2007, Meeran & Katiyar 2008), has been linked to a reduced risk

of developing colon cancer (Slattery et al 2000), stomach cancer (Haenszel et al 1976), liver cancer (Sultana et al 2005) and lung cancer (Galeone et al 2007).

### Antioxidant

There are a number of studies providing evidence of the antioxidative effects of some constituents in celery (Popovic et al 2006, Yeh & Yen 2005, Zidorn et al 2005).

### Lipid-lowering activity

One study of vegetables, including celery, showed that cooking enhanced the amount of phytosterols which are known to decrease plasma cholesterol, mainly the atherogenic low-density lipoprotein cholesterol (Kaloustian et al 2008). In vivo studies of aqueous celery extract on rats showed a significant reduction in total serum cholesterol (Tsi et al 1995, 1996). A significant reduction in total serum cholesterol has been observed in several in vivo studies in rats, which used either aqueous celery extract or diets supplemented with celery leaf (El-Mageed 2011, Tsi et al 1995, 1996).

### Hepatoprotective

An in vivo study using *Pangasius sutchi* freshwater fish found that celery leaf powder reduced hepatotoxic markers aspartate transaminase, alanine aminotransferase and alkaline phosphatase and abnormal liver histology following paracetamol-induced liver damage (Shivashri et al 2013).

### Protection against plasticiser toxicities

In animal studies, a 6-week treatment with celery seed oil extract was found to ameliorate the toxic effects of di (2-ethylhexyl) phthalate, which included normalising of lipid profiles and liver function, reduction of peroxisome proliferator-activated receptor- $\alpha$  expression, and reduced vascular oxidative stress (El-Shinnawy 2013). Another in vivo study showed celery oil pretreatment partially prevented changes to testicular weight, sperm parameters and sperm hormone levels induced by di (2-ethylhexyl) phthalate (Madkour 2012).

### Testicular protection

Pretreatment of rats with celery oil prevented sodium valproate-induced reductions in testes weight, sperm count and sperm motility (Hala 2011). As previously mentioned, celery oil pretreatment partially prevented di (2-ethylhexyl) phthalate-induced testicular toxicities, including changes in weight and sperm parameters (Madkour 2012).

### OTHER ACTIONS

Celery is said to have antirheumatic, carminative, antispasmodic, diuretic, antihypertensive and urinary antiseptic activity. An in vivo study in rats identified that celery seed extracts had antihypertensive properties, which correlated with *n*-butylphthalide content (Moghadam et al 2013). Celery extracts

have also been found to have significant activity as a mosquito repellent (Pitasawat et al 2007, Tuetun et al 2004, 2005, 2008). Research has shown that the flavones and coumarins, as well as the nutritional compounds, of vegetables, including celery, have immunomodulatory functions (Cherng et al 2008). Some antimicrobial activity is also reported from in vitro studies of the essential oil component (Misic et al 2008), while other studies show celery extracts to be ineffective against Gram-negative bacteria (Watt et al 2007). In vitro tests reveal the flavone apigenin has multiple effects on osteoblasts, suggesting that it could prevent bone loss in vivo (Bandyopadhyay et al 2006) and be a useful pharmacological tool for the treatment of osteoporosis (Choi 2007).

### CLINICAL USE

Celery has not been significantly investigated under clinical trial conditions, so evidence is mainly derived from in vitro and animal studies and is largely speculative.

#### Osteoarthritis

Evidence of anti-inflammatory activity in experimental models provides a theoretical basis for its use; however, controlled trials are not available to determine effectiveness.

A small uncontrolled trial of 15 patients with chronic arthritis found that treatment with celery seed extract significantly reduced pain symptoms after 3 weeks (Bone 2003).

#### Urinary tract infection

Celery is used in combination with other herbal medicines for the treatment of this condition. Although it is not certain that the herb has antibacterial activity against microorganisms implicated in urinary tract infection, it is used for its diuretic effect.

### OTHER USES

#### Traditional

Celery has been traditionally used as a diuretic, to improve appetite and digestion, and as a treatment for nervousness and hysteria. The British Herbal Pharmacopoeia gives the specific indication of celery for rheumatoid arthritis and depression (Fisher & Painter 1996).

Oriental medicine uses the seeds to treat headaches and as a digestive aid and emmenagogue.

In Trinidad and Tobago, celery is used as a heart tonic and for low blood pressure (Lans 2006); while in some parts of Indonesia it is one of a number of kitchen plants used in saunas for postpartum recuperation (Zumsteg & Weckerle 2007).

Animal studies on isolated constituents from celery have been found to be valuable in the treatment of acute ischaemic stroke via multiple mechanisms, such as strong antioedema activity (Deng et al 1997) as well as antioxidation, antiapoptosis

and anti-inflammatory actions (Chang & Wang 2003). Animal studies also demonstrate that the phthalide components improve cognitive impairment induced by chronic cerebral hypoperfusion, indicating its therapeutic potential for the treatment of dementia caused by decreased cerebral blood flow (Peng et al 2007).

### DOSAGE RANGE

- Fluid extract (1:2): 4.5–8.5 mL/day in divided doses.
- Decoction of dried fruit: 0.5–2 g three times daily.

### TOXICITY/ADVERSE REACTIONS

Celery can cause food allergy (Luttkopf et al 2000), with cross-reactivity to a number of other foods (Moneret-Vautrin et al 2002, Vieths et al 2002). One incidence of severe anaphylaxis following celery ingestion has been reported (Palgan et al 2012). Topical exposure to celery may cause contact dermatitis, angio-oedema and urticaria (Kauppinen et al 1980). Photodermatitis has been recorded with occupational exposure (Seligman et al 1987) and celery has been suggested to cause ocular phototoxicity (Fraunfelder 2004).

### SIGNIFICANT INTERACTIONS

Controlled studies are not available, so interactions are based on evidence of activity and are largely theoretical and speculative.

### NSAIDs

Celery seed extract may reduce gastrointestinal symptoms associated with NSAIDs — beneficial interaction possible.

### Pentobarbitone

Celery juice has been found to prolong the action of pentobarbitone in rats (Jakovljevic et al 2002) — use with caution.

### Thyroxine

Celery seed might decrease the effects of levothyroxine replacement therapy according to one case report — observe patient.

### Sodium valproate

In animal studies celery was found to have a protective effect against sodium valproate's well-established toxicity to the testes and sperm production (Hamza & Amin 2007).

### Psoralen-UVA (PUVA) therapy

Although celery has been found to contain psoralens, celery extract does not seem to be photosensitising, even after ingestion of large amounts; however, it may increase the risk of phototoxicity with concurrent PUVA therapy (Gral et al 1993) — use with caution.

### Practice points/Patient counselling

- Celery has been traditionally used as a diuretic. It is used to treat osteoarthritis and demonstrates anti-inflammatory activity in experimental models. Celery is likely to be safe when used in quantities commonly used in foods; however, there is the possibility for allergy and contact sensitivity.
- It is prudent to avoid using celery seed essential oil in amounts greater than those ingested when used as a food.

### CONTRAINDICATIONS AND PRECAUTIONS

Usual dietary intakes are likely to be safe.

### PREGNANCY USE

Safe when consumed in dietary amounts; however.

## Chaste tree

**HISTORICAL NOTE** Chaste tree fruits and leaves were a popular remedy in ancient Greece and Rome to promote celibacy. Leaves of the chaste tree were worn by vestal virgins in ancient Rome as a symbol of chastity. In the 17th century it was written that the chaste tree is a ‘remedy for such as would willingly live chaste’ (Gerard 1975). The dried fruits of the chaste tree have a peppery taste and smell and were used in place of pepper in monasteries to ‘check violent sexual desires’, hence one of its common names, monk’s pepper. The berries have also been used to reduce fever and headaches, stimulate perspiration and dispel wind. However, since ancient times the chaste tree has primarily been used for a variety of gynaecological purposes, primarily to treat menstrual abnormalities and mastalgia, to aid in expulsion of the placenta after birth, to facilitate lactation and to promote menstruation. A commercial preparation of chaste tree has been available in Germany for over 50 years and it is still commonly used for menstrual irregularities.

**OTHER NAMES**

*Vitex agnus castus*, chasteberry, monk's pepper, gattilier, hemp tree, Keusch-Lamm-Fruechte, wild pepper.

**BOTANICAL NAME/FAMILY**

*Vitex agnus-castus* (family Labiatae)

**PLANT PART USED**

Dried, ripened or fresh ripe fruits (berries)

**CHEMICAL COMPONENTS**

*Vitex agnus-castus* contains many different chemical constituents: 10 flavonoids (including luteolin-like flavonoids casticin, orientin, isovitexin), five terpenoids (viteagnusins A–E), three neolignans and four phenolic compounds, as well as one glyceride, essential fatty acids (linoleic acid) and the essential oils cineole, limonene and sabinene. The phenolic and flavonoid compounds confer antioxidant and antimicrobial activity. Apigenin, 3-methylkaempferol, luteolin and casticin are weak ligands of delta and mu-opioid receptors, exhibiting dose-dependent receptor binding (Chen et al 2011, Ono et al 2008, Sarikurkcu et al 2009, Stojkovic et al 2011). Casticin is a potent immunomodulatory and cytotoxic compound (Mesaik et al 2009). Several secondary metabolites exhibit significant anti-inflammatory and lipo-oxygenase inhibition activity (Choudhary et al 2009).

**MAIN ACTIONS**

*Vitex* displays multiple mechanisms of action identified through in vitro and experimental model research.

One major area of activity is the pituitary–hypothalamic axis.

**Decreases prolactin release**

The most thoroughly studied mechanism for *vitex* is its interaction with dopamine receptors in the anterior pituitary. Several studies have indicated that *vitex* acts on dopamine D<sub>2</sub> receptors and decreases prolactin levels (Berger et al 2000, Halaska et al 1998, Jarry et al 1994, Meier & Hoberg 1999, Meier et al 2000, Milewicz et al 1993, Sliutz et al 1993, Wuttke et al 2003). It is likely that this mechanism is responsible for the symptom-relieving effects seen with *vitex* in mastodynia and hyperprolactinaemia (Meier & Hoberg 1999, Milewicz et al 1993, Wuttke et al 1997) and provides some rationale for its use by herbalists in disorders complicated by hyperprolactinaemia, such as amenorrhoea, mastalgia or polycystic ovarian syndrome.

Results from one study involving healthy males propose that this effect is dose-dependent, as lower doses (120 mg) were found to increase secretion and higher doses (204–480 mg) were found to decrease secretion (Merz et al 1996).

A study using the *vitex* extract BNO 1095 (70% ethanol, 30% H<sub>2</sub>O extract, Bionorica, Neumarkt, Germany) identified that the major dopaminergic compounds are the clerodadienols, which act as potent inhibitors of prolactin release; however, other active compounds of lesser activity were also identified (Wuttke et al 2003). Dopaminergic

bicyclic diterpenes have also been isolated that inhibit cAMP formation and prolactin release in rat pituitary cell cultures (Jarry et al 2006).

**Oestrogen receptor binding**

*Vitex* contains oestrogenic compounds, the flavonoids penduletin and apigenin. There are inconsistent results on whether *vitex* competitively binds to oestrogen receptors alpha and beta in vitro (Cavieres & Castillo 2011, Jarry et al 2003, Liu et al 2001, Wuttke et al 2003).

**Increases progesterone levels**

In vitro research has found that *vitex* stimulates progesterone receptor expression (Liu et al 2001), significantly increases plasma progesterone and total oestrogen levels and significantly reduces luteinising hormone (LH) and plasma prolactin (Ibrahim et al 2008). A randomised controlled trial of women with hyperprolactinaemia showed that *vitex* extract (20 mg daily) normalises progesterone levels after 3 months' treatment (Milewicz et al 1993).

**Opioid receptors**

Recent research reported that a methanol extract of *vitex* had affinity to the mu-opioid and delta-opioid (but not kappa-opioid) receptors (Webster et al 2011). Of note, the mu-opiate receptor is the primary action site for beta-endorphin in vivo, a peptide which assists in regulating the menstrual cycle through inhibition of the hypothalamus–pituitary–adrenal axis.

**Cytotoxic activity**

Cytotoxic activity has been reported for an ethanolic extract of the dried ripe fruit of *vitex* against various human cancer cell lines (Imai et al 2009, Ohyama et al 2003, 2005, Weisskopf et al 2005). The extract increased intracellular oxidative stress and mitochondrial damage, leading to apoptosis. In vitro studies demonstrate that *vitex* extract inhibits the proliferation of human prostate epithelial cell lines via apoptosis (Weisskopf et al 2005) and induces apoptosis in human colon carcinoma cell lines (Imai et al 2009).

**OTHER ACTIONS**

Conflicting results have been obtained in studies with regard to the effect on follicle-stimulating hormone (FSH), LH and testosterone levels. In vivo research suggests that *vitex* significantly decreases LH and testosterone levels (Nasri et al 2007). However, one clinical study found that *vitex* extract did not alter FSH or LH levels, whereas another showed that it increased LH release (Lauritzen et al 1997, Milewicz et al 1993). Inconsistent clinical results may be due to variations in chemical constituent levels present in the different test herbal products.

In vivo research on male rats demonstrated osteoprotective effects (Sehmisch et al 2009).

**CLINICAL USE**

Although double-blind studies have recently been conducted with chasteberry, uncontrolled trials go

back to the 1940s, when a product known as Agnolyt was tested. The product was developed and patented by Dr Gerhard Madaus in Germany and contained *Vitex agnus-castus*. Several different vitex products have been investigated to date, including: Agnolyt (standardised to 3.5–4.2 mg of dried chaste-berry extract), *Vitex agnus-castus* L. extract Ze440 (each 20 mg tablet standardised for casticin and agnuside), Femicur (contains 1.6–3.0 mg of dried extract per capsule) and Mastodynon (53% v/v ethanol), a homeopathic preparation. The BNO 1095 extract contains 4.0 mg of dried ethanolic (70%) extract of vitex (corresponding to 40 mg of herbal drug) and is found in Agnucaston/Cyclodynon (Bionorica, Neumarkt, Germany).

### Premenstrual syndrome

Vitex is an effective and well-tolerated treatment for mild, moderate and severe premenstrual syndrome (PMS) according to numerous clinical trials (Atmaca et al 2003, Berger et al 2000, Dittmar 1992, He et al 2009, Lauritzen et al 1997, Loch et al 2000, Schellenberg 2001, Schellenberg et al 2012, Zamani et al 2012). According to these studies, the PMS symptoms that respond best to treatment are breast tenderness, irritability, depressed mood, anger, mood changes, headache and constipation. The most studied extract investigated in PMS is Ze440 and, more recently, BNO 1095 extract (see Clinical note).

A recent systematic review evaluated the evidence for the efficacy and safety of vitex extracts from randomised controlled trials investigating women's health. Of the 12 trials included in this review, eight investigated PMS. Seven of the eight trials found vitex extracts to be superior to placebo (five of six studies), pyridoxine (one study) and magnesium oxide (one study). Additionally, adverse events with vitex were mild and generally infrequent (van Die et al 2013). A Cochrane review investigating the use of *Vitex agnus-castus* for the treatment of PMS symptoms is currently underway (Shaw et al 2011).

The most recent double blind study was conducted with 162 women and tested three different doses : Ze 440 (8, 20 and 30 mg) over three menstrual cycles. Improvement in the total symptom score (TSS) in the 20 mg group was significantly higher than in the placebo and 8 mg treatment group. The highest dose of 30 mg did not significantly decrease symptom severity compared to the 20 mg treatment, providing a rationale for the usage of 20 mg daily as the effective dose (Schellenberg et al 2012).

Two prospective randomised double-blind placebo-controlled studies investigating efficacy of vitex extract (BNO 1095) in the treatment of Chinese women suffering moderate to severe PMS ( $n = 67$  and  $n = 217$ , respectively) found that vitex significantly ameliorated all symptoms except abdominal cramping, and especially improved negative affect (depressed mood) and fluid retention. In the treatment arm, there was a significantly greater decrease in depressive symptoms in the luteal phase

and PMS self-assessment compared to placebo after two menstrual cycles, with the differences between placebo and active treatment groups becoming even more significant after 3 months' treatment. This further supports the use of vitex in PMS and indicates that full benefit requires at least three menstrual cycles to become established. Of note, these studies found a placebo effect of 50%, but still a significantly greater effect of vitex (He et al 2009, Ma et al 2010).

A multicentre, randomised, controlled, double-blind study investigating the effects of vitex (Ze440) for PMS involved 170 women and was published in the *British Medical Journal* (Schellenberg 2001). Of the group, 13% were also taking oral contraceptive pills (OCP). Treatment with a 20-mg tablet of dry extract of chasteberry taken daily resulted in a significant improvement of PMS symptoms, particularly headache, breast fullness, irritability, anger and mood changes. Over 50% of women in the active treatment group achieved at least a 50% reduction in symptoms. Similar results were obtained in a 2006 prospective, open, non-comparative study of 121 women with moderate to severe PMS who took vitex (BNO 1095) over three menstrual cycles. Assessment using the validated PMS diary and the premenstrual tension syndrome score showed that the severity of PMS symptoms consistently decreased during treatment (Prilepskaya et al 2006).

Another three-arm double-blind study of women with premenstrual dysphoric disorder ( $n = 108$ ), compared 20–40 mg fluoxetine, 20 mg vitex or multivitamin placebo for 6 months. Women in both treatment arms showed significant improvement on the Hamilton Depression Rating Scale ( $P < 0.001$  and  $P < 0.05$  respectively) compared with placebo, and the vitex group demonstrated no side effects (Ciotta et al 2012).

Previously, a number of open studies had generally produced positive results for vitex as a symptomatic treatment in PMS. One multicentre, open-label study showed that daily treatment with a 20-mg tablet of vitex (Ze440) over three menstrual cycles significantly reduced the Moor menstrual distress self-assessment questionnaire (MMDQ), with 46% of women experiencing a 50% reduction in the MMDQ. Treatment also reduced the duration of PMS symptoms from 7.5 days to 6 days and was as effective for women taking OCP as for those who were not (Berger et al 2000). Once treatment was stopped, PMS symptoms gradually returned to baseline within three further cycles.

The largest multicentre trial was an open study of 1634 women with PMS, which found that treatment with vitex (Femicur) for three menstrual cycles decreased the number of PMS symptoms in 93% of subjects (Loch et al 2000). Symptoms completely resolved in 40% of subjects and 94% overall rated vitex treatment as well tolerated. An early study using vitex (Agnolyt) in 1542 women with PMS reported an improvement in symptoms with an average dose of 42 drops daily taken for an average of 25 days (Dittmar 1992, as reported in

Ulbricht & Basch 2005). According to Ulbricht and Basch (2005), three earlier uncontrolled studies produced inconclusive results.

An open-label clinical trial of 100 women with PMS and migraine headaches was conducted using 40 mg/day vitex extract over a 3-month period. Sixty-six women reported a dramatic reduction of PMS symptoms, 26 a mild reduction, with no effect in eight of the trial participants. Forty-two women experienced greater than 50% reduction in frequency of premenstrual migraine. No patients reported side effects. While this was not a placebo-controlled trial, it points to vitex being a safe and effective treatment for women with premenstrual migraine headaches: the frequency and duration of migraine attacks were reduced (Ambrosini et al 2013).

#### **Clinical note — The opiate system and PMS**

The opiate system consists of mu, delta and kappa opiate receptors and endogenous opiate peptides such as beta-endorphin (Webster et al 2006). The opiate system plays an essential role in regulating tonic pain perception, mood, appetite and other functions. PMS is characterised by a reduction of opiate activity and the severity of symptoms such as anxiety, food cravings and physical discomfort is inversely proportional to the amount of decline in beta-endorphin levels in the luteal phase. Based on recent research, the symptom-relieving effects of vitex in PMS may be due to direct activation of analgesic and mood-regulatory pathways via opiate receptor activation and/or reversal of the loss of opiate inhibition in the luteal phase.

#### **Clinical note — Ze440 extract**

The naming of the Ze440 extract (Premular in Australia) is derived from the name Zeller, the 150-year-old Swiss company manufacturing it, combined with a unique number ascribed during the initial studies. In order to ensure that products deliver consistent results, Ze440 is measured by both composition and consistency from batch to batch. To promote product uniformity, every batch is grown, harvested and manufactured into tablets under controlled conditions and is extracted in a standardised method that ensures consistent and high levels of the important lipophilic compound casticin and an established marker compound, the iridoid glycoside, named agnuside. A daily dose of 20 mg (equivalent to one tablet) has demonstrated effectiveness (Schellenberg et al 2012).

#### **IN COMBINATION**

A 2008 Australian study investigated the effects of a combination of *Vitex agnus-castus* (equivalent to 1000 mg dry fruit) and *Hypericum perforatum* (St John's wort) on PMS-like symptoms in a small subpopulation of

late perimenopausal women participating in a double-blind, placebo-controlled, randomised trial on menopausal symptoms. Of 100 volunteers recruited to the larger study, 14 late perimenopausal women who had menstruated at least once within the last 12 weeks of the treatment phase provided data for PMS-like symptoms. This herbal combination was found to be superior to placebo for total PMS-like symptoms and the subclusters, PMS-D (depression) and PMS-C (cravings) (van Die et al 2009a).

#### **Comparison to SSRI drugs**

A systematic review of herbal treatments for alleviating premenstrual symptoms looked at four clinical trials of vitex and found it had significant efficacy for relieving physical symptoms of PMS, but lesser effectiveness compared with fluoxetine for treating the psychological symptoms of premenstrual dysphoric disorder and a similar incidence to placebo of self-limiting minor adverse reactions (nausea, headaches) (Dante & Facchinetti 2011). In 2003, a randomised 8-week study involving 42 women compared the effects of 20–40 mg daily of fluoxetine, a selective serotonin reuptake inhibitor (SSRI), and 20–40 mg of vitex extract and found no statistically significant difference between the groups with respect to the rate of responders (Atmaca et al 2003). More specifically, patients with premenstrual dysphoric disorder responded well to both treatments; however, fluoxetine was more effective for psychological symptoms such as depression and irritability, whereas the herbal extract was more effective for diminishing physical symptoms such as breast tenderness, cramps, food cravings and swelling. Unfortunately, the authors did not report the type of vitex extract used in the study.

#### **Comparison to vitamin B<sub>6</sub>**

Although vitamin B<sub>6</sub> (pyroxidine) is a popular treatment for PMS symptoms, the results from a double-blind comparative study have found that vitex (Agnolyt) is as effective, and possibly more so (Lauritzen et al 1997). The randomised, double-blind study of 175 women compared vitex, pyridoxine and placebo. In the study, 77% of women receiving vitex reported symptom alleviation compared with 61% with pyridoxine (200 mg/day), which was considered a small but significant difference. Additionally, doctors' assessments were more likely to rate treatment with vitex as 'excellent' compared with pyridoxine.

Commission E approves the use of vitex for PMS.

#### **Mastalgia**

Mastalgia is considered to relate to latent and increased basal prolactin levels; therefore, agents that reduce prolactin levels are anticipated to reduce symptoms. Vitex is a popular treatment for cyclical mastalgia as it interacts with dopamine D<sub>2</sub> receptors to reduce prolactin levels.

In two randomised, double-blind studies, vitex (*Mastodynon*) effectively reduced premenstrual mastalgia (Halaska et al 1998, Wuttke et al 1997, Wuttke et al 2003). Subjects completed a visual analogue scale and rated their breast pain from 0 (lowest breast pain) to 10 (extremely strong breast pain). Active treatment reduced the mastalgia score by 35–40%, an effect significantly stronger than that of placebo (25%). One of these studies also demonstrated that treatment with vitex reduced serum prolactin levels (Wuttke et al 1997, as reported in Wuttke et al 2003). According to Halaska et al (1998), symptom relief was experienced after the first month of treatment, with continued improvements experienced after the second and third months.

Commission E approves the use of vitex for this indication.

### Irregularities of the menstrual cycle

Vitex is used to normalise menstruation in women with shortened, lengthened or infrequent menstruation, particularly when low progesterone and luteal-phase defects are suspected. In practice, vitex has also been used traditionally to treat both amenorrhoea and menorrhagia. Herbalists speculate that beneficial effects obtained in practice may be due to the herb's ability to reduce elevated prolactin levels in these conditions. This is particularly indicated where chronic stress is also present, as this has an effect on the hypothalamus–pituitary axis, resulting in elevated prolactin levels (Mills 2000, Trickey 1998). While the use of vitex in all these indications has not yet been tested under double-blind conditions, one randomised controlled trial of women with luteal-phase defect due to latent hyperprolactinaemia demonstrated that vitex extract (20 mg daily) effectively reduced prolactin levels and normalised luteal-phase length and progesterone levels after treatment for 3 months (Milewicz et al 1993).

Commission E approves the use of vitex for this indication.

### Menopause

Vitex has only recently been utilised for menopause-related complaints. Based on pharmacological studies and clinical research, there is emerging support for its role in the alleviation of menopausal symptoms (van Die et al 2009c). While evidence from rigorous randomised controlled trials is lacking for the use of vitex as an individual herb in this context, further investigation is warranted.

### IN COMBINATION

Vitex has been studied as part of several different polyherbal treatments for effectiveness in treating menopausal symptoms. The use of herbal combinations reflects real-world practice but makes it difficult to assess the value of vitex as a stand-alone treatment for this indication. To date, these studies using combination herbal therapy, including vitex, have produced mixed results.

A systematic review assessed the effectiveness of a combination of vitex and St John's wort versus placebo and found no significant differences in measured end points, including vasomotor symptoms, somatic complaints, sleep disorders, sexual disorders or mental disorders, with side effects comparable between the two (Laakmann et al 2012). It has been suggested, however, that some of the symptoms typically attributed to menopause may be more related to PMS in some women and, in these cases, the vitex and St John's wort combination could provide some relief (van Die et al 2009b).

Vitex (200 mg daily), in combination with other herbs, notably black cohosh, produced a significantly superior mean reduction in menopausal symptoms compared to placebo according to a 2007 randomised controlled study (Rotem & Kaplan 2007). The study of 50 healthy pre- and postmenopausal women found herbal treatment improved menopausal symptoms gradually and, after 3 months of treatment, there was a 73% decrease in hot flushes and a 69% reduction in frequency of night sweats, accompanied by a decrease in their intensity and a significant benefit in terms of sleep quality. Importantly, hot flushes ceased completely in 47% of women in the study group, compared with only 19% in the placebo group. No changes were detected for vaginal epithelium or levels of relevant hormones (oestradiol, FSH), liver enzymes or thyroid-stimulating hormone in either group.

### Poor lactation

Vitex has been used since ancient times as a galactagogue to promote milk production, especially in the first 10 days after delivery.

Currently, there are no double-blind studies to confirm its efficacy; however, an early uncontrolled study provides some support for the use of vitex in lactation, finding a favourable effect on milk production in 80% of women (Noack 1943). Results from a small study of males suggest that increases in prolactin may be possible with low-dose vitex (120 mg daily), whereas higher doses (480 mg daily) result in decreased levels (Merz et al 1996).

### Fertility disorders

Vitex is used in practice with other herbal medicines to enhance fertility in women with progesterone deficiency or luteal-phase defects. Currently, no large studies have been published to evaluate the effectiveness of this approach; however, a double-blind, randomised, placebo-controlled study of 96 women with fertility disorders (38 with secondary amenorrhoea, 31 with luteal insufficiency and 27 with idiopathic infertility) used the vitex product *Mastodynon*, with encouraging results (Gerhard et al 1998). Treatment of 30 drops was administered twice daily for 3 months and resulted in women with amenorrhoea or luteal insufficiency achieving pregnancy more than twice as often as the placebo group, with 15 women conceiving during the study period ( $n = 7$  with amenorrhoea,  $n = 4$  with idiopathic infertility,  $n = 4$  with luteal insufficiency). Although promising, this study has been criticised

for pooling of diverse conditions, unclear reporting of results and variable significance (Ulbricht & Basch 2005).

### Acne vulgaris

An open study of 117 subjects (male and female) with different forms of acne found that, after 6 weeks' treatment with a 0.2% dried extract of *Vitex agnus-castus* and a topical disinfectant, 70% of cases experienced total resolution, with the highest success rates reported for acne vulgaris, follicularis and excoriated acne (Amann 1975). A group that was not treated with the herb took 30–50% longer to achieve similar results. Although encouraging, it is difficult to determine the contribution of vitex treatment to these results. Until controlled studies using vitex as a stand-alone treatment are conducted, the herb's role in this condition is still uncertain.

### OTHER USES

Vitex is used to aid the expulsion of the placenta after birth. It is also used to treat fibroids, to normalise hormones following the use of OCP and in cases of premature ovarian failure. Studies on rats suggest that the dopaminergic agonist action of vitex may be useful to reduce or control epileptic seizures (Saber et al 2008).

### DOSAGE RANGE

#### General guide

- Liquid extract (1:2): 1–2.5 mL in the morning.
- Dried fruit: 1.5–3 g in the morning.
- Dry fruit flesh (solid-dose form): 1000–1800 mg/day.
- Manufacturers have recommended vitex preparations be taken daily as a single dose upon rising, before breakfast, throughout the menstrual cycle.

#### According to clinical studies

##### PMS

- Ze440 extract (Premular) 20 mg daily.
- Femicur 40 mg daily.

##### Cyclic mastalgia

- Mastodynon 60 drops daily or one tablet daily.

##### Menstrual irregularities

- 20 mg daily (extract unknown).

##### Infertility

- Mastodynon 30 drops twice daily.

### ADVERSE REACTIONS

A systematic review of the herb's safety, published in 2005, analysed data from six electronic databases, postmarketing surveillance studies, spontaneous reporting schemes (including the World Health Organization), herbalist organisations and manufacturers (Daniele et al 2005). The review concluded

#### Practice points/Patient counselling

- Clinical trials support the use of vitex in mild, moderate and severe PMS. It is particularly suited to treating common PMS symptoms, such as mood changes and irritability, breast tenderness, headaches and constipation. According to the available evidence, it is more effective than pyridoxine treatment and has a similar response rate to fluoxetine.
- It may also be effective in the treatment of menstrual irregularities and mastalgia.
- Vitex is also used to relieve perimenopausal symptoms, enhance fertility in women with progesterone deficiency or luteal-phase defects, aid the expulsion of the placenta after birth, reduce fibroids and normalise hormones following the use of oral contraceptives.
- Traditionally, it is described as a galactagogue (i.e. a medicine able to increase milk production in lactation) and is used in low doses for this indication.
- A mechanism of action has not been conclusively identified, but it appears to inhibit prolactin release by selective stimulation of pituitary dopamine D<sub>2</sub> receptors, to increase progesterone levels and works via the opiate system.

that vitex is a safe herbal medicine and any adverse effects associated with its use tend to be mild and reversible. The most common adverse effects are nausea, headache, dizziness, tiredness, mild gastrointestinal disturbances, dry mouth, menstrual disorders, acne, pruritus and erythematous rash. Additionally, no drug interactions have been reported. More recently, a 2009 placebo-controlled study of 202 women with moderate to severe PMS found no significant difference between incidence of adverse effects in the placebo- or vitex-treated groups (He et al 2009). Headache was reported as one of the more common side effects experienced by both groups, but was attributed to the PMS itself and not treatment.

### SIGNIFICANT INTERACTIONS

Controlled studies are not available, so interactions are based on evidence of activity and are largely theoretical and speculative.

#### Dopamine antagonists

An antagonistic interaction is theoretically possible — observe patients.

#### Oral contraceptives

There has been speculation about the effectiveness of vitex when OCP are being taken. Several clinical studies involving women taking oral contraceptives have confirmed the herb still reduces PMS symptoms and does not affect OCP.

## CONTRAINDICATIONS AND PRECAUTIONS

People with tumours sensitive to oestrogen or progesterone should avoid using this herb until safety can be established. It has been suggested that the ability of vitex to reduce prolactin levels may inhibit medical investigations and may mask diagnosis and proper treatment of prolactinoma (Gallagher et al 2008).

## PREGNANCY USE

Vitex is not traditionally recommended in pregnancy. In practice, some herbalists use it during the first 10 weeks of pregnancy in cases of difficult conception.

## PATIENTS' FAQs

### What will this herb do for me?

Vitex is used to relieve common symptoms of PMS, such as irritability, mood swings, breast tenderness, headache and constipation. It is also used in combination with other herbal medicines to enhance fertility, relieve menopausal symptoms, regulate irregular menstruation, improve acne and promote milk production in new mothers.

### When does it start to work?

Most trials show that treatment for at least three menstrual cycles may be required before symptom relief is experienced in PMS.

### Are there any safety issues?

In cases of irregular menstruation, investigation for serious pathology should be undertaken before use of this herb.

## Chickweed

**HISTORICAL NOTE** Chickweed is one of the most common weeds worldwide. It has been used since ancient times to treat external inflammatory conditions and is also consumed as a tasty and nutritious vegetable, as well as poultry fodder to improve egg production. Other medicinal claims include its use as an astringent, carminative, antiasthmatic, demulcent, depurative, diuretic, emmenagogue, expectorant, galactagogue, useful in kidney complications, rheumatic joints, wounds and ulcers (Chidrawar et al 2011). Its water is an old wives remedy for obesity (Rani et al 2012). Modern herbalists mainly prescribe chickweed for skin diseases but also bronchitis, rheumatic pains, arthritis and period pain (Ma et al 2012).

### COMMON NAME

Chickweed

### OTHER NAMES

Mouse-ear, star chickweed, starweed, satinflower, starwort, stellaria, winterweed

### BOTANICAL NAME/FAMILY

*Stellaria media* (family Caryophyllaceae)

### PLANT PARTS USED

Aerial parts — leaves, stems and flowers

### CHEMICAL COMPONENTS

Chickweed is commonly used as a food and is rich in essential vitamins A, B-complex and C, and minerals including calcium and iron. It is also a dietary source of carotenoids, including beta-carotene and gamma-linolenic acid (Fisher 2009, Rani et al 2012).

Other chemical constituents which may contribute to the pharmacological action of chickweed include: saponins, coumarins, flavonoids, triterpenoids, pentasaccharide, polysaccharides and sitosterols (Ma et al 2012, Rani et al 2012, Vanhaecke et al 2008).

Chromatography isolates include apigenin 6-C-beta-D-galactopyranosyl-8-C-alpha-L-arabinopyranoside, apigenin 6-C-alpha-L-arabinopyranosyl-8-C-beta-D-galactopyranoside, apigenin 6-C-beta-D-galactopyranosyl-8-C-beta-L-arabinopyranoside, apigenin 6-C-beta-D-galactopyranosyl-8-C-beta-D-galactopyranoside, and apigenin 6,8-di-C-alpha-L-arabinopyranoside (Dong et al 2007).

Chickweed essential oil has been found to contain several well-known contact allergens: borneol, menthol, linalool, 1,8-cineole, and other terpenes such as epoxy-dehydro-caryophyllene, monoterpene alcohol-ester and caryophyllene (Jovanović et al 2003).

## MAIN ACTIONS

The pharmacological actions of chickweed have not been significantly investigated, so traditional use and an understanding of the actions of individual constituents is used.

### Internal use

#### Antitussive, expectorant and demulcent effects

Herbal saponins are well known to irritate mucous membranes and are successfully used as expectorants (e.g. senega). Herbs such as chickweed that contain saponins are also suspected to have a degree of expectorant activity when used internally; however, this has not been investigated in controlled studies.

#### Antimicrobial

Defensins are a family of peptides that exhibit antimicrobial activity and play an important role in resistance against pathogens in the plant kingdom. Two defensins have been successfully isolated from chickweed that display strong antifungal activity. Their amino acid sequence was identified. The understanding of sequence coding of these peptides may lead to further understanding of their antimicrobial action and development of new extractions and applications of chickweed (Slavokhotova 2011).

#### Antiviral effects

An *in vitro* study investigated chickweed against Hepatitis B virus (HBV). The extract was shown to suppress the secretion of Hepatitis B surface antigen (HBsAg) and hepatitis B e antigen (HBeAg) in a cell culture medium — 27.92% and 25.35% after 6 days of treatment, respectively. The chickweed fraction also reduced the level of HBV DNA in a dose-dependent manner. Characterisation of the chemical constituents of the extract found the presence of flavonoid C-glycosides, polysaccharides and protein exhibited antiviral activities (Ma et al 2012).

#### Hepatoprotective

A water-soluble polysaccharide extracted from chickweed was administered to rats with induced hepatitis, at a dose of 100 mg/kg. The extract was shown to reduce liver enzymes ALT, AST and AP by 41%, 37% and 56% respectively. The concentration of total and conjugated bilirubin decreased by 63% and 87% respectively. Histological results revealed a three-fold reduction in the number of necrotic and degenerative hepatocytes; and a significant increase in the regeneration of hepatic tissue with a proliferation of hepatocytes. These results are suggestive of a promising action for the novel constituent of chickweed in promoting liver regeneration and protecting against hepatocyte necrosis associated with liver disease (Gorina et al 2013).

### External use

#### Soothing irritated skin and enhancing wound healing

Chickweed is traditionally thought to have soothing properties when applied to the skin in an appropriate vehicle, although controlled studies are not available to confirm these effects. The saponin content may account for the herb's ability to help reduce itchiness.

### OTHER ACTIONS

An *in vitro* study identified that a chickweed decoction had activity against human hepatoma cell lines (Lin et al 2002). An ethanolic extract of chickweed has been found to strongly inhibit xanthine oxidase *in vitro*, suggesting that it may have a use against hyperuricaemia and gout (Pieroni et al 2002).

### CLINICAL USE

Chickweed has not been significantly investigated under clinical trial conditions, so evidence is derived from traditional, *in vitro* and animal studies.

#### Urticaria, eczema, rashes, burns

Chickweed is most commonly used in external preparations for inflamed and itchy skin conditions such as urticaria, eczema, insect bites and stings, as well as minor wounds and cuts. Anecdotal evidence suggests that it may have some effects; however, controlled studies are not available to confirm effectiveness.

#### Bronchial phlegm and bronchitis

Taken orally, chickweed is often combined with other herbs for treating conditions characterised by fever and bronchial phlegm; however, controlled studies are not available to confirm effectiveness.

#### Obesity/Weight loss

Traditional Indian medicine claims chickweed has anti-obesity activity. Recent investigations using animal models have shown promising results. The effect of methanolic and alcoholic extracts of chickweed on food consumption pattern, change in body weight, thermogenesis, lipid metabolism and histology of fat pad was examined in progesterone-induced obese female mice. Food consumption behaviours, adiposity index, white adipose tissue and liver and body weight increases were significantly decreased in a dose-dependent manner (100 mg, 200 mg, 400 mg per kg body weight). There was no significant change in body temperature. The possible weight loss properties are believed to be due to saponins, flavonols and partly by  $\beta$ -sitosterol, which has a chemical structure similar to dietary fat and thereby competitively inhibits dietary fat absorption (Chidrawar et al 2011).

Moreover, another study investigated a lyophilised juice extract of chickweed and its anti-obesity action at two doses, 400 mg/kg and 900 mg/kg body weight, in mice fed a high-fat-diet for 6

weeks. In addition, pancreatic lipase activity was evaluated by measurement of plasma triacylglycerol levels. The lyophilised juice extract of chickweed significantly suppressed the increase in body weight, retroperitoneal adipose tissue, liver weights and serum parameters of total cholesterol, total triglyceride and LDL-cholesterol levels at the dose of 900 mg/kg body weight. The results indicate that chickweed might confer an anti-obesity action by delaying the intestinal absorption of dietary fat and carbohydrate by inhibiting digestive enzymes (Rani et al 2012).

Further investigations including clinical trials are required to verify the clinical use of chickweed in obesity.

### OTHER USES

Chickweed can be eaten raw in salads, served as cooked greens, juiced or infused as a tea. It has also been used as a mild laxative and diuretic substance.

### DOSAGE RANGE

- Tincture (1:5): 2–10 mL three times daily.
- Infusion of dried herb: 1–5 g three times daily.
- Chickweed is commonly incorporated into a topical ointment or cream base for external use (1 part chickweed to 5 parts base) and applied as required.

### TOXICITY

Allergic skin reactions can occur with topical use.

### ADVERSE REACTIONS

There is insufficient reliable information available about the safety of chickweed when used internally or externally. Allergy to chickweed causing contact erythema multiforme has been reported (Jovanović et al 2003), and it is advised to apply a test patch to a small area before applying more widely.

### SIGNIFICANT INTERACTIONS

Not known.

#### CONTRAINDICATIONS AND PRECAUTIONS

Allergic skin reactions can occur with topical use.

#### PREGNANCY USE

Likely to be safe when consumed in dietary amounts; however, safety is not known when used in larger quantities.

#### Practice points/Patient counselling

- Chickweed has been traditionally used as an ingredient in herbal creams and ointments to soothe inflamed, itchy skin and promote wound healing. Although controlled studies are unavailable, the pharmacological actions of several constituents within the herb suggest that it may be useful.
- Although it is likely to be safe, it is prudent to avoid using chickweed in pregnancy in amounts greater than those ingested when used as a food.

#### PATIENTS' FAQs

##### *What will this herb do for me?*

When chickweed is applied topically it may soothe inflamed and itchy skin. It is taken orally as a cough suppressant and expectorant. Large doses in animal models have shown it may reduce fat absorption in the gastrointestinal tract.

##### *How quickly will it work?*

In practice, topical preparations are reported to produce symptom relief within 30 minutes; however, there are no controlled trials to confirm this.

##### *Are there any safety issues?*

Chickweed can be consumed as a food in salads, cooked as greens or prepared as a juice; however, the safety of larger intakes is unknown. Used as part of a herbal cream, it is likely to be safe, although it would be wise to do a test patch in a small area before applying to large areas. The safety of large doses in pregnancy is unknown.

# Chitosan

C

**HISTORICAL NOTE** With the exception of cellulose, chitin is the most abundant natural polysaccharide on Earth. The most useful chitin derivative is chitosan. It is produced by different crustaceans, molluscs, insects, algae, fungi and yeasts. Recently, the commercial value of chitin has increased because of the beneficial properties of its soluble derivatives, which are used in chemistry, biotechnology, agriculture, food processing, cosmetics, veterinary science, medicine, dentistry, environmental protection and paper or textile production.

## BACKGROUND AND RELEVANT PHARMACOKINETICS

Chitosan is a form of poorly soluble fibre, chemically derived from chitin through deacetylation, which is extracted from the exoskeletons of crustaceans or squid. It is a cationic polysaccharide composed of  $\beta$ -1,4-linked D-glucosamine and N-acetyl-D-glucosamine. Similar to other forms of fibre, such as oat bran, chitosan is thought to bind bile acids and dietary lipids. The solubility, biocompatibility and immunological activity and physicochemical properties of chitosan are altered by its molecular weight and degree of N-acetylation. The most useful chitosan is one that has the highest degree of acylation and lowest molecular weight, for example, 8kD (Synowiecki & Al-Khateeb 2003).

The solubility of chitosan increases in the acidic environment of the stomach, but at a pH above 6.3 (for example, in the intestines) the amino groups of chitosan, together with dietary fatty acids, bile acids, cholesterol and lipids, form a complex (Ylitalo et al 2002). The decreased availability of bile acids limits intestinal emulsification and the absorption of lipids, which are then excreted in the faeces.

## CHEMICAL COMPONENTS

Chitosan is a cationic polysaccharide prepared by N-deacetylation of chitin.

## DEFICIENCY SIGNS AND SYMPTOMS

Chitosan is not an essential nutrient, so deficiencies do not occur.

## MAIN ACTIONS

### Binds to fat

Chitosan displays unique cationic properties which enables it to bind fatty acids via electrostatic forces. As it passes through the digestive tract, positively-charged chitosan binds to negatively-charged fat, bile acids and cholesterol, preventing their absorption. The complexes that form between chitosan and various fats are then excreted in the faeces.

A human study investigating whether this effect is clinically significant found that a dose of 4.5 g/day, taken in divided doses 30 minutes before meals, trapped only negligible amounts of fat as measured by fat excretion in stools (Gades & Stern 2003). A

subsequent study by the same authors investigated 2.5 g chitosan/day in 12 men and 12 women, and found faecal excretion of fat increased by 1.8 g/day in men and was negligible in women (Gades & Stern 2005). However, another trial using a larger dose of chitosan (6.3 g/day) found a mean increase of 3.63 g/day faecal fat excretion (Barroso Aranda et al 2002).

These trials suggest the ability for chitosan to bind fats is clinically insignificant unless taken in doses >6 g/day; however, chitosan's binding of fatty acids appears to be selective, determined by chain length and degree of fatty acid saturation. Animal models suggest chitosan binds strongly with lauric and myristic acid, both highly atherogenic fats, but it has a lower affinity for stearic acid. Chitosan also binds more strongly to omega-6 isomers than omega-3, suggesting that in addition to reducing fat absorption generally, it may ultimately have a positive effect on balancing this ratio in the Western diet (Santas et al 2012).

### Antibacterial and antifungal activity

Animal studies have identified antibacterial activity against *Bifidobacterium* and *Lactobacillus*, which are part of the normal flora of the intestinal tract (Tanaka et al 1997). Clinical trials with a chitosan mouthwash and chewing gum have shown antibacterial activity against *Streptococcus mutans* (Sano et al 2003). Chitosan also inhibits the adhesion of *Candida albicans* to human buccal cells and has antifungal activity (Senel et al 2000). The mechanism of its antimicrobial action is believed to be due to its cationic properties. The positively charged anions of chitosan bind to the cell wall of bacteria causing damage and leakage of cytoplasmic content, leading to cell lysis (Hayashi et al 2007a, 2007b). Due to differences in cell wall characteristics, chitosan is more effective against Gram-positive than Gram-negative bacteria. In vitro studies against *Candida albicans* demonstrated the cell wall was still identifiable; however, intracellular structure had either disappeared or changed, suggesting a different mechanism of action.

### Wound healing

Chitosan exhibits a wound-healing action. When applied topically it is considered a haemostatic agent

by binding with blood cells, assisting to form a clot (Dai et al 2011). It has been reported to enhance inflammatory cells involved in wound healing, including leucocytes, macrophages and fibroblasts. As a result, chitosan leads to acceleration of granulation and organisation of the healing process (Ueno et al 2001). Because infection can significantly impair healing time, the antimicrobial actions mentioned previously also contribute to chitosan's attributes as a wound healer.

### OTHER ACTIONS

Chitosan can also absorb urea and ammonia and generally displays similar actions to other dietary fibres (Hendler & Rorvik 2001).

### CLINICAL USE

The most biologically effective products contain a chitosan fraction having a low molecular weight, for example, 8kD. The smaller the chitosan fraction, the stronger the positive charge. Unfortunately, not every clinical study indicates whether low-molecular-weight chitosan has been used. Therefore, aside from the usual variables, discrepant results may be due to differences in the type of chitosan used. Some applications of chitosan also use chemically modified chitosan derivatives, in particular, for wound-healing applications, but this remains unknown. The process aims to favourably change the physical properties such as solubility, for use in film- or gel-forming capabilities (Chang et al 2013).

### Weight loss

Chitosan is sometimes marketed as a weight-loss aid, primarily due to its ability to bind to fats and reduce their absorption in the digestive tract.

A Cochrane systematic review published in 2005 analysed the results of 14 randomised studies involving 1131 subjects and concluded that use of chitosan resulted in a significantly greater weight loss, decrease in total cholesterol and decrease in systolic and diastolic blood pressure than placebo (Ni et al 2005). The studies were a minimum of 4 weeks duration and were conducted in overweight or obese subjects. With regard to the frequency of adverse events or faecal fat excretion, no clear differences were observed between the placebo and chitosan groups. Although encouraging, the authors noted that the quality of the studies were suboptimal and, overall, results were variable. A look at the studies of highest quality suggests that the effects are minimal. The mean trial duration was 8.3 weeks (range 4–24 weeks) and eight of the 14 studies combined the use of chitosan or placebo with a low-calorie or weight-reducing diet. Interpretation of the data is not straightforward because the dose of chitosan used in studies varied considerably, from 0.24 g/day to 15 g/day (mean 3.7 g/day), and six of the studies used treatment preparations that contained other active ingredients in addition to chitosan. Additionally, the review excluded some potentially important trials because they did not

meet criteria for inclusion (for example, subjects were not enrolled for being overweight but selected for other reasons).

In 2008, an updated Cochrane systematic review was published which evaluated 15 clinical studies ( $n = 1219$ ) (Jull et al 2008). Analyses indicated that chitosan preparations result in a significantly greater weight loss (weighted mean difference  $-1.7$  kg;  $P < 0.00001$ ), decrease in total cholesterol ( $-0.2$  mmol/L;  $P < 0.00001$ ), and a decrease in systolic and diastolic blood pressure compared with placebo. Chitosan treatment was well tolerated, as there were no clear differences between intervention and control groups in terms of frequency of adverse events or in faecal fat excretion. While these results appear more positive than the initial Cochrane review, their clinical significance is unclear, and reviewers once again reported that the quality of many studies was sub-optimal and analysis of only high-quality trials yielded less convincing evidence.

Since the 2008 Cochrane review, a double-blind study was conducted in 60 hyperlipidaemia patients treated with low molecular chitosan (2 g/day) or placebo. Both the supplement and the placebo were administered in conjunction with a physical activity program for 4 months duration. Caloric intake was similar in both groups. In comparison to the placebo, chitosan significantly reduced body weight (respectively  $6.9 \pm 1.87$  vs  $3.0 \pm 1.61$  kg), waist circumference ( $7.3 \pm 2.49$  vs  $3.1 \pm 4.21$  cm), LDL cholesterol ( $44 \pm 14.7$  vs  $12.5 \pm 12.6$  mg/dL), and triacylglycerol ( $52 \pm 29.3$  vs  $39 \pm 15.2$  mg/dL); HDL increase was also higher ( $6 \pm 3.6$  vs  $3 \pm 4.2$  mg/dL). Metabolic syndrome was reduced in 12 cases of the chitosan group, compared with three cases in the placebo (Cornelli et al 2008).

Further well-reported research is required, using longer time frames and clearly stating the complete characteristics of the chitosan preparations.

### Hyperlipidaemia

The ability of chitosan to form complexes with various fats, including cholesterol, provides a theoretical basis for its use in hyperlipidaemia. Dietary chitosan has been tested and found to be effective in reducing serum cholesterol levels and atherosclerosis in normal and diabetic mice, and, therefore, has been investigated in the treatment of hypercholesterolaemia in humans (Muzzarelli 1999).

A 2002 review stated that in humans, dietary chitosan reduces serum total cholesterol levels by 5.8–42.6% and LDL levels by 15.1–35.1% (Ylitalo et al 2002). Reduction in LDL cholesterol was evident after 4 weeks' treatment with chitosan (1.2 g twice daily) according to one double-blind study (Wuolijoki et al 1999) and after 8 weeks treatment using a low dose of 1.2 g/day of chitosan in another randomised double-blind study (Bokura & Kobayashi 2003).

These results, however, are not a reflection of more recent investigations. One randomised

double-blind study found no effect with 1.5 g chitosan tablets taken three times daily (Zahorska-Markiewicz et al 2002). In a randomised placebo-controlled study, no significant effect on total cholesterol, LDL cholesterol or triglycerides was seen, which tested chitosan capsules (1 g twice daily) (Guha et al 2005). The group receiving chitosan did report a significant reduction in mean body weight (3.14% versus 1.29% of body weight,  $P < 0.05$ ) and a significant rise in HDL cholesterol value (3.8% versus 1.07%,  $P = 0.02$ ). At higher doses which reflect those used in weight-loss studies, a more recent 2008 study found no significant effects on total cholesterol levels or LDL cholesterol concentration for chitosan (4.5 or 6.75 g/day) after 8 weeks of treatment (Tapola et al 2008).

The 2008 Cochrane review concluded that based on the current evidence, chitosan supplementation significantly reduced total cholesterol (Jull et al 2008). A second meta-analysis published in 2008 concurred that chitosan supplementation lowers total cholesterol but not LDL cholesterol or triglycerides, nor did it significantly increase HDL cholesterol (Baker et al 2009). The electrically neutral nature of triglycerides may mean that chitosan is unable to form complexes with it, and, therefore, is unable to influence its absorption.

### Insulin sensitivity

Both preliminary animal and human studies have investigated chitosan and its derivatives for hypoglycaemic potential. A randomised, double blind trial involving 12 obese men treated with chitosan (750 mg, 3 times daily) or placebo for 3 months found a significant increase in insulin sensitivity ( $2.4 \pm 1.4$  vs  $3.6 \pm 1.4$  mg kg<sup>-1</sup> min<sup>-1</sup>;  $P = 0.43$ ) in those taking chitosan. This group also had a significant decrease in weight, BMI, waist circumference and TG. As there was no significant change in actual glucose levels, the authors concluded that the change in insulin sensitivity may be secondary to the decrease in weight and lipid profile (Hernandez-Gonzalez et al 2010). However, oral treatment with chitosan for 12 weeks was shown to decrease fasting plasma glucose, plasma insulin and leptin levels in rats (Liu et al 2012). Larger human trials, specifying the molecular weight of chitosan used, are required to clarify its effects on insulin sensitivity.

### Hypertension

A patented NaCl salt containing 3% chitosan has been clinically trialled in a randomised, double-blind crossover trial involving 40 patients with mild hypertension. The chitosan salt was compared with standard sea salt to determine if this substitute was effective at lowering salt intake and BP. In addition to lifestyle advice, patients were ordered to consume no more than 3 g total salt per day. Patients were given saltshakers of either NaCl with chitosan 3% or NaCl alone for a period of 8 weeks. Following

a 2-week washout period the patients crossed over and were given the other salt for a further 8-weeks. The results found a significantly greater reduction in BP using the patented chitosan salt compared with standard sea salt;  $8.7 \pm 10$  mmHg vs  $3.2 \pm 8.5$  mmHg ( $P = 0.0156$ ) for systolic BP and  $7.2 \pm 8.00$  mmHg vs  $3.7 \pm 7.4$  mmHg ( $P = 0.0285$ ) for diastolic BP. The exact mechanism for this effect is still unclear (Allaert 2013).

### Dental plaque prevention

Because of chitosan's antibacterial activity against *Streptococcus mutans* and antifungal action against *Candida albicans*, it has been added to mouthwashes and dental gels. One randomised, crossover clinical trial involving 24 volunteers found that rinsing with a mouthwash containing 0.5% chitosan for 14 days was significantly more effective in reducing plaque formation than a placebo (Sano et al 2003). Several clinical studies have investigated the effect of chitosan-containing chewing gum. One clinical study reported that chewing the gum significantly decreased oral bacterial counts and significantly increased salivary secretion (Hayashi et al 2007a). Another confirmed antibacterial activity for the gum, especially reducing total streptococci, streptococci mutans in saliva (Hayashi et al 2007b). Hayashi et al suggested that chewing chitosan-containing gum could be an effective method for controlling the number of cariogenic bacteria in situations where it is difficult for a person to brush their teeth. The gum used in the study was xylitol-based and supplemented with chitosan so it dissolved in saliva at a rate of about 2% (w/v).

### Periodontal disease

Chitosan was tested both as a carrier in gel form for the antibiotic metronidazole and as an active agent in the treatment of chronic periodontitis (CP) (Aknabay et al 2007). The chitosan gel (1% w/w) incorporated with or without 15% metronidazole was prepared and applied adjunctive to scaling and root planing (SRP) and compared to SRP alone in CP patients. All groups experienced significant improvements for clinical parameters between baseline and week 24 ( $P < 0.05$ ). Chitosan was found to be effective in itself, as well as in combination with metronidazole in CP treatment due to its antimicrobial properties.

A small pilot trial involving 20 patients with periodontitis investigated three applications of chitosan after initial periodontal surgery: chitosan gel 1% w/v; chitosan gel plus demineralised bone matrix; and chitosan gel plus collagenous membrane. The control group received a flap only that contained no chitosan. Clinical and radiographic evaluation found no significant differences between the chitosan treatment groups; however, radiographic results indicated that compared with the control, all three chitosan groups showed statistically significant bone fills indicative of periodontal regeneration (Boynuegri et al 2009).

**Clinical note — Periodontal disease**

Periodontal disease is a collective term used to describe several pathological conditions characterised by degeneration and inflammation of gums, periodontal ligaments, alveolar bone and dental cementum. It is a localised inflammatory response caused by bacterial infection of a periodontal pocket associated with subgingival plaque. Periodontal disease has been considered as a possible risk factor for other systemic diseases such as cardiovascular diseases and preterm, low-birth-weight infants. Increasingly, chitosan is being used as a polymeric matrix in the form of film enriched with taurine (antioxidant agent). Taurine enhances the wound-healing ability of chitosan and is considered beneficial in tissue repair in destructive diseases like periodontitis (Jain et al 2008).

**Kidney failure**

One open study of 80 patients with renal failure undergoing haemodialysis found that 1350 mg of chitosan taken three times daily effectively reduced total serum cholesterol levels (from  $10.14 \pm 4.40$  mmol/L to  $5.82 \pm 2.19$  mmol/L) and increased serum haemoglobin levels (from  $58.2 \pm 12.1$  g/L to  $68 \pm 9.0$  g/L) (Jing et al 1997). After 4 weeks, significant reductions in serum urea and creatinine levels were observed. After 12 weeks, patients reported subjective improvements, such as feeling physically stronger, with increased appetite and improved sleep, which were also significantly greater than the placebo group. Importantly, during the treatment period, no clinically problematic symptoms were observed.

Hyperphosphataemia is a common complication of chronic renal failure and is a risk factor for cardiovascular calcification in these patients. Chitosan strongly binds to salivary phosphate and lower serum levels in haemodialysis patients. In 13 haemodialysis patients with elevated serum phosphate levels, 20 mg of chewing gum containing a highly de-acetylated chitosan, was administered twice daily for 2 weeks in addition to their prescribed regimen. At the end of the 2 weeks, salivary phosphate had decreased by 55% from baseline ( $73.21 \pm 19.19$  to  $33.19 \pm 6.53$ ;  $P = 0.00001$ ), and serum phosphate decreased 31% from baseline ( $7.60 \pm 0.91$  to  $5.25 \pm 0.89$  mg/dL;  $P = 0.00001$ ). Serum phosphate took 30 days to return to baseline after the trial (Savica et al 2009). Interestingly, in a separate publication, the authors later analysed the CRP values from the blood samples of the patients, and found the chitosan chewing gum significantly lowered CRP values (from  $1.38 \pm 0.61$  mg/L before the gum use to  $0.39 \pm 0.16$  after the gum,  $P = <0.0003$ ). The reduction was parallel with the reduced phosphate levels and is an important biomarker for cardiovascular health risk.

**Wound healing — topical use**

Chitosan is applied to burns and wound dressings in the form of films, bandages, cotton-like materials and non-woven napkins. Chitosan dressings have good hygroscopicity, show high bacteriostatic effect and are completely biodegradable in the human body. Another significant advantage is that repeated dressings are not usually needed (Synowiecki & Al-Khateeb 2003). Topical application of chitosan enhances wound healing and has been used to promote donor-site tissue regeneration in plastic surgery. Its use is supported by findings that indicate chitosan accelerates the reformation of connective tissue (Ueno et al 2001).

Chitosan was compared alongside conventional wound dressings in 20 patients undergoing skin grafts. These related to either skin malignancy, limb trauma or burn wounds. Compared with silicone net gauze, healing time was significantly shorter in the chitosan group; however, compared with alginates there was no significant benefit. However, three patients agreed to punch biopsy at the newly-healed time point. Histology results compared to the alginates showed chitosan biopsies had a marked looser connective tissue stroma, which was richer in both glycosaminoglycan matrix and capillaries. Small dermal nerve fibres were also more numerous. In addition, digital images of the scars demonstrated an earlier return to normal skin colour at the chitosan-treated areas (Stone et al 2000).

In a randomised controlled trial of 40 patients undergoing endoscopic sinus surgery for the treatment of chronic rhinosinusitis, chitosan was applied in the form of a gel and compared to control (no treatment). Chitosan achieved rapid haemostasis compared to the control group; 2–4 minutes compared with 10 minutes ( $P < 0.001$ ). There was also significantly less adhesions at all follow-up time points (2, 6 and 12 weeks post-surgery). There was no change with respect to crusting, mucosal oedema, infection or granulation tissue formation (Valentine et al 2010).

**OTHER USES****Drug delivery systems**

Chitosan is considered a good carrier for the controlled release of drugs over an extended period of time (Synowiecki & Al-Khateeb 2003). Additionally, it has been shown to excel in transcellular transport.

Chitosan is also used as a component of different cosmetics, toothpaste, hand and body creams and hair-care products (Synowiecki & Al-Khateeb 2003).

**DOSAGE RANGE**

- The standard dose of chitosan is 3–6 g/day, taken with food.

**According to clinical studies**

- Weight loss: 3.0–4.5 g taken daily in divided doses, 30 minutes before meals.

- Hyperlipidaemia: 1.2–4.5 g/day in divided doses.
- Insulin sensitivity: 750 mg 3 times daily.
- Hypertension: NaCl with chitosan 3% used as a salt replacement.
- Dental plaque prevention: rinse daily with mouth-wash containing 0.5%.
- Periodontal disease: chitosan gel (1% w/w) applied as an adjunct to scaling and root planing.
- Renal failure: 1.35 g taken three times daily.
- Hyperphosphataemia: 20 mg chewing gum loaded with highly deacetylated chitosan; twice daily for 1 hour.

## ADVERSE REACTIONS

A systematic review of 14 randomised studies found that the most common side effects reported were constipation, nausea, bloating, indigestion and abdominal pain (Ni et al 2005). Increased water consumption may reduce some of these side effects.

Overall, chitosan is considered very safe and well tolerated according to safety studies in experimental models (Kim et al 2001).

## SIGNIFICANT INTERACTIONS

### Fat-soluble nutrients

Given chitosan's capacity to bind dietary fats and reduce their absorption, chitosan can also affect the absorption of fat-soluble vitamins. However, the effect may be dose-dependent as one study using a dose of 2 g/day found no changes to the levels of vitamins A, D, E and beta-carotene after 4 weeks use (Pittler et al 1999). A more recent study confirmed that there were no significant effects on serum vitamins (vitamin A, vitamin E, 25-hydroxyvitamin D) and carotenes (alpha- and beta-carotene) with oral chitosan after 8 weeks, even at a dose of 6.75 g daily (Tapola et al 2008).

### Lipophilic drugs

Considering chitosan binds to dietary fats and reduces their absorption, it can also affect the absorption of lipophilic drugs, such as those that require passage across the blood–brain barrier, for example, some antihistamines, sleep aids and other psychiatric medications. Separate doses by at least 2 hours.

### Vitamin C

According to a preliminary study in rats, taking vitamin C together with chitosan might provide additional benefit in lowering cholesterol.

### B-group vitamins

In vitro studies using fluorescence and ultraviolet-visible absorption measurements have shown vitamin B<sub>2</sub> and B<sub>12</sub> interact with chitosan in an acid-aqueous environment replicating the stomach. These studies suggest chitosan may inhibit the absorption of these nutrients; however, the degree of clinical significance is unknown (Rodrigues et al 2011, 2012).

## Warfarin

Chitosan may potentiate warfarin by inhibiting absorption of fat-soluble vitamin K. A case report details an 83-year-old patient on a regimen of 2.5 mg warfarin/day. After 6 months supplementation of 1.2 g chitosan twice daily, the patient's INR levels had risen significantly. The patient was administered vitamin K intravenously and INR levels returned to normal. Against medical advice, the patient restarted chitosan supplementation and INR levels increased over the following 3 months. Once discontinued, the levels returned to within target range (Huang et al 2007).

## CONTRAINDICATIONS AND PRECAUTIONS

Chitosan is contraindicated in people with allergies to shellfish.

### PREGNANCY USE

Pregnant women should avoid taking chitosan at mealtimes as it may reduce absorption of essential dietary nutrients.

### *Practice points/Patient counselling*

- Chitosan is a form of poorly soluble fibre, chemically derived from chitin, which is extracted from the exoskeletons of crustaceans or squid. The most biologically active forms have a low molecular weight.
- It forms insoluble complexes with dietary fats, fatty acids, bile acids, cholesterol and other lipids in the digestive tract and has antibacterial and antifungal activity that is useful in dental hygiene and topically for wound healing.
- Chitosan is a popular weight-loss supplement. Clinical studies have produced mixed results; however, best effects occur when chitosan is used over several months and combined with dietary and lifestyle modifications.
- Chitosan has been shown to significantly lower total cholesterol in hypercholesterolaemic patients, but not LDL cholesterol, HDL cholesterol or triglycerides. Clinical studies suggest chitosan is most beneficial in individuals consuming high cholesterol diets.
- Chitosan is contraindicated in people with allergies to shellfish and should be recommended together with a multivitamin supplement with long-term use.

## PATIENTS' FAQs

### *What will this supplement do for me?*

Taken orally, chitosan may aid in weight loss when combined with dietary and lifestyle modifications and may reduce total cholesterol levels.

### *When will it start to work?*

Effects in weight loss require at least 8 weeks continual use before effects are seen, according to research, whereas cholesterol-lowering requires 4–8 weeks.

**Are there any safety issues?**

Chitosan is contraindicated in people with allergies to shellfish and must not be used in patients taking warfarin.

# Chondroitin

**OTHER NAMES**

Chondroitin sulfate, chondroitin sulfuric acid, chondroitin 4-sulfate, chondroitin 4- and 6-sulfate

**BACKGROUND AND RELEVANT PHARMACOKINETICS**

Chondroitin sulfate is an amino sugar polymer, made up of glucuronic acid and galactosamine, that is in the class of large polymers known as glucosaminoglycans or mucopolysaccharides. These compounds act as the flexible connecting matrix between the protein

filaments in cartilage and connective tissue (Liesegang 1990) as well as being a major component of the extracellular matrix in the brain (Kwok et al 2012). It has been found that serum levels of chondroitin sulfate are increased in patients with both rheumatoid arthritis and osteoarthritis (OA) and this may provide the basis for systemic detection of OA (Pothacharoen et al 2006).

Chondroitin sulfate molecules represent a heterogeneous population, the structure of which varies with source, manufacturing processes, presence of contaminants and other factors (Lauder 2009). There

are also differences in the absorption and bioavailability of chondroitin formulations due to differences in molecular mass, charge density and cluster of disulfated disaccharides of the parental molecules (Volpi 2003). This has led to a call for reference standards with high specificity, purity and well-known physico-chemical properties for use in accurate and reproducible quantitative analyses (Volpi 2007).

Chondroitin is generally manufactured from natural sources, such as shark and bovine (usually tracheal) cartilage and may have a molecular weight that varies from 10 to 50 kDa, depending on the product's source or preparation (Ross 2000). Low-molecular-weight chondroitin appears to be absorbed orally in both animals and humans (Adebowale et al 2002, Du et al 2004) and displays accumulation after multiple dosing (Adebowale et al 2002). Chondroitin is concentrated in the intestine, liver, kidneys, synovial fluid and cartilage (Conte et al 1995) and the elimination half-life is about 5–6 hours, with 40–50% being excreted in the urine (Conte et al 1991, Ronca & Conte 1993). Oral chondroitin is absorbed as several metabolites, and as the active moiety has not yet been identified it is difficult to establish bioequivalence between different products (Volpi 2003).

### CHEMICAL COMPONENTS

Chondroitin sulfate is a linear polymer of two alternating sugars, alpha-D-N-acetylgalactosamine and beta-D-glucuronic acid, with the sulfate moiety being a covalent part of the molecule and not a counter ion, as is the case with glucosamine sulfate (Ross 2000).

### FOOD SOURCES

Chondroitin is naturally present in the gristle in meat. As a supplement it is generally produced from natural sources, such as shark or bovine (usually tracheal) cartilage and it can also be manufactured in the laboratory using various methods. The purity and content of products have been questioned in the United States, where it is regarded as a nutritional supplement and its quality is unregulated (Consumer-lab 2009).

### MAIN ACTIONS

#### Chondroprotective effect

A review of chondroitin sulfate in the pathophysiology of OA suggests that chondroitin exerts its anti-arthritic effects via the stimulation of proteoglycan synthesis and reduction of chondrocyte catabolic activity. It does this by inhibiting the synthesis of proteolytic enzymes as well as via anti-inflammatory activity and actions on osteoblasts in subchondral bone, with modulation of osteoprotegerin/receptor activator of NF- $\kappa$ B ligand ratio in favour of reduced bone resorption (Martel-Pelletier et al 2010). Chondroitin appears to protect cartilage by providing it with the raw material required for repair, as well as inhibiting the enzymes in synovial fluid, such as elastase and hyaluronidase, that damage joint cartilage. It improves chondrocyte nutrition by increasing

hyaluronic acid production in articular cells (Raoufi et al 2005) and hence, the fluid content of the extracellular matrix (Sasada et al 2005), which not only acts as a shock absorber but also brings nutrients into the cartilage (Krane & Goldring 1990).

In vitro studies have shown that low-dose combinations of glucosamine hydrochloride and chondroitin sulfate stimulate collagen and non-collagenous protein synthesis by ligament cells, tenocytes and chondrocytes (Lippiello 2007). An overall chondroprotective effect of chondroitin has also been demonstrated in different animal models. In a rabbit model oral or intramuscular chondroitin sulfate was shown to protect articular cartilage from experimental chymopapain injury (Uebelhart et al 1998a) and inhibit the destruction of the cartilage extracellular matrix (Sumino et al 2005). In a dog model, chondroitin sulfate was seen to stimulate articular cartilage and decrease or delay the alterations of degenerative joint disease (Melo et al 2008). In other animal models, co-administration with glucosamine was shown to prevent both biochemical and histological alterations and provide pain reduction (Silva et al 2009).

It has been suggested that at least some of the chondroprotective action of chondroitin sulfate is due to the provision of a source of additional inorganic sulfur which is essential for glycosaminoglycan synthesis, as well as being a structural component of glutathione and other key enzymes, coenzymes and metabolites that play fundamental roles in cellular homeostasis and control of inflammation (Nimni et al 2006). This is supported by the finding that the chondroprotective action of chondroitin is potentiated by high-sulfur mineral water (Caraglia et al 2005).

Urinary chondroitin sulfate and keratan sulfate excretion is reported to reflect the turnover rates of cartilage matrix proteoglycans, leading to the suggestion that the measurement of these compounds could provide an objective means of evaluating and monitoring joint diseases (Baccarin et al 2012). Furthermore, it has been found that technetium-99m-chondroitin sulfate accumulates in cartilage tissue, either by acting as a substrate for proteoglycan synthesis or by adsorption to cartilage, suggesting that this compound could serve to target and radioimage OA (Sobal et al 2009).

#### Anti-inflammatory

Chondroitin exerts an anti-inflammatory action with an inhibitory effect over complement (Pipitone 1991). In an in vitro study of bovine cartilage, chondroitin alone, and in combination with glucosamine, was found to regulate gene expression and synthesis of nitric oxide and prostaglandin E<sub>2</sub>, suggesting a basis for its anti-inflammatory properties (Chan et al 2005). Chondroitin sulfate has been found to increase the levels of antioxidant enzymes and reduce inflammation and cirrhosis of liver tissue in an ovariectomised rat model, suggesting that it enhances antioxidant activity (Ha 2004). It has been suggested that chondroitin's multiple anti-inflammatory effects in chondrocytes and synoviocytes are primarily

due to a common mechanism, through the inhibition of NF- $\kappa$ B nuclear translocation (Iovu et al 2008). Chondroitin sulfate has also been shown to inhibit the production of prostaglandin E<sub>2</sub> and matrix metalloproteinases in osteoblasts, leading to the suggestion that chondroitin's action in OA is not only due to effects on cartilage but may also be due to effects on subchondral bone (Pecchi et al 2012).

Based on in vitro and in vivo evidence, it is suggested that the antioxidant and anti-inflammatory effects of chondroitin contribute to neuro-protective properties (Egea et al 2010). A recent review further suggests that chondroitin improves moderate to severe psoriasis and experimental and clinical data suggest chondroitin might be a useful therapeutic agent in inflammatory diseases such as inflammatory bowel disease, atherosclerosis, Parkinson's and Alzheimer's disease, multiple sclerosis, amyotrophic lateral sclerosis, rheumatoid arthritis and systemic lupus erythematosus (Vallieres & du Souich 2010).

### Viscoelastic agent

Chondroitin sulfate is a viscoelastic agent and, together with similar substances such as sodium hyaluronate and hydroxypropyl methylcellulose, is used in ophthalmic surgery to protect and lubricate cells and tissues (Larson et al 1989, Liesegang 1990).

### OTHER ACTIONS

There are suggestions from laboratory studies and uncontrolled human trials that chondroitin may have potential antiatherogenic properties (Morrison 1969, 1971, Morrison & Enrick 1973).

A review of the potential therapeutic applications of chondroitin sulfate/dermatan sulfate suggest that chondroitin sulfate may have potential applications in parasitic and viral infections, regenerative medicine and development of antitumour therapies (Yamada & Sugahara 2008).

### CLINICAL USE

#### Osteoarthritis: symptom control and retarding disease progression

There are now a number of reviews and meta-analyses of clinical data (Bruyere & Reginster 2007, Hochberg 2010, Monfort et al 2008, Uebelhart 2008, Vangsness et al 2009), including a critical appraisal of five separate meta-analyses (Monfort et al 2008), which indicate that oral chondroitin sulfate is a valuable and safe symptomatic treatment for OA disease (Kubo et al 2009). Chondroitin sulfate appears to produce a slow but gradual reduction of the clinical symptoms of OA. Multiple human clinical trials lasting from a few weeks to 3 years have shown that chondroitin sulfate can significantly alleviate symptoms of pain and improve function in patients with OA of the knee, finger and hip (Bourgeois et al 1998, Bucsi & Poor 1998, Fioravanti et al 1991, Lazebnik & Drozdov 2005, Mazieres et al 2001, Morreale et al 1996, Oliviero et al 1991, Rovetta 1991, Uebelhart 2008, Zegels

et al 2013) and that these effects last months after the cessation of treatment (Mazieres et al 2005), as well as being evident with intermittent treatment (Uebelhart et al 2004).

There is also evidence from double-blind clinical trials that chondroitin can reverse, retard or stabilise the pathology of OA (Volpi 2005), as evidenced by stabilisation of the joint space (Uebelhart et al 1998b), less progression of erosions (Rovetta et al 2002, Verbruggen et al 1998) and improved articular cartilage thickness (Pipitone et al 1992, Raynauld et al 2012) and interarticular space, as observed by X-rays (Conrozier 1998, Michel et al 2005, Uebelhart et al 2004). A subanalysis of patients involved in the Glucosamine/Chondroitin Arthritis Intervention Trial (GAIT) study (see below and Glucosamine monograph) further suggests that chondroitin sulfate may have differential effects on OA symptoms depending on the degree of radiographic involvement, and that chondroitin may provide improvements in knee pain in patients with relatively early radiographic disease (Clegg et al 2005). These results are supported by a more recent controlled trial that found that chondroitin sulfate, but not paracetamol, reduced synovitis and clinical symptoms of OA with a carry-over effect and high safety profile (Monfort et al 2012). In contrast to the above findings, a 24-month, double-blind, placebo-controlled study of 572 patients conducted as part of the GAIT study did not demonstrate reductions in joint space narrowing, although there was a trend for improvement in knees with Kellgren/Lawrence grade 2 radiographic OA. The authors state, however, that power of this study was diminished by the limited sample size, variance of joint

#### Clinical Note

In 2014 the European Society for Clinical and Economic Aspects of Osteoporosis and Osteoarthritis (ESCEO) gathered an international task force of 13 members to determine clinical management of patients with OA. They concluded that the first step in patients with OA and pain is to use either glucosamine sulfate  $\pm$  chondroitin sulphate or paracetamol on a regular basis, while NSAIDs should only be used as an advanced step, if response is not adequate. They recommended that the safer, more sensible approach is not to use paracetamol due to its side effects and questionable efficacy on pain with chronic use, but to recommend chronic symptomatic, slow-acting drugs for osteoarthritis such as chondroitin sulphate. For chondroitin, the effect size on pain is clinically significant and there are benefits on joint structure changes in patients with mild-to-moderate disease using prescription chondroitin 4&6 sulfate. (Bruyere et al 2014). Interestingly, they noted that US groups are reluctant to recommend dietary supplements due to quality issues, whereas there is less concern in Europe as pharmaceutical grade preparations are used.

space width measurement and a smaller than expected loss in joint space (Sawitzke et al 2008).

### Comparisons with NSAIDs

Although chondroitin appears to be at least as effective as non-steroidal anti-inflammatory drugs (NSAIDs) in treating the symptoms of OA (Fioravanti et al 1991, Morreale et al 1996), it has a slower onset of action, taking 2–4 months to establish an effect (Leeb et al 2000, Morreale et al 1996). Chondroitin may, however, provide benefits that persist after treatment is stopped (Mazieres et al 2001, Morreale et al 1996). A cost-effectiveness analysis suggests that chondroitin sulfate in the treatment for OA has less cost and better gastrointestinal tolerability compared than NSAIDs and that, for every 10,000 cases treated, 2666 cases of gastrointestinal adverse events (including 90 serious adverse events) will have been avoided (Rubio-Terres & Grupo del estudio 2010).

### Combined use of chondroitin sulfate and glucosamine sulfate

Chondroitin and glucosamine are frequently marketed together in combination products and some studies suggest that this combination is effective in treating symptoms (Das & Hammad 2000, Leffler et al 1999, McAlindon et al 2000, Miller & Clegg 2011, Nguyen et al 2001) or reducing joint space narrowing (Rai et al 2004, Fransen et al 2014). These findings are supported by an *in vitro* study on horse cartilage that found that a combination of glucosamine and chondroitin was more effective than either product alone in preventing articular cartilage glycosaminoglycan degradation (Dechant et al 2005), as well as an *in vivo* study on rats that found that the combined treatment prevented the development of cartilage damage and was associated with a reduction in interleukin-1-beta and matrix metalloproteinase-9 synthesis (Chou et al 2005). The GAIT trial (see above and Glucosamine monograph) provides evidence that glucosamine hydrochloride and chondroitin are more effective when given in combination than when either substance is given alone, with the combined treatment being more effective than the cyclooxygenase-2 inhibitor, celecoxib, for treating moderate to severe arthritis compared with chondroitin alone (Clegg et al 2006). A substudy of the GAIT trial on the pharmacokinetics of glucosamine and chondroitin sulfate when taken separately or in combination suggests that pain relief following ingestion of chondroitin probably does not depend on simultaneous or prior intake of glucosamine and that any effect on joint pain probably does not result from ingested chondroitin reaching the joint space but rather from changes in cellular activities in the gut lining or in the liver, where concentrations of ingested chondroitin, or its breakdown products, could be substantially elevated following oral ingestion (Jackson et al 2010). More recently, a large double-blind, placebo-controlled, randomised study (n = 605) conducted in Australia concluded that 2 years of

treatment with glucosamine sulfate 1500 mg/day, taken together with chondroitin sulfate 800 mg/day, resulted in significant and clinically relevant joint structure modification (Fransen et al 2014). The same effect was not seen for stand-alone chondroitin sulfate or glucosamine sulfate.

A small randomised controlled trial has suggested that the addition of high-molecular-weight hyaluronate to glucosamine and chondroitin may provide additional benefits to the use of glucosamine and chondroitin alone (Bucci et al 2005).

### Topical preparations

A topical preparation containing chondroitin with glucosamine and camphor has been shown to reduce pain from OA of the knee in one randomised controlled trial (Cohen et al 2003).

### OTHER USES

#### Heart disease

There are suggestions that chondroitin in doses of up to 10 g/day may have antiatherogenic actions and beneficial effects on serum lipid levels and may be useful for reducing the risk of myocardial infarction (Morrison 1969, 1971, Morrison & Enrick 1973, Morrison et al 1969).

#### Snoring

The results of a pilot crossover study of seven subjects suggest that chondroitin sulfate instilled into the nostril at bedtime may reduce snoring (Lenclud et al 1998).

#### Ophthalmic surgery and dry eyes

Chondroitin sulfate is used as a viscoelastic substance to protect and lubricate cells and tissues during ophthalmic surgery, as well as to preserve corneas before transplantation (Larson et al 1989, Liesegang 1990). In a double-blind, crossover study of 20 subjects, 1% chondroitin sulfate was found to be as effective as polyvinyl alcohol artificial tear formulation and 0.1% hyaluronic acid in reducing itching, burning and foreign-body sensation in people with keratoconjunctivitis sicca (Limberg et al 1987).

#### Psoriasis

It has been found that some patients with psoriasis experience a significant clinical and histological improvement in their psoriatic lesions after taking chondroitin to treat their OA (Verges et al 2004, 2005), and this has been confirmed in a clinical trial which suggests that chondroitin could represent a special benefit in patients with both pathologies, since NSAIDs have been reported to induce or exacerbate psoriasis (Moller et al 2010).

#### Interstitial cystitis

Evidence from community-based clinical practice studies along with small randomised controlled trials suggests that intravesical chondroitin sulfate may play a role in the treatment of interstitial cystitis

(Berger 2011, Gentile et al 2011, Nickel et al 2009, 2010, 2012).

### DOSAGE RANGE

- Oral doses of chondroitin range from 800 to 1200 mg/day in either single or divided doses. Intramuscular, intravenous and topical forms are also available.
- A 4–5-month trial is generally used in order to determine whether it is effective for an individual patient.
- A dose-finding study in patients with knee OA suggests that administration of 800 mg of chondroitin sulfate orally had nearly the same effect as 1200 mg/day, while the use of a sequential 3-month administration mode, twice a year, was also shown to provide the same results as continuous treatment (Uebelhart 2008). More recently a double-blind randomised placebo-controlled trial found no significant difference in efficacy, security or tolerability between a single oral daily dose of 1200 mg and three divided doses of 400 mg (Zegels et al 2013).

### ADVERSE REACTIONS

Chondroitin is generally deemed to be extremely safe, with the incidence of adverse reactions being comparable to placebo in studies lasting from 2 months to 6 years (Bourgeois et al 1998, Bucsi & Poor 1998, Hathcock & Shao 2007, Leeb et al 2000, McAlindon et al 2000, Uebelhart et al 1998b, Vangsness et al 2009).

Oral chondroitin may cause mild gastrointestinal disturbance. While there is a theoretical risk of anticoagulant activity, this has not been demonstrated in clinical trials (Chavez 1997) and chondroitin has been assessed as having a complete absence of adverse effects and an observed safe level at doses of up to 1200 mg/day (Hathcock & Shao 2007).

### SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

#### Anticoagulants

Additive effect theoretically possible — observe patient.

#### Non-steroidal anti-inflammatory drugs

Chondroitin may enhance drug effectiveness, suggesting a beneficial interaction is possible — drug dosage may require modification.

### CONTRAINDICATIONS AND PRECAUTIONS

Due to theoretical anticoagulant activity, chondroitin should be used with caution in people with clotting disorders.

Some forms of chondroitin are produced from bovine (usually tracheal) cartilage, so it is theoretically possible that it may be a source of transmission of bovine spongiform encephalopathy (mad-cow disease) and other diseases. This transmission has not been demonstrated and is deemed unlikely.

### PREGNANCY USE

Insufficient reliable information is available to advise on safety in pregnancy.

### Practice points/Patient counselling

- Chondroitin is a naturally-occurring building block of joint tissue and cartilage. Supplements are made from shark cartilage or bovine tracheal cartilage.
- Chondroitin is an effective symptomatic treatment in OA and considered to improve the disability associated with the condition. It appears to slow disease progression when used long-term with positive results most consistently reported when it is used with glucosamine sulphate together. Its symptom-relieving effects occur after several weeks as it is a slow-acting substance.
- It is considered extremely safe and may reduce the need for NSAIDs, which can have serious side effects. In 2014, the European Society for Clinical and Economic Aspects of Osteoporosis and Osteoarthritis (ESCEO) recommended that chondroitin sulfate, glucosamine sulfate or paracetamol be used before NSAIDs in OA.
- Taking chondroitin in conjunction with glucosamine for treating arthritis provides the best results when being used long-term for delaying disease progression.
- Patients undergoing anticoagulant therapy or with clotting disorders should have their blood clotting monitored while taking chondroitin.

### PATIENTS' FAQs

#### What will this supplement do for me?

Multiple scientific studies have shown that chondroitin sulfate reduces the symptoms of OA and may also slow down further progression of the condition. When used long term for slowing the progression of OA, it should be used together with glucosamine. Some people find that they do not require NSAIDs as often when taking chondroitin sulfate.

#### When will it start to work?

Symptom relief takes 2–4 months to reach maximal effect, but protection effects on the joints occur only with long-term use of several years.

#### Are there any safety issues?

Generally considered a very safe treatment and far safer than pharmaceutical anti-inflammatory drugs; however, it should be used with caution by people with clotting disorders or taking anticoagulants.

## Chromium

**HISTORICAL NOTE** Shortly after its discovery in 1959, chromium's importance and role in insulin sensitivity and glucose control was observed *in vitro* (Schwarz & Mertz 1959). Its importance was confirmed in 1977 when a woman on long-term total parenteral nutrition (TPN), without chromium, developed symptoms of diabetes that could not be controlled by insulin. After further investigation it was noted that she was deficient in chromium and when < 50 mcg was added to her TPN solution, symptoms resolved. This led to the US FDA listing chromium as an essential trace nutrient. However, problems in elucidating the effects of chromium supplementation persist, due to a lack of practical methods for diagnosing deficiency (Mertz 1998). Over the years researchers have focused on investigating the effects of chromium supplementation on insulin sensitivity and management and prevention of type 2 diabetes (and to a lesser extent PCOS and other presentations) and cardiovascular disease (Hummel et al 2007), and more recently, mental health and atypical depression (Arthur 2008).

### BACKGROUND AND RELEVANT PHARMACOKINETICS

Absorption of chromium occurs by passive diffusion and is inversely related to dietary intake (e.g. from

a dose of 10 mcg, 2% is absorbed; from a dose of 40 mcg, 0.5% is absorbed) (Anderson & Kozlovsky 1985). Absorption may be inhibited by zinc (Hahn & Evans 1975) and phytates, and enhanced by

oxalate (Bryson & Goodall 1983) and ascorbic acid (Offenbacher 1994). Unfortunately, much of the current information is based on chromium chloride, which is an inorganic and poorly absorbed form, so effects may vary for different forms (Arthur 2008). For example, the complexation of picolinic acid with chromium increases its bioavailability (Press et al 1990). Nicotinic acid is a metabolite of tryptophan that also improves the absorption of chromium (Arthur 2008).

Chromium is transported around the systemic circulation primarily by transferrin (Campbell et al 1997), therefore potentially competing with iron and other microminerals that use this transport mechanism, and accumulates in kidney, muscle and liver (Hepburn & Vincent 2003). It is excreted primarily in urine, but small amounts are lost in hair, perspiration and faeces.

### CHEMICAL COMPONENTS

Chromium exists mostly in two valence states in nature: hexavalent chromium (chromium (VI)) and trivalent chromium (chromium (III)). The hexavalent form is toxic and poses a significant risk mainly via occupational exposure. It is recognised as a potent carcinogen to animals and humans, orally, often as a result of water contamination from industry (Kirman et al 2013, Sedman et al 2006) or when inhaled (Haney 2012). Trivalent chromium is an essential trace element in the human body and approved as a supplement.

Supplemental forms used in trials include organic chromium complexes, such as chromium picolinate and chromium nicotinate/polynicotinate (niacin-bound chromium [NBC]), and inorganic salts such as chromium chloride. While a number of different commercial trivalent chromium supplements exist the best evidence is for the picolinate and polynicotinate forms (Preuss et al 2008).

The picolinate form has been plagued by some controversy over the years — relating to both questions over its effects on iron levels and DNA damage (see below).

### FOOD SOURCES

The chromium content of food is geochemically dependent and Australian soils appear to vary widely in chromium content, thus dietary sources are likely to vary in chromium content due to growing location together with processing methods. In particular, Australian soils appear to be low in chromium, unlike some other locations such as USA (Thor et al 2011). Recommended dietary sources of chromium in Australia include Brewer's yeast, wholegrain breads and cereals, processed meat products and chocolate products (Ashton et al 2003). Other sources documented in the international literature include organ meat, cheese, green beans, broccoli, egg yolk, nuts, poultry, spices, tea, beer, wine (Arthur 2008).

#### Clinical note — Problems testing for chromium deficiency

Currently, testing for chromium deficiency is a serum assay. This is problematic as it is unclear whether serum levels correlate with tissue levels. Previous studies have shown that subjects with widely varying serum chromium levels respond favourably to chromium supplementation, suggesting that this marker is misleading (Bahijri 2000). As a consequence, serum tests should not be solely relied upon, leaving the diagnosis of deficiency up to a practitioner's clinical judgement. Other tests have been proposed, such as toenail chromium concentration (Ayodele & Ajala 2009, Guallar et al 2005) and urinary chromium response to glucose load (Bahijri & Mufti 2002), as conditions that increase circulating glucose and insulin concentrations increase urinary chromium output (Vincent 2004); however, further research is required to confirm the validity of these tests. The recent development and change towards a more sensitive and accurate whole blood test (Cieslak et al 2013) may be better than serum testing; however, there still remains some uncertainty as to whether this newer test provides an accurate reflection of tissue levels.

### DEFICIENCY SIGNS AND SYMPTOMS

#### Primary deficiency

Symptoms of weight loss, glucose intolerance and neuropathy have been noted in patients on TPN deficient in chromium (Verhage et al 1996). Deficiency may also be a precursor to the development of insulin resistance, and thus associated with hyperglycaemia, hypoglycaemia and obesity. Up to 90% of US diets have been found to be below the minimum suggested adequate daily intake for chromium of 50 mcg/day (Anderson & Kozlovsky 1985); as previously mentioned, Australian foods have been found to contain lower levels of this mineral (Ashton 2003), suggesting that the average Australian diet is likely to be lower.

Animal studies suggest that maternal chromium deficiency prior to and during gestation may also have detrimental effects in the offspring such as increased body weight, central obesity and overall percentage of body fat, together with impaired glycaemia (Padmavathi et al 2011). It remains to be tested whether the same results occur in humans.

#### Secondary deficiency

Factors that may exacerbate deficiency, generally by increasing requirements for or urinary excretion of chromium, include pregnancy, excessive exercise, infection, physical trauma and stress (Anderson 1986). Diets high in simple sugars have been found to increase urinary chromium excretion up to 30-fold, thereby increasing the risk of deficiency

(Kozlovsky et al 1986). Corticosteroids also increase urinary losses of chromium (Kim et al 2002).

### MAIN ACTIONS

Most of chromium's main actions are ultimately related to its role in glycaemic control and regulation and secondary benefits for antioxidant systems.

#### Important cofactor

Chromium is an essential trace mineral required for carbohydrate, lipid, protein and corticosteroid metabolism (Kim et al 2002).

#### Improves blood sugar control

Trivalent chromium is an essential trace element for normal carbohydrate metabolism and insulin sensitivity (Wilson & Gandy 1995), aiding the ability of insulin to transport glucose into cells. In particular, chromium improves the ability of insulin to bind to cells by enhancing skeletal muscle Glut4 translocation; enhancing beta-cell sensitivity; increasing the number of insulin receptors; and activating insulin receptor kinase, thus increasing insulin sensitivity; it also appears to reduce the cholesterol ratio in plasma membrane, improving insulin sensitivity (Anderson 1997, Hua 2012, Penumathsa 2009, Wang 2009). Additionally, in vitro studies have shown that chromium inhibits the secretion of TNF-alpha, a cytokine known to reduce the sensitivity and action of insulin, and that this appears to be mediated by its antioxidant effects (Jain & Kannan 2001). In vitro studies also show that chromium chloride prevents the increase in protein glycosylation and oxidative stress caused by high levels of glucose in erythrocytes (Jain et al 2006).

#### Lipid-lowering activity

Although the mechanism of action is yet to be fully explained, studies show that chromium supplementation may decrease triglyceride levels, total and LDL-cholesterol and modestly increase HDL-cholesterol (Bahijri 2000, Lee & Reasner 1994, Press et al 1990, Preuss et al 2000, Sundaram 2013b). In a study by Cefalu (2010), chromium decreased and modulated peripheral tissue lipids in insulin-resistant subjects with improved insulin response post-chromium supplementation. Another in vitro study suggested chromium may have a role in modulating cellular cholesterol accumulation induced by hyperinsulinaemia; mechanisms are thought to involve the upregulation of HDL-C (Sealls et al 2011).

#### Antihypertensive, cardioprotective

In rats with sugar-induced hypertension, niacin-bound chromium lowers systolic blood pressure, at least in part due to its effects on the renin-angiotensin system (Perricone et al 2008). Niacin-bound chromium and chromium phenylalanine also demonstrated improvement in cardiac contractile function and protection in ischaemic-reperfusion injury in a diabetic rat model (Hua 2012).

#### Antidepressant/neurotransmitter effects

According to McCarty (1994), a large proportion of unipolar depressive patients may also have insulin resistance, indicating that people with diabetes may have an increased risk of depression. Increased brain insulin levels, secondary to elevated cortisol or insulin resistance, influences the normal functioning of catecholaminergic neurons, contributing to a depressive state (McCarty 1994). The reputed antidepressant effects of chromium may be explained by improvements in insulin sensitivity (Davidson et al 2003) and related increases in tryptophan availability and/or noradrenaline release (McLeod & Golden 2000). Chromium has also been shown to lower the cortisol response to challenge with 5-hydroxy-L-tryptophan (5-HTP) and decrease the sensitivity of 5-HT<sub>2A</sub> receptors (Attenburrow et al 2002). Influences on serotonergic pathways have also been reported in animal studies using chromium picolinate (Khanam & Pillai 2006) and potassium channels are thought to be involved. Chromium chloride in a rodent model of depression showed antagonistic activities to glutamanergic NMDA and AMPA receptors, as well as a 5-HT<sub>1A</sub> agonistic effect, resulting in antidepressant effects (Piotrowska 2008).

#### OTHER ACTIONS

##### Immunomodulation

A review detailing the effects of chromium on the immune system found that chromium has both immunostimulatory and immunosuppressive effects, as shown by its effects on T- and B-lymphocytes, macrophages and cytokine production (Shrivastava et al 2002).

##### Bone density protection

It has been suggested that modulation of insulin by chromium may have positive effects on bone density, reducing bone resorption and promoting collagen production by osteoblasts (McCarty 1995). One placebo-controlled study using chromium picolinate (equivalent to 200 mcg chromium/day for 60 days) has shown a 47% reduction in the urinary hydroxyproline:creatinine ratio, indicating a decrease in calcium excretion and a potential role in the prevention of osteoporosis (Evans et al 1995).

##### Antioxidant

A placebo-controlled trial using 1000 mcg/day of chromium (in yeast form) for 6 months found chromium to be an effective treatment in reducing oxidative stress in people with type 2 diabetes (T2DM) and severe hyperglycaemia (HbA<sub>1C</sub> > 8.5%); however, the authors noted that it may act as a pro-oxidant in euglycaemic people (Cheng et al 2004).

A similar randomised study confirmed chromium's antioxidant capacity in a similar cohort; chromium (1000 mcg in yeast form), alone or in combination with vitamin C (1000 mg) and vitamin E

(800 IU), reduced oxidation markers after 6 months in 30 T2DM subjects with similar Cr and oxidation markers plasma baseline values (Lai 2008).

The histadinate form of chromium may be superior to picolinate for antioxidant activity according to *in vivo* research with a diabetic model, notably by decreasing cerebral levels of NF- $\kappa$ B and 4-HNE, two inflammatory markers found in diabetic subjects (Sahin et al 2012).

### Anti-inflammatory

In diabetic rats, chromium supplementation can lower the risk of vascular inflammation. Chromium niacinate appears to be more effective than the picolinate form in lowering blood levels of pro-inflammatory cytokines (TNF-alpha, IL-6) and C-reactive protein, and in reducing oxidative stress and lipid levels (Jain et al 2007).

### Increases dehydroepiandrosterone (DHEA)

In a placebo-controlled trial, chromium picolinate (equivalent to 200 mcg chromium/day for 60 days) increased DHEA by 24% in postmenopausal women (Evans et al 1995).

### Hepatoprotection

In alloxan-induced diabetic rats with mild chronic hepatic injury, supplementation with chromium picolinate prevented and ameliorated histopathological damage, elevation in AST and ALT, as well as LFABP, a biomarker of hepatic injury (Fan 2013).

## CLINICAL USE

Supplemental forms used in trials include organic chromium complexes, such as chromium picolinate and chromium nicotinate, and inorganic salts such as chromium chloride. Chromium is known to improve insulin sensitivity and metabolic markers, and as such its clinical applications reflect this central action; it is used in conditions associated with insulin resistance such as T2DM, gestational diabetes (GDM), polycystic ovarian syndrome (PCOS), obesity and syndrome X. It is also used in practice to curb sugar cravings and stabilise blood sugar levels. More recently, it is attracting interest as a potential treatment in mental health disorders, depression in particular.

### Deficiency states: prevention and treatment

Although frank demonstrable chromium deficiency is uncommon (Vincent 2004) and is mostly described in relation to the use of TPN with inadequate chromium levels, subclinical deficiency states in the USA and Australia are thought to be more prevalent (Anderson & Kozlovsky 1985, Ashton 2003); however, it is difficult to detect chromium deficiency via pathology testing so true estimates remain unknown. Chromium supplementation is used in cases *at risk* of deficiency, such as long-term corticosteroid use (Kim et al 2002), patients with evidence of impaired insulin sensitivity, people with a high sugar intake (Kozlovsky et al 1986) or those

suspected to be deficient after a thorough clinical history has been taken.

### Diabetes

Subjects with diabetes (both T1DM & T2DM) appear to have lower tissue levels of chromium and a correlation exists between low circulating levels of chromium and incidence of T2DM (Hummel et al 2007). Additionally, insulin resistance has been associated with higher rates of chromium excretion (Bahijri & Alyssa 2011) and a study of people with T2DM of less than 2 years' duration found they had lower chromium plasma levels (33%) and increased chromium excretion (100%) compared with healthy controls (Morris et al 1999). While still controversial, a number of studies and reviews suggest that chromium supplementation may facilitate insulin signalling and therefore improve systemic insulin sensitivity. A review of 15 clinical studies involving a total of 1690 subjects (1505 of which received chromium picolinate) reported significant improvement in at least one outcome of glycaemic control. The pooled data showed substantial reductions in both hyperglycaemia and hyperinsulinaemia (Broadhurst & Domenico 2006).

### Type 2 diabetes mellitus (T2DM)

Results have shown that chromium supplementation appears to be more effective in patients with T2DM than in those with T1DM (Ravina & Sleczak 1993, Wang & Cefalu 2010).

In 2013, a meta-analysis of seven RCTs comparing chromium supplementation (>250 mcg/day for at least 3 months) to placebo on glucose and lipid profiles in patients with T2DM concluded that chromium significantly reduced fasting blood sugar compared to the placebo ( $P < 0.0001$ ), but had no significant effects on glycated haemoglobin, total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), very low-density lipoprotein cholesterol (VLDL-C), triglyceride (TG) or body mass index (BMI) (Abdollahi et al 2013).

Despite this conclusion, not all studies have produced positive results and several researchers have sought to identify the best responders. It is accepted that chromium supplementation given to human subjects in documented deficiency states experience improved glucose levels. However, it also appears that a clinical response to chromium (i.e. decreased glucose and improved insulin sensitivity) may be more likely in insulin-resistant individuals with T2DM who have more elevated fasting glucose and haemoglobin A(1C) levels (Wang & Cefalu 2010).

In support of this, a more recent study seeking to evaluate the metabolic and physiological differences in responders and non-responders found that a clinical response to a dose of 1000 mcg was correlated to baseline values of poorer insulin sensitivity, high glycosylated haemoglobin (HbA<sub>1c</sub>) and high fasting blood glucose (Cefalu 2010).

Furthermore, in a double-blind RCT of 31 non-obese, normo-glycaemic subjects, those with the highest serum chromium at the start experienced a worsening of their insulin sensitivity after treatment with chromium (500 mcg twice daily for 16 weeks) compared to placebo (Marashani et al 2012).

Some study findings suggest that improvements are dose-related but may also be affected by treatment duration, initial chromium status (Ghosh et al 2002, Amato et al 2000, Masharani et al 2012) and age. A controlled trial of elderly T2DM patients (average age 73 years) reported that supplementation with chromium (200 mcg twice daily) for 3 weeks improved fasting blood glucose, HbA<sub>1C</sub>, and total cholesterol levels (Rabinovitz et al 2004), suggesting lower doses may be effective in older patients. Another study (single blind prospective) in 40 newly diagnosed T2DM subjects (ages 35–67 years) supplemented with 9 g of a chromium-containing brewer's yeast for 3 months also yielded improvements of glycaemia, reducing glycosylated haemoglobin and fasting blood glucose values as well as improving their lipid profile (Sharma 2011).

The most promising RCT to date tested chromium picolinate at doses of 200 and 1000 mcg/day in subjects with T2DM who were instructed to maintain their current medications, diet and lifestyle habits. HbA<sub>1C</sub> values improved significantly in the higher treatment group after 2 months and in both groups after 4 months' treatment. Fasting glucose was lower in the 1000 mcg group after 2 and 4 months (4-month values:  $7.1 \pm 0.2$  mmol/L vs placebo  $8.8 \pm 0.3$  mmol/L). Two-hour glucose values were also significantly lower in the 1000 mcg group after both 2 and 4 months (4-month values:  $10.5 \pm 0.2$  mmol/L vs placebo  $12.3 \pm 0.4$  mmol/L). Fasting and 2-hour insulin values decreased significantly in both groups receiving supplemental chromium after 2 and 4 months. Plasma total cholesterol also decreased in the subjects receiving 1000 mcg chromium after 4 months (Anderson et al 1997). In another study T2DM patients taking sulfonylurea agents, chromium picolinate supplementation (equivalent to 1000 mcg chromium) for 6 months significantly improved insulin sensitivity and glucose control; and attenuated bodyweight gain and visceral fat accumulation compared with the placebo (Martin et al 2006).

Studies using chromium nicotinic acid have proven more promising with higher doses of nicotinic acid (100 mg/day) (Urberg & Zemel 1987) than those with low-dose nicotinic acid (1.8 mg) (Thomas & Gropper 1996), demonstrating a synergistic effect with chromium (200 mcg/day).

It appears the picolinate form of chromium is crucial in obtaining improvements of glycaemic parameters.

#### Type 1 diabetes mellitus (T1DM)

As chromium appears to improve insulin sensitivity rather than secretion its therapeutic potential in T1DM is limited (Edmondson 2002). One study did

show reduced requirements for insulin in 33.6% of patients with T1DM taking 200 mcg chromium/day (Ravina & Slezack 1993), and another showed a 30% reduction in insulin requirements in 71% of subjects at the same dose (Ravina et al 1995), but it is unclear which patients might respond to treatment. No further studies have been done on this population.

#### Gestational diabetes mellitus (GDM)

Pregnancy can be described as an increased insulin resistant state, which may result in GDM if the pancreas is unable to increase insulin levels to maintain blood glucose balance (Jovanovic & Peterson 1996). While chromium serum measurement in pregnancy yielded inconclusive results (Sundaraman 2012, Wood 2008), it appears that chromium excretion is elevated in normal pregnancy, potentially contributing to the insulin resistance (Morris et al 2000). The beneficial effect of chromium on insulin sensitivity provides a theoretical basis for its use in this condition. A small placebo-controlled trial using 4 or 8 mcg/kg of chromium daily in GDM found a significant dose-dependent improvement in fasting insulin, 1-hour insulin and glucose, and postprandial glucose levels after 8 weeks supplementation (Jovanovic et al 1999).

#### Corticosteroid-induced diabetes mellitus

Human trials have shown that corticosteroid use significantly increases urinary chromium excretion. Supplementation with chromium picolinate (equivalent to 600 mcg chromium/day) in patients experiencing steroid-induced diabetes resulted in decreased fasting blood glucose values (from  $>13.9$  mmol/L to  $<8.3$  mmol/L). Furthermore, hypoglycaemic medications were also reduced by 50% in all patients within 1 week (Ravina et al 1999).

#### Antiretroviral medication-induced dysglycaemia

In a study of people with HIV ( $n = 56$ ) and evidence of elevated glucose, altered lipids or body-fat redistribution secondary to antiretroviral medication, supplementation with chromium nicotinate (400 mcg daily) for 16 weeks significantly decreased insulin, triglycerides and total body fat mass; however, blood glucose, HbA<sub>1C</sub>, HDL and LDL values remained unchanged (Aghdassi 2010).

#### Prevention of long-term diabetic complications

Both QTc interval prolongation and chronic hyperinsulinaemia have been associated with atherosclerosis progression and increased cardiovascular morbidity in patients with T2DM. In a crossover trial of 60 subjects, chromium picolinate (1000 mcg/day) for 3 months was shown to reduce both QTc interval duration and plasma insulin levels (Vrtovec et al 2005), probably by reducing the adrenergic activation of the sympathetic nervous system due to hyperinsulinaemia. Benefits were most significant in obese patients with higher peripheral insulin resistance (Vrtovec et al 2005).

In a retrospective study of patients hospitalised with uncontrolled acute hyperglycaemia non-responsive to intravenous insulin, treatment with intravenous chromium chloride at 20 mcg/hour for 10 to 15 hours decreased insulin needs and improved glucose control at 12 and 24 hours post-treatment (Drake 2012).

Animal studies have found that chromium supplementation in mice with T2DM reduces the symptoms of hyperglycaemia and improves the renal function by recovering renal chromium concentration (Mita et al 2005, Mozaffari et al 2005, 2012, Selcuk 2012), which may hold promise for human trials investigating the potential role of chromium in reducing the incidence of diabetic nephropathy.

### Hypoglycaemia

Eight patients with reactive hypoglycaemia were given chromium chloride (equivalent to 200 mcg chromium) for 3 months in a double-blind crossover study. Chromium supplementation significantly improved blood sugar regulation, insulin binding to receptors and red blood cells, and alleviated symptoms of hypoglycaemia (Anderson et al 1987).

A double-blind crossover study using chromium chloride (equivalent to 200 mcg/day elemental chromium) for 8 weeks found a significant improvement in glycaemic control in subgroups where the 2-hour glucose level was >10% above or below the fasting level (Bahjri 2000). In these subgroups chromium supplementation resulted in a 2-hour mean not significantly different to the fasting mean, suggesting an amphoteric effect on glycaemic control.

### Hyperlipidaemia

It has been suggested that some of the potential benefits of HRT on total and LDL-cholesterol and total:HDL-cholesterol ratio may be related to its ability to improve chromium status (Bureau et al 2002, Roussel et al 2002), and trials yielding both positive and negative results for supplemental chromium in hyperlipidaemia have been reported. In a systematic review of 41 trials, 18 studies, with a total 655 participants, reported lipid data for participants with either T2DM or glucose intolerance (Balk 2007). Overall, chromium supplementation was not found to exert a statistically significant effect on lipid levels in either group, although brewer's yeast supplementation did result in a statistically significant increase in HDL cholesterol (+0.21 mmol/L) compared to chromium picolinate.

Currently, it is unclear what circumstances or conditions and type of subjects are most likely to respond to treatment, so in practice a treatment trial period is often used to establish usefulness in individual patients.

A placebo-controlled trial using chromium trypicolinate (equivalent to 200 mcg chromium/day) for 42 days found a reduction in total cholesterol, LDL and apolipoprotein B (the major protein of the LDL fraction) with a slight increase in HDL and a

significant increase in apolipoprotein A1 (the major protein of the HDL fraction) (Press et al 1990). Another RCT of 40 hypercholesterolaemic subjects found that chromium polynicotinate (equivalent to 200 mcg elemental chromium) twice daily for 2 months decreased total (10%) cholesterol and LDL-cholesterol (14%) (Preuss et al 2000).

Another double-blind RCT of young, non-obese adults taking chromium nicotinate (equivalent to 220 mcg elemental chromium) for 90 days found no statistically significant differences in lipid levels (total cholesterol, HDL-cholesterol, LDL-cholesterol, triglycerides) at this dose compared to the placebo; however, this dose is lower than used in most successful studies (Wilson & Gondy 1995).

Lipid-lowering activity does not appear to be significant in people with T2DM according to a meta-analysis of seven RCTs that tested chromium supplementation (>250 mcg/day) taken for at least 3 months (Abdollahi et al 2013).

### Obesity

As chromium has a role in maintaining carbohydrate and lipid metabolism, it has been suggested that chromium supplementation may positively impact body composition, including reducing fat mass and increasing lean body mass (Vincent 2003).

A meta-analysis of RCTs concluded that chromium picolinate elicited a relatively small effect compared with placebo for reducing body weight (Pittler et al 2003). One study, however, did show promising results using 200 mcg niacin-bound chromium TIDS (600 mcg/day) with moderate exercise. At these high doses, while overall reduction in body weight was similar for both the chromium and the placebo groups, total fat loss was more significant in the chromium group, suggesting a muscle-sparing effect (Crawford et al 1999). More recent RCTs using chromium picolinate (equivalent to 200 mcg and 1000 mcg/day) were unable to reproduce these effects (Lukaski et al 2007).

A more recent meta analysis of 20 RCTs concurred with Pittler's findings, and found a small but significant difference in weight loss (1 kg) over placebo for studies lasting at least 16 weeks, but not in studies of shorter duration (Onakpoya et al 2013).

### Atypical depression

The anti-depressant activity of chromium has been noted in a small number of rodent and human studies (Khanam & Pillai 2006, Komorowski et al 2012), however mechanisms are poorly understood (Iovieno et al 2011). Preclinical studies provide a biological basis for its use in depression, chiefly relating to neurotransmitter synthesis and release (McCarty 1994, Liu & Lin 1997) with decreases seen for serotonergic 5-HT<sub>2A</sub> receptor expression and increased receptor sensitivity (Attenburrow et al 2002, Piotrowska et al 2008), antagonistic effects on NMDA and AMPA glutamatergic receptors (Piotrowska et al 2008) and antagonist effects on the dopamine and noradrenergic pathway (Piotrowska et al 2013).

In humans, a case series and a single blind trial conducted by [McLeod and colleagues \(1999, 2000\)](#) have shown that supplementation with chromium 400–600 mcg/day alone or in conjunction with sertraline or nortriptyline antidepressant led to the improvement of symptoms of patients with various treatment-resistant mood disorders.

A small placebo-controlled double-blind study of chromium picolinate (600 mcg/day) for 8 weeks was conducted in 15 patients with DSM-IV major depressive disorder, atypical type. Seven (70%) of 10 patients receiving chromium picolinate and none of the placebo group responded to treatment. Six subjects in the chromium group also experienced remission compared with none in the placebo group. However, only a moderate difference was detected in the Hamilton Depression Scale at the end of treatment for a small number of patients ([Davidson et al 2003](#)). A replication of the Davidson study by [Docherty and colleagues \(2005\)](#) with a larger cohort ( $n = 113$ ) demonstrated similar significant improvements compared to the placebo. The study highlighted that patients with carbohydrate cravings, increased appetite and hyperphagia and diurnal mood variation responded particularly well. While these studies have limitations because they include patients with varied depressive pathologies, they provide encouraging evidence for further studies ([Iovieno et al 2011](#)).

## OTHER USES

Chromium is also used in the following conditions, based on a theoretical understanding of its pharmacological actions.

### Exercise aid – not effective

Chromium has demonstrated an ability to enhance insulin-mediated glucose uptake in cultured cells; however, human supplementation does not appear to exert such benefits. In a small RCT, 16 overweight men were randomised to receive chromium picolinate (equivalent to 600 mcg chromium/day) for 4 weeks before being subjected to supramaximal cycling exercises to deplete glycogen stores, followed by high glycaemic index carbohydrate feedings. At this dose, supplementation did not appear to improve glycogen synthesis during the recovery phase ([Volek et al 2006](#)).

In addition, studies in female athletes have shown no effect on body composition or muscle strength following supplementation with 500 mcg chromium picolinate daily during 6 weeks of resistance training ([Livolsi et al 2001](#)). In a clinical trial of older women a high-dose chromium picolinate supplement did not affect body composition, skeletal muscle size or maximal strength above that of resistance training alone ([Campbell et al 2002](#)). A meta-analysis of trials of dietary supplements for enhancing lean muscle mass and strength during resistance training did not support the use of chromium for this purpose ([Nissen & Sharp 2003](#)).

## POLYCYSTIC OVARIAN SYNDROME (PCOS)

The relationship between PCOS and insulin resistance provides a theoretical basis for the use of chromium in this condition. A small study has found that chromium picolinate (200 mcg/day) appears to improve glucose tolerance but not ovulatory frequency in women with polycystic ovary syndrome ([Lucidi et al 2005](#)). Larger studies are required to investigate the potential benefits of chromium supplementation in this population.

### Critical care

It is reported that up to 67% of critical care patients present on admission to intensive care with acute insulin resistance and blood sugar control may have better outcomes with intra-venous (IV) chromium ([Surani et al 2012](#)). Surani reports a case study of a 62-year-old diabetic, hypercholesterolaemic woman presenting to ICU with cardiac arrest and respiratory failure secondary to aspiration pneumonia and septic shock presenting with acute insulin resistance and requiring 7000 units of insulin over 12 hours, successfully stabilised with an IV infusion of chromium chloride at the rate of 3 mcg/hr (100 mcg in 1 L of saline infused at 30 mL/hr) and leading to the cessation of the insulin infusion.

### Osteoporosis

Effects on bone resorption, calcium excretion and collagen production suggest a role in the prevention of osteoporosis ([Evans et al 1995](#), [McCarty 1995](#)); however, there are no controlled trials to determine clinical effectiveness.

### DOSAGE RANGE

The ESADDI is 50–200 mcg/day. The most common doses studied include 200, 400, 600 and 1000 mcg daily. Doses in the upper range appear to produce more convincing trial results.

- Glycaemic control – 200–1000 mcg for at least 1 to 3 months.

### Australian adequate intake

- Women: 25 mcg/day.
- Men: 35 mcg/day.

Chromium picolinate is the best absorbed form ([Press et al 1990](#)); chromium nicotinate, which also improves absorption ([Arthur 2008](#)), may have a better safety profile and the synergistic effects with nicotinic acid (providing a minimum of 100 mg) may have further benefits in some conditions, especially with regard to lipid profiles and anti-inflammatory effects ([Jain et al 2007](#)).

### ADVERSE REACTIONS

It is important to differentiate between hexavalent chromium (Cr IV) and trivalent chromium (Cr III) when discussing the potential toxicity of chromium. Cr IV is used in industry and is highly toxic, whereas Cr III is approved for use as a supplement and does not attract the same concerns. Recent *in vitro*

**Clinical note — Does chromium picolinate cause cancer?**

There has been some concern in the past arising from *in vitro* studies suggesting chromium picolinate exerts clastogenic effects in hamster ovarian cells (Stearns et al 1995a, 2002) and possible DNA damage (Levina & Lay 2008, Speetjens et al 1999). While some recent reviews seem to maintain the controversy (Jana 2009, Wise 2012, Golubnitschaja 2012), this genotoxicity has been refuted by a number of authors, suggesting the doses tested were several thousand times higher than equivalent human doses (McCarty 1997, Salmon 1996) and that chromium has a relatively short half-life so that the accumulated doses suggested by researchers (Stearns et al 1995a) were not clinically relevant (Hepburn & Vincent 2003). Furthermore, *in vivo* evidence from animals and humans suggests that under normal circumstances trivalent chromium (Cr III) has only restricted access to cells, which would limit or prevent genotoxic effects. A recent rodent study by Komorowski (2008) showed no DNA deletions, chromosome gaps or breaks after a single megadose of 7,500 mg/kg. A 2-year study in rats and mice fed CrPic daily at doses three to five times higher than those commonly recommended showed a general lack of toxicity, except in male rats which developed preputial gland adenomas at the highest doses. The reasons for this remain unclear (Stout 2009). Another study showed no histopathological changes or DNA damage in the kidney of male rats supplemented chromium picolinate (100 mg/kg diet), despite accumulation in the kidney (Mozaffari 2012). Therefore, supplementation at low to moderate doses is not currently considered to be detrimental (Eastmond et al 2008). It should also be noted that picolinic acid appears to be the source of the concern and other forms of chromium have not been implicated (Bagchi et al 2002, Stearns et al 1995b).

studies suggest a possibility that Cr III may oxidise to Cr V, a potential carcinogen (Shrivastava et al 2005); however, this requires confirmation from *in vivo* studies.

Irritability and insomnia have been reported with chromium yeast supplementation (Schrauzer et al 1992).

A follow-up survey found no side effects for doses up to 1000 mcg/day of chromium picolinate at 1 year (Cheng et al 1999).

Of five anecdotal adverse reports attributed to chromium picolinate and reviewed by Lamson and Plaza (2002), only one reporting transient and vague symptoms was considered to be a possible adverse reaction (Huszonek 1993). Three could not

be validated by the reviewers due to concurrent medications (Cerulli et al 1998, Martin & Fuller 1998, Wasser et al 1997), and another involved the inappropriate use of potassium dichromate, a strong oxidising agent known to elicit reactions in a majority of people (Fowler 2000). A case report exists of toxic hepatitis and greatly elevated hepatic chromium levels (>10-fold normal) after 5 months' ingestion of chromium polynicotinate in combination with vegetable extracts (Lanca et al 2002). Whether chromium supplementation was responsible for this incident is currently unclear.

**No adverse effects on iron status**

As chromium competes with iron for binding to transferrin it has been suggested that high-dose chromium supplementation may adversely affect iron status. While some studies support this (Ani & Moshtaghie 1992), others show that serum iron concentrations and serum ferritin concentrations are unaffected by chromium picolinate supplementation (Campbell et al 1997, Lukaski et al 2007). Iron does not use all available transferrin binding sites and therefore this situation is unlikely under normal conditions.

**SIGNIFICANT INTERACTIONS****Corticosteroids**

Corticosteroids increase urinary losses of chromium, and chromium supplementation has been shown to aid in recovery from steroid-induced diabetes mellitus. Therefore a beneficial interaction may be possible (Kim et al 2002).

**Hypoglycaemic medicines**

Chromium may reduce requirements for hypoglycaemic agents (Ravina & Sle Zack 1993, Ravina et al 1995). While a beneficial interaction is possible, this combination should be used with caution and drug requirements monitored and adjusted if necessary by a healthcare professional.

**Hormone replacement therapy**

Women receiving HRT appear to have improved chromium status (Bureau et al 2002, Roussel et al 2002) and the addition of trivalent chromium to 17-beta-oestradiol may enhance IL-6 inhibition in experimental models (Jain et al 2004). Whether this alters chromium requirements is unknown.

**Lipid-lowering medicines**

Additive effects are theoretically possible as some clinical studies have indicated lipid-lowering effects. Observe patients taking this combination and monitor drug requirements.

**CONTRAINDICATIONS AND PRECAUTIONS**

Hypersensitivity to chromium.

**PREGNANCY USE**

Oral ingestion of doses typically found in the diet are likely to be safe. Taken under professional supervision, supplements are also likely to be safe and may be beneficial in the prevention and treatment of gestational diabetes (Jovanovic & Peterson 1996, Jovanovic et al 1999).

**Practice points/Patient counselling**

- Chromium is an essential trace mineral required for carbohydrate, lipid, protein and corticosteroid metabolism.
- Dietary intakes are generally below the minimum suggested safe and adequate levels, and factors such as high-sugar diets, corticosteroid use, excessive exercise, infection, physical trauma and psychological stress further increase the risk of deficiency.
- Chromium supplements are used in the management of T2DM, hypoglycaemia, gestational diabetes and hyperlipidaemia. It appears chromium supplementation taken by people with T2DM for at least 3 months can reduce fasting glucose levels, but have no significant effect on lipids.
- It is also used in the treatment of obesity, atypical depression, polycystic ovary syndrome, to curb sugar cravings and improve osteoporosis.
- Supplemental forms used in trials include organic chromium complexes, such as chromium picolinate and chromium nicotinate, and inorganic salts such as chromium chloride.

**PATIENTS' FAQs****What will this supplement do for me?**

Chromium is essential for health and wellbeing. It reduces fasting glucose levels in people with T2DM when taken as a supplement for at least 3 months. It may also have benefits in gestational diabetes, hypoglycaemia and elevated cholesterol and triglyceride levels in some people, although scientific research has produced mixed results. In practice, it is also used to curb sugar cravings.

**When will it start to work?**

Effects in T2DM take at least 3 months.

**Are there any safety issues?**

Used under professional supervision, chromium supplements are considered safe.

## Cinnamon

**HISTORICAL NOTE** Since ancient times cinnamon has been used for a variety of purposes and was valued as a precious commodity. In ancient Egypt it was used as a flavouring for beverages, in combination with other spices for embalming, and as a medicinal agent. Ancient Chinese herbals document it as a medicinal treatment as early as 2700 BC (Castleman 1991), and it has a long history of use as a remedy for diabetes in China, Korea, Russia and India. In medieval Europe, cinnamon was a common ingredient in cooking, often used together with ginger. Due to the high demand for cinnamon, discovering lands where it grew was a primary motive for a number of explorers in the 15th and 16th centuries. There are more than 250 evergreen shrubs and trees in the genus *Cinnamomum*. Today, two main species of cinnamon are cultivated, *Cinnamomum verum*, also known as Ceylon cinnamon, and *Cinnamomum cassia*, also known as Chinese cinnamon.

## OTHER NAMES

*Cinnamomum verum* (also known as *C. zeylanicum*): cannelle de ceylan, Ceylon celonzimi cinnamon, Ceylon cinnamon, cinnamon bark, cortex cinnamomi ceylanici, dalchini, ecorce de cannellier de Ceilan, echter, gujerati-dalchini, kannel, kuei-pi, kurundu, kulit kayumanis, ob choei, tamalpatra, wild cinnamon.

*Cinnamomum cassia* Blume: cassia, Chinese cinnamon, dalchini, guipi, kannan keihi, keishi, lavanga-pattai, lurundu, macrophyllous cassia bark tree, rou gui, Saigon cinnamon, saleekha, taj, toko keihi, Viet Nam cinnamon.

## BOTANICAL NAME/FAMILY

*Cinnamomum verum* J.S. Presl (also known as *C. zeylanicum* Nees) and *C. cassia* Blume (family Lauraceae).

## PLANT PARTS USED

Dried inner bark of the shoots grown on cut stock of *C. verum* or of the trunk bark, freed from the underlying parenchyma; outer cork of *C. cassia* Blume.

## CHEMICAL COMPONENTS

Both forms of cinnamon contain an essential oil that consists primarily of cinnamaldehyde (up to 80% in *C. verum* and 90% in *C. cassia*) and differ primarily in their eugenol and coumarin content. The volatile oil from *C. verum* contains 10% eugenol, whereas the oil from *C. cassia* contains only trace amounts. Also, *C. cassia* contains coumarin, which is not found substantially in *C. verum*. The bark of *C. verum* contains caryophyllene, cinnamyl acetate and linalool, whereas the bark of *C. cassia* contains catechin and 1,8 cineole. A- and B-type procyanidin oligomers are recognised as bioactive in a number of species, including *C. parthenoxylon*, *C. cassia*, *C. japonica* and *C. burmannii* (Lu et al 2011).

## MAIN ACTIONS

Cinnamon has diverse mechanisms of action. The cinnamaldehyde constituent in cinnamon is attributed with producing most of the herb's biological activity. This component is found in large amounts in both forms of cinnamon. More recently, several other constituents have also been tested in isolation and found to exert significant pharmacological effects.

### Antibacterial and fungicidal effects

Several in vitro studies have identified broad-spectrum antibacterial and fungicidal effects for both forms of cinnamon. This has been chiefly attributed to cinnamaldehyde although other constituents such as eugenol, caryophyllene and 1,8 cineole also exhibit antimicrobial properties.

*C. verum* demonstrated activity against a wide range of bacteria and fungi, including *Bacillus subtilis*, *Escherichia coli*, *Saccharomyces cerevisiae*, *Candida albicans*, *Listeria monocytogenes* and *Salmonella enterica* (De et al 1999, Friedman et al 2002, Matan et al

2006, Simic et al 2004, Tampieri et al 2005). Cinnamon and thyme extracts were found to be superior to two other botanical antifungals (garlic and marigold) in an in vitro study, and recommended as an effective herbal treatment for candidiasis (Moghimi & Shahabi 2011).

*C. cassia* extracts significantly inhibited *Helicobacter pylori* in vitro and produced zones of inhibition greater than or equal to commonly used antibiotics (Tabak et al 1999). The essential oil of *C. cassia* also exhibited strong antifungal properties in vitro (Giordani et al 2006). When tested with amphotericin, a reduced amount of drug was required for adequate antifungal effects.

Antibacterial activity for the oil has also been demonstrated against antibiotic-resistant *E. coli* and *Staphylococcus aureus* (Friedman et al 2004).

### Fungi in bakery products

Antifungal activity against the more common fungi causing spoilage of bakery products, *Eurotium amstelodami*, *E. herbariorum*, *E. repens*, *E. rubrum*, *Aspergillus flavus*, *A. niger* and *Penicillium corylophilum*, was demonstrated for cinnamon oil in vitro (Guynot et al 2003).

### Respiratory tract pathogens

An in vitro study of the antibacterial activity of essential oils and their major components against the major bacteria-causing respiratory tract infection indicated that cinnamon bark oil was effective against *Haemophilus influenzae*, *Streptococcus pneumoniae* and *S. pyogenes* (Inouye et al 2001).

### Oral pathogens

According to in vitro research, cinnamon bark oil is an effective inhibitor of bacteria-causing dental caries and periodontal disease (Saeki et al 1989).

### Carminative

The essential oil exhibits carminative activity and decreases smooth muscle contractions in guinea-pig trachea and ileum, and in dog ileum, colon and stomach (WHO 2004). The oil has also demonstrated antifoaming activity in a foam generator model for flatulence (ESCOPE 2003). The active antispasmodic constituent is considered to be cinnamaldehyde.

### Hypoglycaemic activity

Using an experimental model of diabetes, Kim et al (2006) observed that cinnamon extract significantly reduced blood glucose levels after two weeks of treatment. Both A- and B-type procyanidin oligomers in different *Cinnamomum cassia* extracts have been identified as having hypoglycaemic activity and may improve insulin sensitivity in the treatment of rats with induced type 2 diabetes (Lu et al 2011). In vitro studies on related species of cinnamon, with the same polyphenols as *C. cassia*, have also demonstrated potential for hypoglycaemic effects (Cao et al 2010).

### Enhanced insulin sensitivity

Water-soluble compounds extracted from *C. cassia* potentiate insulin activity, as measured by glucose oxidation in the rat epididymal fat-cell assay. The most active compound, methylhydroxy chalcone polymer (MHCP), increased glucose metabolism approximately 20-fold and was an effective mimetic of insulin according to an in vitro study. When combined with insulin, the responses were greater than additive, indicating synergism between the two compounds (Jarvill-Taylor et al 2001). According to Anderson et al (2004), MHCP is actually a water-soluble polyphenolic type-A polymer that increases insulin sensitivity by activating the key enzymes that stimulate insulin receptors, while inhibiting the enzymes that deactivate them. More specifically, extracts of cinnamon activate insulin receptor kinase and inhibit dephosphorylation of the insulin receptor, leading to maximal phosphorylation of the insulin receptor.

The United States Agricultural Research Service has filed a patent application on the active substances.

### Anti-atherosclerotic activity

Data from animal experiments suggest that cinnamon may be of benefit in controlling lipid metabolism (Jin et al 2010, Qin et al 2008). In an in-vivo and ex-vivo animal study, rats and hamsters were fed a high-fructose diet and given an olive oil loading and a water soluble cinnamon extract, called Cinnulin PF (10 or 50 mg/kg body weight). Cinnulin PF is a 20:1 extract of whole cinnamon powder, standardised to contain at least 3% of the active type A polyphenols. The treatment induced an acute inhibition of elevated postprandial serum triglycerides and an overproduction of intestinal apoB48-lipoproteins. The observed intestinal effects of the cinnamon extract were partly mediated by regulating both abnormal mRNA expression of intestinal insulin signalling and the key proteins involved in intestinal lipoprotein metabolism. The cinnamon extract improved insulin sensitivity in the rats' intestinal enterocytes (Qin et al 2008).

In vitro studies have demonstrated that cinnamon hydrophilic extracts exhibit strong anti-glycation activity; inhibit copper-mediated LDL oxidation and LDL phagocytosis by macrophages; display some ferric ion removal ability; and also exhibit hypolipidaemic activity in vivo. These activities indicate potential in the treatment of chronic metabolic diseases (Jin et al 2010).

### Antitumour activity

Cinnamon extract displayed antitumour activity when administered orally or by intra-tumour injection (Kwon et al 2009). It strongly inhibited the expression of pro-angiogenic factors and master regulators of tumour progression. The effects were seen not only in melanoma cell lines but also in an experimental melanoma model. In addition, cinnamon extract treatment increased the anti-tumour activities of CD8<sup>+</sup> T cells by increasing the levels of

cytolytic molecules and their cytotoxic activity. These findings are important as tumour cells recruit new blood vessels by excessive production of pro-angiogenic factors that play a pivotal role in tumour progression and tumour survival.

According to a study in mice grafted with human melanoma cells, cinnamon effectively impaired human metastatic melanoma cell proliferation and tumour growth. The equivalent dose in humans is 120 mg/kg daily, which is large. This chemopreventive and chemotherapeutic anti-cancer activity occurs via different intracellular mechanisms, namely G1 cell-cycle arrest, elevated intracellular ROS and impairing invasiveness (Cabello et al 2009). Aqueous extract of cinnamon has also been shown to disrupt the G2/M phase of leukaemic cells in vitro affecting cell proliferation (Schoene et al 2009).

### Anti-allergy and anti-asthmatic effects

Cinnamon extract mediates anti-allergy activities in vitro, by reducing degranulation, reducing cysteinyl leukotriene production and reducing the expression of proinflammatory cytokines and proteases in human intestinal mast cells (Hagenlocher et al 2012).

Animal studies using type-A procyanidine polyphenols from *Cinnamomum zeylanicum* bark showed anti-asthmatic effects, and may have potential as a therapeutic agent in asthma management. This study demonstrated histological reductions in lung inflammation, increased oxygen supply to the cells, reduction in goblet cell hyperplasia, reduced mucous secretion, reduced inflammatory cell infiltrates (eosinophils) and mast cell stabilisation. Overall an anti-inflammatory, bronchoprotective and mucolytic potential was suggested; however, additional studies are needed to fully elucidate the exact mechanism (Kandhare et al 2013).

### OTHER ACTIONS

A myriad of other effects have been demonstrated in various in vitro and animal models.

Cinnamon extract may have anti-depressant activity, according to research with a preclinical model. An evaluation of rat behaviours in a forced swimming test showed that *C. zeylanicum* at both 150 and 300 mg/kg had similar effects to imipramine (Emamghoreishi & Ghasemi 2011).

In vitro studies suggest that type A cinnamon polyphenols may exhibit neuroprotective effects by upregulating prosurvival proteins, activating mitogen-activated protein kinase pathways and decreasing proinflammatory cytokines (Qin et al 2013).

Potent antioxidant and anti-inflammatory activity for cinnamon bark oil has been demonstrated in vitro and for the dry ethanolic extract in vivo (ESCOP 2003, Jarvill-Taylor et al 2001, Lee et al 2003, Mathew & Abraham 2006).

A dose-dependent antinociceptive activity has been demonstrated for *Cinnamomum zeylanicum* when administered orally to mice in the hot plate and acetic acid writhing induced tests (Atta & Alkofi 1998).

*C. cassia* also possesses antipyretic activity (Kurokawa et al 1998) and reduced the occurrence of ulcers in rats in a dose-dependent manner in a study that administered an aqueous extract (Tanaka et al 1989).

Besides antispasmodic and broad-spectrum antibacterial and fungicidal activities, cinnamaldehyde exhibits antitumour effects (Kwon et al 1998) and cytotoxicity (Moon & Pack 1983).

*C. zeylanicum* exhibits strong inhibitory effects on osteoclast-like cell formation without affecting cell viability (Tsuji-Naito 2008). This finding presents a novel approach in the treatment of osteopenic disease and warrants further investigation.

### CLINICAL USE

Cinnamon has been used as a medicinal agent in several traditional healing systems. In the last two decades, scientific investigation has been undertaken to investigate its clinical effects. Evidence to support its clinical use is predominantly derived from in vitro and in vivo research, and from traditional usage; however, an increasing number of clinical trials are now being published.

### Dyspepsia and related symptoms

Cinnamon bark oil and crushed cinnamon bark is used in the treatment of dyspeptic conditions, such as mild spastic conditions of the gastrointestinal tract, fullness and flatulence, loss of appetite and diarrhoea. Although controlled studies are unavailable, evidence of antispasmodic and antifoaming activity in animal models and a long tradition of use provide some support for its use in these indications.

Cinnamon bark and Chinese cinnamon are approved by the German Commission E for the treatment of loss of appetite and dyspeptic complaints such as mild gastrointestinal spasms, bloating and flatulence (Blumenthal et al 1998).

### *Helicobacter pylori* infection

A placebo-controlled study of 15 volunteers, 11 women and 4 men aged 16–79 years, with documented *H. pylori* infection, demonstrated that an ethanolic extract of cinnamon was ineffective at eradicating the infection, when used at a dose of 40 mg twice daily for 4 weeks (Nir et al 2000). Considering this is an extremely low dose, and *C. cassia* extracts significantly inhibit *Helicobacter pylori* in vitro to a greater or equal extent than commonly used antibiotics (Tabak et al 1999), further research may be warranted.

### Diabetes and blood glucose regulation

Cinnamon has a long history of use for diabetes in China, India, Korea and Russia. Additionally, a plethora of studies have shown the beneficial metabolic effects of cinnamon and its components in vitro and in animal models. To date, clinical investigations into the effects of cinnamon on blood glucose regulation have produced mixed results. There are several possible explanations for this, which should be addressed in future studies.

### Theories proposed to explain inconsistent clinical results

It appears that duration of use, dosage and baseline glycaemic levels may be important factors influencing results and worthy of further investigation. Additionally, effects on type 2 diabetes (T2DM) are more promising than type 1 diabetes (T1DM), which could be expected as T1DM is primarily a disease of insulin secretion and not insulin resistance. Another factor is the type of cinnamon used as many different species are available in commercial products and they may differ in chemical composition and resultant activities. For example, some studies have used the water-soluble extract of cinnamon, rather than the whole spice. Unfortunately, some studies do not specify which cinnamon has been used, making interpretation of the evidence difficult. Finally, the concomitant diabetic drugs used may also be a factor. An initial and very successful study, showing that oral cinnamon had significant effects on fasting glucose levels involved patients also taking sulfonylurea drugs, which increase insulin secretion; increased secretion coupled with the role of cinnamon in reducing insulin resistance may have led to improved outcomes (Rafehi et al 2012).

The first major study suggesting oral cinnamon may be useful in T2DM was reported in 2003 (Khan et al 2003). The randomised, placebo-controlled study of 60 people demonstrated that cinnamon extracts at all test doses (1, 3 or 6 g daily) produced a clinically significant glucose- and lipid-lowering effect. The volunteers were not using insulin therapy and had a fasting blood glucose reading between 140 and 400 mg/dL. After 40 days of treatment, all three doses of cinnamon reduced mean fasting serum glucose by 18 to 29%, triglycerides by 23 to 30%, LDL-cholesterol by 7 to 27% and total cholesterol by 12 to 26%. No significant changes were observed in the placebo groups. The effect on glucose and lipid levels was sustained 20 days after treatment had ceased, suggesting that cinnamon would not need to be consumed every day. The cinnamon used was *C. cassia*, which was finely ground and put into capsules.

Since then, numerous other interventional studies have been performed, allowing for systematic reviews and meta-analyses to be conducted, producing inconsistent conclusions.

A 2013 systematic review and meta-analysis of ten RCTs ( $n = 543$ ) reported that cinnamon in doses of 120 mg to 6 g per day for 4 to 18 weeks was associated with a significant decrease in levels of fasting plasma glucose, total cholesterol, LDL-C and triglyceride levels. Cinnamon also significantly increased levels of HDL-C but had no significant effect on HbA<sub>1c</sub> (Allen et al 2013).

In 2012 several systematic reviews and meta-analyses were also published.

A 2012 Cochrane review reported that cinnamon did not significantly affect HbA<sub>1C</sub> levels, serum insulin or postprandial glucose when administered at a mean dose of 2 g daily, for a period of 4 to 16 weeks (Leach & Kumar 2012). Importantly, they combined studies involving people with either type 1 or type 2 diabetes and analysed results from 10 prospective, parallel-group design, randomised controlled trials, involving a total of 577 participants. The authors concluded there is insufficient evidence to support the use of cinnamon for type 1 or type 2 diabetes and stated that poor trial reporting standards was a major problem.

Rafehi et al (2012) reviewed 16 clinical studies of which only five found no significant effect on the parameters studied, while all of the other studies found significant beneficial changes caused by cinnamon. Of the studies conducted, five investigated the effects of cinnamon consumption in healthy individuals and six studies investigated effects in individuals with T2DM. The remaining studies have investigated the effects of cinnamon in people with T1DM, metabolic syndrome, impaired fasting glucose, postmenopausal women and women with polycystic ovarian syndrome. Of the five studies performed in healthy individuals, four showed some beneficial effects of cinnamon, whereas only one did not. The authors concluded that positive results were most often seen in studies of at least 12 weeks duration and less likely in short-term studies. Since cinnamon is believed to promote insulin sensitivity, it may be expected that the effectiveness would be greater in those whose disease state was more progressed such as in T2DM, rather than those with milder insulin resistance or minimal insulin resistance.

Another 2012 systematic review and meta-analysis was conducted using results from six clinical trials ( $n = 435$ ). Test doses ranged from 1–6 g cinnamon per day, with follow-up periods from 40 days to 4 months. The review also concluded that the majority of studies did not demonstrate therapeutic efficacy for people with T2DM but acknowledged that cinnamon may be a viable addition to conventional diabetes management in patients with an HbA<sub>1C</sub> exceeding 7%. The meta-analysis demonstrated that the short-term effects of cinnamon on glycaemic control were promising (Akilen et al 2012). The HbA<sub>1C</sub> cut-off had been demonstrated previously in a randomised study by Akilen et al (2012), which showed that 2 g daily of encapsulated cinnamon powder (*C. cassia*) over 12 weeks significantly decreased HbA<sub>1C</sub> ( $P < 0.005$ ) compared to placebo in volunteers with T2DM, HbA<sub>1C</sub> > 7% and treated with hypoglycaemic agents that remained unchanged during the study.

Since these reviews and meta-analyses were published, three more clinical trials have been published, demonstrating positive results.

One small 2012 clinical study of 15 young adults, testing apple cider vinegar and cinnamon, alone and combined, showed that cinnamon may mitigate

postprandial blood glucose in healthy adults, but has no impact on satiety (Chezem et al 2012). Another trial ( $n = 30$ ) using 6 g of ground cinnamon indicated that the postprandial glucose response in both obese and normal weight adults may be moderated by cinnamon (Magistrelli & Chezem 2012). In addition, a trial of 66 Chinese subjects with T2DM taking only gliclazide showed that a water-extracted Chinese cinnamon supplementation (at 120 and 360 mg/day) for 3 months was able to significantly improve blood glucose in this cohort. The low dose cinnamon group also demonstrated reduced blood triglycerides (Lu et al 2012).

### Gestational diabetes

A randomised, double-blind placebo-controlled study of 51 women with gestational diabetes found that 6 weeks of treatment with 1 g of cinnamon daily produced a trend towards decreased insulin requirements (53.85% cinnamon vs 44% placebo,  $P = 0.58$ ); however, this did not reach significance (Graham et al 2005). The cinnamon used was *C. cassia*. The researchers suggested that a longer duration of treatment may be required to produce better results.

### Hypertension

In 2010, Akilen et al demonstrated that a dose of 2 g daily of encapsulated cinnamon powder (*C. cassia*) over 12 weeks significantly decreased systolic and diastolic blood pressure compared to placebo (systolic blood pressure 129 vs 135,  $P = 0.011$ ; diastolic blood pressure 81 vs. 86,  $P = 0.008$ ) in volunteers with T2DM, HbA<sub>1C</sub> > 7% and treated with hypoglycaemic and antihyperlipidaemic agents that remained unchanged during the study. Salt, carbohydrate and protein intake was similar for the two groups during the test period.

A systematic review and meta-analysis of three studies evaluated the short-term effect of cinnamon on blood pressure regulation in patients with pre-diabetes and type 2 diabetes. Cinnamon significantly decreased SBP and DBP by 5.39 mmHg (95% CI, -6.89 to -3.89) and 2.6 mmHg (95% CI, -4.53 to -0.66) respectively (Akilen et al 2013).

### Metabolic syndrome

A water-soluble extract of cinnamon (Cinnulin PF 500 mg/day) significantly reduced fasting blood glucose, systolic blood pressure and increased lean body mass according to a placebo-controlled trial of 22 subjects with prediabetes and metabolic syndrome (Ziegenfuss et al 2006). The study was conducted over 12 weeks and also detected small but statistically significant decreases in body fat in the cinnamon-treated group when within-group analyses were performed.

### Polycystic ovarian syndrome

A pilot study involving 15 non-diabetic women with oligomenorrhoea or amenorrhoea and polycystic ovaries compared cinnamon (333 mg cinnamon extract taken three times a day) to placebo (Wang

et al 2007). The randomised study found oral cinnamon extract resulted in a significant reduction in fasting glucose as well as insulin resistance, as measured by various indices of insulin sensitivity from fasting and oral glucose tolerance test (OGTT) values. Specifically, fasting glucose was reduced by 17% during the 8-week treatment period. The reduction in insulin resistance appears to be mediated through an increase in glucose utilisation, as there were no significant alterations in hyperinsulinaemia measured by fasting insulin or mean insulin levels during OGTT. These preliminary findings are consistent with prior in vivo animal and human studies.

### OTHER USES

Administration of 3 g cinnamon for 6 weeks in 60 athletic women resulted in a reduction in muscle soreness but no significant effect on IL-6 levels (Mashhadi et al 2013a), body composition or exercise performance (Mashhadi et al 2013b).

### Traditional uses

Cinnamon has been used traditionally by ancient healers from many backgrounds for stomach cramps, flatulence, nausea, vomiting, diarrhoea, infant colic, common infections and also female reproductive problems such as dysmenorrhoea, menorrhagia, lactation and pain in childbirth. It has also been used as an ingredient in topical preparations for pain and inflammation. Cinnamon is often used in combination with other herbs and spices for most of these indications. In TCM it is considered to warm the kidneys and fortify yang, so is used for impotence, among other indications. In Ayurvedic medicine and in China, Korea and Russia, it has long been used as a treatment for diabetes.

#### Practice points/Patient counselling

- Cinnamon has been used since ancient times as a flavouring and medicinal agent.
- It is a natural food preservative with antioxidant and wide-ranging antimicrobial and antifungal properties.
- It has been used traditionally to treat dyspepsia, nausea, flatulence, poor appetite, stomach cramps and diarrhoea. Some evidence suggests it may be effective for some of these indications.
- Whether ground cinnamon (*C. cassia*) reduces blood glucose and lipid levels and can be useful for people with type 2 diabetes is uncertain as clinical studies have produced mixed results — individuals wanting to try cinnamon should try a 12-week trial to determine whether they respond.
- Cinnamon oil can cause allergic contact dermatitis when used topically and should be avoided by people with allergies to cinnamon or Peru balsam, pregnant women or those with active gastrointestinal ulcers.

### Natural food preservative

Spices such as cinnamon have been used traditionally to preserve food products. The considerable antimicrobial, fungicidal and antioxidant properties of cinnamon provide a theoretical basis for its use.

### DOSAGE RANGE

#### General guide

- Dried bark (crushed cinnamon): 1.5–4 g taken up to four times daily.
- Fluid extract 1:1: 0.5–1.0 mL taken up to three times daily.
- Tea: half to three-quarters teaspoon of powdered cinnamon in a cup of boiling water taken 2–3 times daily with meals.
- Essential oil: 0.05–0.2 mL diluted in carrier oil.

#### According to clinical studies

##### Diabetes Type 2

- 1–6 g daily of powdered cinnamon (*C. cassia*) — a 12-week trial will determine whether an individual responds

##### Loss of appetite or digestive complaints

- Essential oil: 0.05–0.2 g daily.
- Fluid extract (1:1 g/mL): 0.7–1.3 mL three times daily.
- Infusion or decoction: 0.7–1.3 g in 150 mL water three times daily.
- Tea: 1–4.5 g daily using *C. cassia* bark.

### TOXICITY

The oral LD<sub>50</sub> for cinnamon bark oil in rats is 4.16 g/kg and 3.4 mL/kg body weight.

### ADVERSE REACTIONS

When the powdered herb is ingested orally, it is generally well tolerated; however, when cinnamon oil is applied topically, allergic reactions are possible as cinnamaldehyde may cause allergic contact dermatitis (Cheung et al 2003).

### SIGNIFICANT INTERACTIONS

Controlled studies are not available, therefore interactions are based on pharmacological activity and are largely theoretical and speculative.

#### Hypoglycaemic agents

Oral ingestion of cinnamon capsules may reduce blood glucose levels, therefore theoretically, an additive effect is possible with concurrent use — observe; potential beneficial interaction under professional supervision.

#### CONTRAINDICATIONS AND PRECAUTIONS

Cinnamon is contraindicated in people with an allergy to cinnamon or Peru balsam, in cases of fever of unknown origin or active stomach or duodenal ulcers (WHO 2004).

## PREGNANCY USE

*C. cassia* or *C. zeylanicum/verum* should not be used in pregnancy; however, usual dietary intakes are likely to be safe. Currently, evidence of teratogenicity from animal studies is contradictory.

## PATIENTS' FAQs

### *What will this herb do for me?*

Cinnamon is a natural food preservative with wide-ranging antimicrobial and antifungal properties. It may improve digestion and ease symptoms of dyspepsia, flatulence and nausea. It may also lower blood glucose, total cholesterol and triglyceride levels, however more research is required to confirm these effects and the best dose and form.

### *When will it start to work?*

The effects on digestion should start rapidly; however, effects on blood glucose and lipid levels may take 1 month or more.

### *Are there any safety issues?*

Cinnamon oil can cause allergic contact dermatitis when used topically and should be avoided by people with allergies to cinnamon or Peru balsam, pregnant women or those with active gastrointestinal ulcers.

## Cloves

**HISTORICAL NOTE** Spices such as cloves have been used as food preservatives, disinfectants and antiseptics for centuries (De et al 1999). Modern research has confirmed that cloves are an effective preservative that inhibits the growth of many food-poisoning and food-spoiling bacteria.

### COMMON NAME

Cloves

### OTHER NAMES

Oil of cloves, *Oleum caryophylli*, *Eugenia caryophyllata*, *Eugenia aromatica*, *Caryophyllus aromaticus*, Myrtaceae

### SCIENTIFIC NAME

*Syzygium aromaticum* (family Myrtaceae)

### PLANT PART USED

Dried flower buds (clove oil is distilled from this plant part)

### CHEMICAL COMPONENTS

The main constituent of clove oil is eugenol. Other components include beta-caryophyllene, acetyl eugenol, isoeugenol, eugenine, kaemferol, tannins, gallic acid, vitamin C, minerals (boron, calcium, chromium, iron, manganese, magnesium, potassium, phosphorus) and flavonoids (Nassar 2006).

### MAIN ACTIONS

Because of cloves' significant eugenol content, most pharmacological activity is based on studies involving eugenol.

#### Local analgesic, local anaesthetic and anti-inflammatory

The analgesic action of clove oil and aqueous extract of clove has been established in animal models. It is mainly due to the eugenol component, although other active constituents also exist. Recently, an aqueous extract of clove demonstrated significant analgesic activity that is reversible by naloxone, indicating it is mediated by an opiate pathway (Kamkar et al 2012). Eugenol acts on contact to depress

nociceptors, the sensory receptors involved in pain perception (Brodin & Roed 1984). Eugenol also inhibits prostaglandin biosynthesis through potent cyclooxygenase-1 (COX-1) and COX-2 inhibitory activity (Huss et al 2002, Kelm et al 2000) and modulates inflammatory pathways by inhibiting the release of leukotrienes (Kamatou et al 2012, Raghavenra et al 2006). According to experiments with an animal model, daily doses of eugenol produce a cumulative effect after 5 days of continuous administration, producing a statistically significant reduction in neuropathic pain (Guénette et al 2007). Although eugenol is chiefly responsible for much of the pharmacological activity of cloves, other constituents are also involved (Ghelardini et al 2001a). Eugenol is thought to activate vanilloid 1 receptors, resulting in the modulation of pain (Kamatou et al 2012). In an induced osteoarthritis rat model, daily oral administration of eugenol (40 mg/kg) resulted in improved gait parameters, decreased levels of spinal substance P and calcitonin gene-related peptide and increased dynorphin (Ferland et al 2012).

Inhibitory 15-lipo-oxygenase (LOX) and 5-LOX (involved in asthma and allergic rhinitis) activity of clove has also been demonstrated (Kamatou et al 2012).

Beta-caryophyllene is another key component of clove oil, which exhibits significant anti-inflammatory and rapid local anaesthetic activity in several animal models (Ghelardini et al 2001b, Muruganandan et al 2001). Local anaesthetic effects develop within 5 minutes of application and diminish after about 15 minutes.

#### Fungicidal

Clove oil has an inhibitory effect against yeasts and fungi in vitro (Arora & Kaur 1999). Cloves are

effective against species belonging to the *Eurotium*, *Aspergillus* and *Penicillium* genera in vitro (Guynot et al 2003) and clove essential oil has exhibited strong antifungal activity against *Aspergillus* and aflatoxigenic strains (Bluma et al 2008, Viuda-Martos et al 2007), as well as various other fungal and dermatophyte species (Park et al 2007, Pinto et al 2009), including fluconazole-resistant strains of *Candida* spp. and *Aspergillus* spp. (Kamatou et al 2012, Pinto et al 2009).

Experiments with animal models have identified significant activity against *Candida albicans*. Vaginal candidiasis responded to treatment of topical application of clove oil in animal models, suggesting that further investigation is warranted to determine clinical relevance (Ahmad et al 2005). Another animal experiment found that oral intake of cloves reduced *Candida albicans* growth in the alimentary tract (Taguchi et al 2005). The eugenol component is important for such effects, as in vitro experiments identified that eugenol displays anticandidal activity by affecting the envelope of the organism (Braga et al 2007, Fu et al 2007), specifically through the disruption of the cell membrane sterol pathway (thus decreasing ergosterol, a fungi-specific cell membrane component), leading to cell demise (Kamatou et al 2012, Pinto et al 2009).

### Antibacterial

Antibacterial activity has also been demonstrated for cloves and several of its key constituents. Cloves has activity against Gram-negative, anaerobic, periodontal oral pathogens, including *Porphyromonas gingivalis* and *Prevotella intermedia* (Cai & Wu 1996), *Streptococcus mutans* strains and *Streptococcus salivarius* and 15 other strains of pathogenic bacteria frequently involved in tooth decay and other oral pathologies (Koba et al 2011). In vitro experiments demonstrated a synergistic effect of clove oil and gentamicin against 11 strains of cariogenic bacteria. Eugenol also demonstrated a synergistic effect, except for *S. mutans* and *S. rattii*. A synergistic effect was also demonstrated for both clove oil and eugenol and ampicillin against all 11 strains tested (Moon et al 2011).

Hydroethanolic extract of clove showed significant antimicrobial activity against nosocomial strain isolates of *Klebsiella pneumoniae*, *Escherichia coli* and *C. albicans* (Khan et al 2009). Clove oil also produced a significant decrease in *K. pneumoniae* colonies in the lung of mice induced with acute pneumonia (Saini et al 2009).

Activity has also been demonstrated against *Bacillus subtilis*, *Listeria monocytogenes*, *Salmonella enterica*, *E. coli* and *Saccharomyces cerevisiae* (Burt & Reinders 2003, Chami et al 2005, De et al 1999, Dorman & Deans 2000, Friedman et al 2002, Fu et al 2007) and *Staphylococcus epidermidis* (Fu et al 2007). Ethanolic extract of clove showed superior activity to a garlic extract against a variety of Gram-negative and Gram-positive food-associated bacteria and moulds, including *Staphylococcus aureus* and *E. coli* (Pundir et al 2010). Aqueous extract of cloves demonstrated a strong inhibitory action against six *Helicobacter pylori* strains in vitro (Yang et al 2005).

Eugenol is thought to act through disruption and destruction of the cytoplasmic membrane via rapid ATPase inhibition and release (Devi et al 2010, Gill & Holley 2006a, 2006b). Hemaiswarya and Doble (2009) demonstrated a 50% membrane integrity loss after a 10-minute exposure to eugenol in vitro. Furthermore, a synergistic interaction of eugenol with hydrophilic antibiotics (vancomycin,  $\beta$ -lactam, ampicillin, gentamicin) against Gram-negative bacteria has been demonstrated, with no cytotoxic effects to erythrocytes (effects to erythrocytes is a measurement of substance toxicity) (Hemaiswarya & Doble 2009, Kamatou et al 2012). Further pharmacodynamic studies are needed to establish an effective dosage and potential as treatment strategy to reduce antibiotic resistance and toxicity in clinical trials (Hemaiswarya & Doble 2009).

### Antiviral

In vitro assays have identified inhibitory effects on hepatitis C virus protease (Hussein et al 2000) and human cytomegalovirus (Shiraki et al 1998, Yukawa et al 1996). An animal model confirmed significant activity against herpes simplex virus type 1 (Kurokawa et al 1998). An inhibitory effect against parasitic growth has been demonstrated in vitro for clove oil (Santoro et al 2007).

### Acaricidal

Clove essential oil and eugenol demonstrated potential for further in vivo and clinical trials for acaricidal properties against permethrin-resistant and permethrin-sensitive scabies mites (*Sarcoptes scabiei*). In vitro bioassays against live populations of scabies mites showed clove oil and eugenol to be of toxicity levels equivalent or superior to the positive control benzyl benzoate (a topical acaricide). The acaricidal effect was more rapid in sensitive specimens than non-sensitive ones.

### Antiprotozoan

The essential oil of clove and eugenol inhibited the adhesion of *Giardia lamblia* to bovine epithelial cells in vitro by altering viability, adherence and incubation time. The essential oil, but not eugenol, induced death by lysis, suggesting another constituent is responsible. No cytotoxic effect on the bovine epithelial cells was noted (Machado et al 2011).

### Antioxidant

Several constituents within the flower have antioxidant activity, especially eugenol, which has been the focus of most antioxidant research (Duke 2002). Studies with cloves and eugenol have demonstrated protective effects against several agents, which cause damage to cells and tissues via an oxidative stress mechanism.

Cloves illustrated a protective effect against a cytotoxic agent (peroxynitrite) that causes damage to proteins, lipids and DNA (Ho et al 2008) and significantly reversed isoprenaline-induced cardiac hypertrophy in rats (Choudhary et al 2006). In

other studies, eugenol was shown to reduce radiation-induced membrane damage (Pandey et al 2006), and to demonstrate a 97.3% inhibition of lipid peroxidation (Gülçin et al 2012, Kabuto et al 2007) and increase glutathione (Kabuto et al 2007). Further activities against a number of reactive oxygen species were demonstrated (DPPH, ABTS, superoxide anion radical, hydrogen peroxide-scavenging and ferric ion  $[\text{Fe}^{3+}]$ -reducing and ferrous ion  $[\text{Fe}^{2+}]$ -chelating activities) (Gülçin et al 2012).

### Anticarcinogenic

Eugenol essential oil showed anticancer apoptosis activity on HL-60 human promyelocytic leukaemia cells in vitro (Yoo et al 2005). Further chemopreventive potential was explored in mice with induced lung carcinogenesis. A clove infusion, administered orally, was found to significantly reduce proliferating cells and increase apoptosis. The cloves down-regulated some growth-promoting proteins, while at the same time upregulating the expression of some proapoptotic proteins (Banerjee et al 2006). Later in vitro studies confirmed apoptosis induction of eugenol (and its analogues) as well as anti-inflammatory action through downregulation of Bcl-2, COX-2 and interleukin-1 $\beta$  (IL-1 $\beta$ ) (Hussein et al 2011), suggesting that it may have a chemotherapeutic role (Carrasco et al 2008). An aqueous infusion of cloves, administered orally, in a mouse experiment delayed the formation and reduced skin papilloma (Banerjee & Das 2005).

A comparative in vitro study showed indiscriminate cytotoxicity of gemcitabine (a chemotherapeutic agent used in cervical cancer) to both healthy and cancerous cell lines, whereas a crude clove extract diluted in 2% Dubecco's modified Eagle medium was found to preferentially be more cytotoxic to cancer cell lines. A low-dose gemcitabine and crude clove extract was synergistically more cytotoxic towards cervical cell lines than individual preparations (Hussein et al 2009).

Clove essential oil and eugenol showed a 40–80% inhibition of melanin production in B16 melanoma cells in vitro at a concentration of 100–200 mcg/mL; however, the essential oil showed cytotoxicity at higher concentration, a strong consideration in establishing safe therapeutic dose in the development of further studies (Arung et al 2011).

A 2012 review (Jaganathan & Supriyanto 2012) established the antiproliferative, apoptotic and chemopreventive activities as well as the molecular mechanisms of eugenol and some of its dimers against melanomas, skin tumours, osteosarcoma, leukaemia, androgen-insensitive prostate, hepG2 hepatoma, lymphoma and gastric in vitro cancer cell lines and in animal models (Jaganathan & Supriyanto 2012, Kamatou et al 2012).

Antigenotoxic and antimutagenic activity of eugenol was non-significant in vitro. A small human study of 10 healthy non-smoking males administered a dose of 150 mg of eugenol/day did not

demonstrate any antigenotoxic activity (Kamatou et al 2012).

## OTHER ACTIONS

### Improvement of cognition — memory

An animal study found that intraperitoneally-administered clove extract (200 mg/kg) improved short-term memory recall but caused some impairment in learning ability (Morshedi et al 2006). A 3-week treatment with clove oil (0.05 mL/kg) has been shown to reverse memory acquisition latency and memory deficit in a rodent model of scopolamine-induced memory impairment. Malondialdehyde and glutathione brain levels in the clove mice were increased; the reversal of short-term and long-term memory deficit is thought to be due to antioxidant activity on clove (Halder et al 2011).

### Antihistamine

Clove bud extracts inhibit histamine release from mast cells in vivo and in vitro (Kim et al 1997, 1998, Shakila et al 1996).

### Immunomodulatory

An in vitro study found that clove inhibited murine macrophage production of cytokines IL-1 $\beta$ , IL-6 and IL-10 and eugenol inhibited IL-6 and counteracted significantly lipopolysaccharide (endotoxins produced by Gram-negative bacteria) (Bachiega et al 2012).

A previous study found no significant influence in Th1/Th2 modulation in mice fed a water extract of clove (Bachiega et al 2009).

### Antispasmodic

Both beta-caryophyllene and eugenol have antispasmodic activity (Duke 2002).

### Anticholinesterase

Clove extract, its oil and eugenol showed inhibition of AChE in vitro (Dalai et al 2014).

### Antiplatelet

Eugenol inhibits platelet aggregation in vitro (Srivastava 1993, Srivastava & Malhotra 1991). It was more potent than aspirin in several experimental models and equivalent to indomethacin in one (Srivastava 1993).

### Antidiabetic

In vitro tests have identified hypoglycaemic activity for cloves. It appears that a phenolic compound in cloves may be the key constituent responsible and acts by repressing the expression of genes which control hepatic gluconeogenesis (Prasad et al 2005). Commercially sold culinary cloves were also shown to be potent inhibitors of fructose-mediated protein glycation and so may have antidiabetic potential (Dearlove et al 2008). Further research is required with in vivo models of diabetes to determine whether these effects may have clinical significance.

### Gastroprotective and antiulcerogenic

Prophylactic use of both *Syzygium aromaticum* steamed distilled essential oil and eugenol displayed antiulcer and gastroprotective activity through increased quantification of free gastric mucus production in indomethacin and ethanol-HCl-induced rat models (Santin et al 2011).

### CLINICAL USE

The clinical effects of cloves and clove oil have not been significantly investigated; however, an understanding of the herb's pharmacological activity suggests a role in the treatment of several conditions.

### Toothache and relief of dry-socket pain

Clove oil and dried clove buds are used in dentistry to relieve dental pain and reduce infection. The anaesthetic effects of eugenol, the main component of clove, as well as its analgesic and anti-inflammatory effects have been well documented in vivo. Based on the evidence available, Commission E has approved cloves for use as a local anaesthetic and antiseptic (Blumenthal et al 2000). In one study, 2 g of a 2:3 clove:glycerin gel was found to be as effective as 2 g of a 20% benzocaine gel as a topical anaesthetic before needle insertion in dentistry (Alqareer et al 2006).

### Oral hygiene

Used as an antiseptic and antibacterial agent for the oral mucosa, clove is used as an ingredient in mouth rinses and gargles. Its established antiseptic activity provides a theoretical basis for efficacy. Aqueous extract of cloves has also demonstrated significant analgesic activity mediated by an opiate pathway, according to in vivo research (Kamkar et al 2012).

### Anal fissures

A small ( $n = 55$ ) single-blind randomised trial comparing topical application of 1% clove oil cream or a 5% lignocaine cream and stool softeners in the treatment of anal fissure showed statistically significant healing of fissures and reduction in anal pressure with the clove cream (60%) compared to the lignocaine treatment (12%) (Elwakeet 2006, Nelson et al 2012).

### Herpes simplex virus type 1

One study using a combination of aciclovir and cloves administered orally found this to be superior to aciclovir alone in the treatment of herpes simplex virus type 1 infection (Kurokawa et al 1995). The combination significantly reduced the development of skin lesions and/or prolonged survival times of infected mice and reduced viral loads.

### Headache (as part of a combination)

Tiger balm is a popular over-the-counter preparation that contains clove oil, menthol, cassia oil, camphor, cajuput oil and sometimes peppermint oil. It is generally used to relieve the symptoms of sore

muscles, but a randomised, double-blind study found that it is also as effective as paracetamol in reducing headache severity (Schattner & Randerson 1996). Although encouraging, the role of cloves in this combination is difficult to assess from the study.

### Type 2 diabetes

In a small study, 36 people with type 2 diabetes were given 0, 1, 2 or 3 g capsules of cloves for 30 days. All the groups administered with cloves had significantly lowered serum glucose, triglycerides, total and low-density lipoprotein cholesterol and there was no change in high-density lipoprotein cholesterol. After a 10-day washout period all these parameters were still significantly lower than at the start of the trial (Khan et al 2006). Further research is warranted to confirm clinical use in type 2 diabetes and to assess any side effects with oral ingestion of cloves.

### OTHER USES

Cloves have been investigated as an agent to protect harvests from fungal contamination (Ranasinghe et al 2002).

#### Practice points/Patient counselling

- Clove flower buds and clove oil have antiseptic, analgesic, anti-inflammatory and local anaesthetic properties.
- As a gel, it is directly applied to relieve the symptoms of toothache, dry socket and anal fissures.
- Clove oil is also used in mouth rinses and gargles to improve oral hygiene.
- Massaging one drop of oil into the temples has been used to treat headache.
- This herb and its essential oil should not be taken internally.

### DOSAGE RANGE

- Powder: 120–300 mg as a single dose.
- Oil: 0.05–0.2 mL as a single dose.
- Toothache or gum inflammation: oil of clove is applied directly to the site.
- Dry socket: the area is packed with dried flower buds steeped in oil.
- Anal fissure: 1% clove essential oil in base cream.
- Headache: one drop of oil massaged into each temple or area of pain.

### ADVERSE REACTIONS

According to one review, contact dermatitis and several adverse reactions to eugenol used in dentistry have been reported, and local application may cause irritation to mucous membranes in sensitive individuals (Kamatou et al 2012). Used neat, clove oil is considered hazardous, and dermal irritation is reported with topical ointment at concentrations above 20% (Lis-Balchin 2006). Oral use of the oil can cause nervous system depression, seizures,

hepatic dysfunction and irritation and necrosis to mucosal tissues. Five cases of fulminant hepatic failure were reported by the [European Medicine Agency \(2011\)](#). All were associated with the ingestion of 5–10 mL of clove oil by children under 2 years.

### SIGNIFICANT INTERACTIONS

Cloves have been found *in vitro* to strongly inhibit metabolism mediated by CYP3A4 and CYP2D6, but clinical relevance has yet to be established ([Usia et al 2006](#)). If cloves are only used topically, these interactions are unlikely to be relevant.

### CONTRAINDICATIONS AND PRECAUTIONS

None known.

### PREGNANCY USE

Safety unknown.

### PATIENTS' FAQs

#### *What will this herb do for me?*

Clove flower buds and clove oil have antiseptic, anti-inflammatory properties. As a gel, its analgesic and local anaesthetic properties are useful in the treatment of toothache, dry socket and common mouth infections. It has applications with anal fissure as a 1% cream. Massaging one drop of the oil into the temples may relieve the symptoms of headache.

#### *When will it start to work?*

Research suggests that effects are almost immediate, although short-lasting.

#### *Are there any safety issues?*

Clove buds and clove oil should not be taken internally, and only applied externally in diluted form, as pure essential oil is reportedly hazardous. Using cloves as a spice in cooking may give you some of the antioxidant benefits.

## Cocoa

**HISTORICAL NOTE** Cocoa originates from Mexico, where the Mayas, Incas and Aztecs considered it the food of the gods. Chocolate, mixed with vanilla and sugar, was first introduced as a beverage in Europe by Columbus and was considered an aphrodisiac and a symbol of wealth and power. The phenolics in chocolate prevent the fat becoming rancid, decreasing the need for added preservatives. This quality was exploited during World War II when at times US troops were rationed three chocolate bars per day during heavy combat as their sole source of nourishment (Waterhouse et al 1996). While an amusing association between countries' annual chocolate consumption and the number of Nobel laureates per capita has been described, direct correlation between past Nobel prize winners' chocolate intake and their academic success hasn't been established (Maurage et al 2013, Messerli 2012).

### COMMON NAME

Chocolate, cocoa, cocoa liquor, cocoa mass, baking chocolate, Cacoapro, Acticoa

### BOTANICAL NAME/FAMILY

*Theobroma cacao* (family Sterculiaceae)

## PLANT PARTS USED

Cocoa is produced through a process of fermenting the seeds from the pods of the cacao tree, *Theobroma cacao*. The beans are dried, roasted and crushed to produce high-fat, unsweetened chocolate, which is also called baking chocolate. This intermediate is pressed and alkalisated to form cocoa powder, which is then homogenised with sugar and cocoa butter, and sometimes milk, to ultimately form chocolate. Dark chocolate generally contains more than 50% cocoa, whereas mass-produced milk chocolate contains only around 10% cocoa. White chocolate is based on cocoa butter (or theobroma oil) without the cocoa solids.

Although many different types of cocoa beans grow throughout the world, three varieties of cocoa beans are mainly used to make chocolate products: (1) criollo (meaning 'native'), distributed to the north and west of the Andes; (2) forastero (meaning 'foreign'), found mainly in the Amazon basin; and (3) trinitario (meaning 'sent from heaven') (Bruinsma & Taren 1999).

Cocoa beans from different countries along with postharvesting and processing procedures can have a striking influence on the flavanol content of chocolate and cocoa (Hollenberg et al 2004). As flavanols impart a bitter, astringent flavour, chocolate often undergoes extensive processing, dilution and the addition of flavour modifiers to improve its palatability, despite these processes having the potential to negatively impact on cocoa's nutritional and clinical value (McShea et al 2008). While a study that examined the total phenolic content of chocolate found that the antioxidant properties of the artisan-made chocolate were significantly better than those of the factory-produced chocolate (Cervellati et al 2008), recent attention to flavonoid content has led to the development of commercial processes that protect and preserve the naturally occurring flavonoids, with Cocompro being developed by Mars and Acticoa by the Swiss-based Barry Callebaut.

## CHEMICAL COMPONENTS

Cocoa is among the most concentrated sources of the flavanols, catechin and epicatechin, with four times the catechin content of tea (Arts et al 1999). Chocolate also contains additional flavonoids not found in tea, with high concentrations of oligomeric procyanidins (Lazarus et al 1999). Dark chocolate has the highest total catechin content, with approximately 53.5 mg/100 g, whereas milk chocolate contains approximately 15.9 mg/100 g (Arts et al 1999). White chocolate primarily contains cocoa butter with minimal levels of polyphenols. The bioavailability of cocoa flavanols may change depending on the type of sugar used in the chocolate formulation, with maltitol-containing chocolate being associated with reduced flavanol absorption compared to its sucrose-containing equivalent (Rodríguez-Mateos et al 2012).

In addition to flavanols, cocoa also contains the methylxanthines caffeine and theobromine, the biogenic amines phenylethylamine, phenylalanine and tyrosine (Bruinsma & Taren 1999) and the cannabinoid-like fatty acid anandamide analogues, *N*-oleoylethanolamine and *N*-linoleoylethanolamine (Di Tomaso et al 1996). Chocolate is also a rich source of minerals, including magnesium, calcium, iron, copper, phosphorus, potassium and zinc (Steinberg et al 2003) and it is suggested that the presence of methylxanthines, peptides and minerals could synergistically enhance or reduce cocoa's antioxidant properties (Jalil & Ismail 2008).

## Food source

Cocoa and chocolate are nutritious foods that contribute to caloric as well as trace mineral intake (Steinberg et al 2003). Milk chocolate has a relatively low glycaemic index of approximately 40 (Foster-Powell et al 2002) and this is attributed to the fat in chocolate slowing gastric emptying and thus the rate of subsequent digestion and absorption. The glycaemic effect of milk chocolate can be further reduced by replacing the sucrose with fructose or isomalt (Gee et al 1991).

## MAIN ACTIONS

### Antioxidant

Cocoa has been found to have much higher levels of total phenolics and flavonoids, with a correspondingly higher antioxidant capacity per serving, than black tea, green tea or red wine (Lee et al 2003). It has been suggested that the antioxidant capacity of cocoa polyphenols is greater than synthetic antioxidants and that they have the potential to complement or replace synthetic antioxidants in aqueous and oil-based food applications (Osman et al 2004). There is, however, tremendous variability in cocoa processing, flavonoid content and measurement of flavonoids,

Cocoa has been consistently shown to confer significant protection against oxidation both in vitro (Martin et al 2008, Sies et al 2005, Waterhouse et al 1996) and in vivo (Kondo et al 1996). In addition to reducing lipid oxidation, consumption of a flavanol-rich cocoa beverage has been shown to reduce susceptibility of erythrocytes to haemolysis and to increase their ability to buffer free radicals (Zhu et al 2005).

While the antioxidant activity of cocoa is well established, questions remain around best forms for maximal bioavailability and dosing frequency (Fisher & Hollenberg 2006).

Cocoa powder dissolved in milk as one of the most common ways of cocoa powder consumption seems to have a negative effect on the absorption of polyphenols; however, statistical analyses have shown that milk does not impair the bioavailability of flavonoids (Keogh et al 2007, Roura et al 2007). High-flavonoid cocoa products may lead to greatly

enhanced flavonoid bioavailability in humans (Tomas-Barberan et al 2007).

A feeding study demonstrated that procyanidins were remarkably stable in the stomach environment and thus most ingested procyanidins reach the small intestine intact and are available for absorption or metabolism (Rios et al 2002). Epicatechin and its metabolites reach maximal levels 2 hours after either chocolate or cocoa intake, with rapid excretion in the urine (Baba et al 2000) and dimeric procyanidins have been detected in human plasma as early as 30–60 minutes after the consumption of flavanol-rich beverages providing 0.25–0.50 g/kg cocoa/kg body weight (Holt et al 2002, Zhu et al 2005). Human studies have confirmed that the polyphenols in chocolate are indeed bioavailable and able to increase the antioxidant capacity of plasma, with one study reporting that ingestion of 80 g of procyanidin-rich chocolate increased plasma epicatechin concentrations 12-fold, significantly increased plasma total antioxidant capacity by 31% and significantly decreased 2-thiobarbituric acid-reactive substances by 40% after 2 hours, with levels returning to normal within 6 hours (Rein et al 2000a). Similarly, a 2012 study identified that both dark chocolate and high-antioxidant dark chocolate had a peak total antioxidant capacity 2 hours postingestion, with the high-antioxidant dark chocolate showing raised levels for over 5 hours postingestion (Lettieri-Barbato et al 2012).

There is evidence that the polyphenols are not the only antioxidants in chocolate, as suggested by a study that found that consumption of chocolate containing 200 mg of polyphenols, as well as chocolate with less than 10 mg of polyphenols, reduced faecal free-radical production (Record et al 2003). Furthermore, similar reductions in markers of lipid peroxidation have been observed after daily consumption of 75 g of dark chocolate and dark chocolate enriched with cocoa polyphenols, as well as with white chocolate, which contains very little polyphenols (Mursu et al 2004).

In a crossover study in 23 healthy subjects, cocoa powder and dark chocolate were seen to modestly reduce low-density lipoprotein (LDL) oxidation susceptibility while increasing serum total antioxidant capacity and high-density lipoprotein (HDL) cholesterol concentrations (Wan et al 2001), and another crossover trial of 25 healthy subjects found that supplementation with 36.9 g of dark chocolate (30 g of cocoa powder drink) for 6 weeks reduced LDL oxidisability (Mathur et al 2002). Similar results were seen in a randomised, double-blind crossover trial that found that a high-flavanol cocoa drink providing 187 mg flavan-3-ols/100 mL significantly reduced lipid peroxidation, compared with a low-flavanol cocoa drink providing only 14 mg/100 mL (Wiswedel et al 2004).

In contrast to these studies a further randomised, double-blind, placebo-controlled study of 21 healthy adults, however, found that intake of high-flavonoid (213 mg procyanidins, 46 mg epicatechin) dark chocolate bars for 2 weeks did not alter resistance

to LDL oxidation, total antioxidant capacity, 8-isoprostanes, blood pressure, lipid parameters, body weight or body mass index (BMI), despite increasing plasma epicatechin concentrations and improving endothelium-dependent flow-mediated dilation of the brachial artery (Engler et al 2004).

### Lipid-modifying

A 3-week clinical supplementation trial of 45 non-smoking, healthy volunteers consuming high-polyphenol chocolate found a significant increase in serum HDL cholesterol with dark and high-polyphenol chocolate (11.4% and 13.7%, respectively), whereas white chocolate consumption resulted in a small decrease in HDL. Markers of lipid peroxidation decreased 11.9% in all three study groups, suggesting that, while cocoa polyphenols may increase the concentration of HDL cholesterol, chocolate fatty acids may modify the fatty acid composition of LDL, making it more resistant to oxidative damage (Mursu et al 2004).

A new soluble cocoa fibre product rich in soluble dietary fibre and antioxidant polyphenols diminished the negative impact of the cholesterol-rich diet in an animal model of dietary-induced hypercholesterolaemia (Ramos et al 2008). Similarly, in an animal model of hypercholesterolaemia a cholesterol- and triglyceride-lowering effect along with a reduction of biomarkers of oxidative stress and increasing faecal bulking was seen after 3 weeks of consuming a fibre-rich cocoa product (Bravo et al 2008).

It appears that chronic intake of cocoa-based products is required for effects, as an acute dosing study using 100 g of either dark chocolate (55% dry cocoa solids) or high-antioxidant dark chocolate (66% dry cocoa solids) did not significantly affect total cholesterol levels 5 hours afterwards, although triacylglycerol was significantly increased in both products after 1 hour (Lettieri-Barbato et al 2012).

### Effects on microcirculation and nitric oxide

Flavanols have been shown in several in vitro or ex vivo studies to modify the production of proinflammatory cytokines, the synthesis of eicosanoids, the activation of platelets and nitric oxide (NO)-mediated mechanisms (Selmi et al 2008). A double-blind, dose-finding study found that flavanol-rich cocoa increased circulating NO species in the plasma of male smokers, with maximal effects seen with ingestion of 176–185 mg flavanols (Heiss et al 2005). Another double-blind trial found that ingestion of a high-flavanol cocoa drink, but not a low-flavanol one, enhanced NO bioactivity and increased plasma concentrations of nitroso compounds and flow-mediated dilation of the brachial artery (Sies et al 2005). Similarly, ingestion of flavanol-rich cocoa is associated with acute elevations in levels of circulating NO species, enhanced flow-mediated dilation response of conduit arteries and an augmented microcirculation, with these effects being mimicked by ingestion of chemically pure epicatechin. Moreover, chronic consumption of a

cocoa-flavanol-rich diet has been associated with augmented urinary excretion of NO metabolites (Schroeter et al 2006).

Double-blind, crossover intervention studies in both humans and rats suggest that an increase in the circulating NO pool following flavanol consumption is correlated with decreased arginase activity as the availability of L-arginine can be a rate-limiting factor for cellular NO production by nitric oxide synthase (NOS) (Schnorr et al 2008).

### Cardioprotection

A significant reduction in experimentally induced myocardial infarct size was observed following treatment with the cocoa-derived flavanol (–)-epicatechin in vivo. Test animals who were 48 hours and 3 weeks post permanent coronary occlusion experienced a 52% and 33% reduction in myocardial infarct size respectively (Yamazaki et al 2010). The left ventricular scar area strain was improved following (–)-epicatechin treatment, suggesting possible cardioprotective mechanisms (Arranz et al 2013).

### Inhibits platelet activation

Numerous dietary intervention studies in humans and animals indicate that flavanol-rich foods and beverages might exert cardioprotective effects with respect to vascular function and platelet reactivity (Keen et al 2005). Acute doses of flavanols and oligomeric procyanidins from cocoa have been observed to inhibit platelet activation (Pearson et al 2002, Rein et al 2000b) and have an aspirin-like effect on primary haemostasis 2 and 6 hours after consumption (Hermann et al 2006, Pearson et al 2002, Rein et al 2000b), with the effects being similar to, but less profound than, aspirin (Pearson et al 2002). Similar results have been observed in longer studies with lower doses of cocoa flavanols, with a double-blind, controlled trial demonstrating significantly lower platelet aggregation and significantly higher plasma ascorbic acid concentrations after supplementation with cocoa flavanols (234 mg cocoa flavanols and procyanidins/day) over 28 days (Murphy et al 2003).

In a randomized controlled trial (RCT) of 30 healthy volunteers, 100 mg of dark chocolate, but not white or milk chocolate, was found to significantly inhibit collagen-induced platelet aggregation (Innes et al 2003). The alteration of eicosanoid synthesis has been suggested as a plausible mechanism by which procyanidins can decrease platelet activation, and this has been observed in an in vitro study of the effect of procyanidin on aortic endothelial cells, as well as in a randomised, blinded, crossover study of high-procyanidin chocolate (4.0 mg/g) (Schramm et al 2001).

### Diabetes — glycaemic control

Pretreatment with a cocoa extract high in polyphenols was seen to normalise body weight, plasma glucose levels, total cholesterol, triglycerides and HDL levels in streptozotocin-diabetic rats (Ruzaidi et al 2008). The supplementation of 0.5% epicatechin

in drinking water of non-obese diabetic mice reduced the incidence of hyperglycaemia (16.6% of treated vs 66.7% of control mice), significantly increased plasma insulin levels (0.392 mcg/L in treated vs 0.129 mcg/L in controls) and lowered glycosylated haemoglobin levels (5.2% in treated vs 7.4% in controls) (Fu et al 2013). In preadipocytes, cocoa polyphenol extract is able to inhibit insulin receptor activity, as well as prevent the development of obesity in mice given a high-fat diet (Min et al 2013).

In humans, short-term administration of flavonoid-rich dark chocolate significantly improved insulin sensitivity and endothelial function in healthy and hypertensive subjects (Grassi et al 2008b), while a double-blind, placebo-controlled crossover study found that flavanol-rich dark chocolate but not flavanol-free white chocolate ameliorated insulin sensitivity and beta-cell function, decreased blood pressure and increased flow-mediated dilation in hypertensive patients with impaired glucose tolerance (Grassi et al 2008a). Similar results were obtained from another small RCT that found that high-flavanol cocoa reversed vascular dysfunction in diabetic patients (Balzer et al 2008). In contrast to these findings, a double-blind, crossover study found that daily consumption of flavanol-rich cocoa for 2 weeks was not sufficient to reduce blood pressure or improve insulin resistance in human subjects with essential hypertension (Muniyappa et al 2008). Similarly, a randomised crossover study determined that the short-term (5-day) intake of cocoa flavanols (30–900 mg per day) did not have any effect on glucose metabolism in 20 obese participants at risk of insulin resistance; however markers of oxidative stress, inflammation and haemostasis were significantly reduced (Stote et al 2012).

### Psychological effects

Chocolate is purported to have a range of psychological effects, including enhanced arousal and cognitive function, stimulation of feelings of wellbeing and euphoria, as well as initiating cravings. The orosensory aspects of chocolate, including its taste, smell and texture, certainly contribute to chocolate's positive appeal. Chocolate contains large amounts of fat in the form of cocoa butter, which melts at body temperature, producing a pleasurable melt-in-the-mouth experience. Chocolate also often contains large amounts of sugar and thus satisfies the seemingly innate preference for sweet, high-fat foods (Bruinsma & Taren 1999).

In addition to unique sensory properties, chocolate also contains many pharmacologically active substances. Several endogenous biogenic amines with sympathomimetic properties are found in chocolate, most notably tyramine and phenylethylamine (Hurst et al 1982). Phenylethylamine is an amphetamine analogue structurally related to methylenedioxy-methamphetamine that may act to potentiate dopaminergic and noradrenergic neurotransmission and modulate mood (Bruinsma & Taren 1999).

Cocoa is also known to contain methylxanthines, including caffeine and theobromine, both of which are stimulants. Although the stimulatory and sympathomimetic effects of caffeine are well documented, the psychological effects of theobromine are less certain.

A group of biologically active constituents, including *N*-oleoylethanolamine and *N*-linoleoylethanolamine, have been identified in chocolate and appear to be related to anandamide, the 'internal bliss' chemical, which is the endogenous lipoprotein that binds cannabinoid receptors within the brain (Di Tomaso et al 1996). Although it has been suggested that these compounds may elicit heightened sensitivity and euphoria by directly activating cannabinoid receptors or by increasing anandamide levels (Bruinsma & Taren 1999), measurements have suggested that their amount in cocoa is several orders of magnitude below those required to reach the blood and cause observable central effects (Di Marzo et al 1998).

Chocolate craving, which is reported to be the most common food craving (Weingarten & Elston 1991), is more common in women, with fluctuations occurring with hormonal changes just before and during the menses (Rozin et al 1991). The basis for chocolate craving, however, remains undetermined, but it is suggested that aroma, sweetness, texture and calorie content are likely to play a more important role in chocolate cravings than pharmacological factors (Bruinsma & Taren 1999, Michener & Rozin 1994, Rozin et al 1991, Smit et al 2004).

In 2013, a randomised, placebo-controlled trial ( $n = 72$ ) identified that ingesting a cocoa treatment (500 mg polyphenols) daily for 30 days significantly improved self-rated calmness and contentedness compared to placebo (Pase et al 2013). This effect was not observed after acute treatment, and cognition was unaffected both acutely and after 30 days.

### Modulation of immune function and inflammation

The procyanidin fraction from cocoa demonstrates immunomodulatory function in vitro, with stimulation of tumour necrosis factor- $\alpha$  (Mao et al 2002) and modulation of the secretion of the cytokine transforming growth factor (Mao et al 2003), as well as inhibiting induced nuclear transcription of human interleukin-1 $\beta$  (IL-1 $\beta$ ) (Mao et al 2000a), phytohaemagglutinin-induced stimulation of IL-2 (Mao et al 1999) and mitogen-stimulated secretion of IL-4 (Mao et al 2000b) in peripheral blood mononuclear cells in vitro. In vivo cocoa intake has been shown to modulate intestinal immune responses in young rats (Ramiro-Puig et al 2008), while cocoa polyphenols have been shown to reduce leukotriene synthesis through inhibition of human 5-lipo-oxygenase in humans (Sies et al 2005).

In vivo rat studies have also shown that a diet supplemented with 10% (w/w) cocoa for 7 weeks resulted in significantly reduced serum immunoglobulin A (IgA), IgG2b and IgM levels compared

to those fed an isocaloric unsupplemented diet (Pérez-Berezo et al 2012). Additionally gut IgA and IgM levels were significantly reduced to approximately 30% and 50% of control animals, respectively.

### Anti-inflammatory

While flavanols are known to modify the production of proinflammatory cytokines, the synthesis of eicosanoids, the activation of platelets and NO-mediated mechanisms (Selmi et al 2008), evidence for any beneficial effects of cocoa flavanols in providing a meaningful anti-inflammatory action has been gathered predominantly from in vitro experiments and only more recently have in vivo studies been conducted.

An in vivo study of induced colon carcinogenesis found that a cocoa-rich diet reduced NF- $\kappa$ B levels and the expression of proinflammatory enzymes, including cyclooxygenase-2 and iNOS (Rodríguez-Ramiro et al 2013). A study which investigated the effects of cocoa supplementation on trigeminal nerve inflammation identified that 1% (w/w) and 10% (w/w) cocoa repressed MKP-1 and -3, as well as resulted in reduced MAPK proteins, all of which indicates a reduced inflammatory response (Cady & Durham 2010). This study was conducted using immunofluorescence as the main indicative biomarker.

More recently, a randomised, crossover study of 20 obese volunteers confirmed that beverages containing cocoa flavanols (30–900 mg flavanol per day) produced a dose-dependent effect on the inflammation marker C-reactive protein and also significantly reduced IL-6 concentrations (Stote et al 2012).

### Altered cellular signalling

Flavonoids have been shown to modulate tumour pathology in vitro and in animal models, and the pentameric procyanidin fraction isolated from cocoa is reported to slow the growth of cultured human aortic endothelial cells (Kenny et al 2004a), as well as inhibit the proliferation of human dermal microvascular endothelial cells in vitro through inhibition of tyrosine kinase ErbB2 expression. This has led to the suggestion that polyphenols may influence endothelial growth signalling in vitro, with potential beneficial effects for specific neoplasias in which cells overexpress ErbB2 (Kenny et al 2004b).

### Inhibition of dental caries

Cocoa contains substances that protect against dental caries (Palenik et al 1977, s'Gravenmade et al 1977) and in vitro experiments have shown that monomeric polyphenols and tannins from cocoa may interfere with glucosyltransferase activity of *Streptococcus mutans* and reduce plaque formation (Kashket et al 1985). Similar results were reported in hamsters, with a marked caries-inhibitive effect found with a water extract of cocoa (Stralfors 1966). Cocoa bean husk, while not used in cocoa or chocolate, demonstrates antibacterial properties attributed

to its unsaturated fatty acids and antiglycosyltransferase activities attributed to epicatechin polymers, as well as being shown both *in vitro* and *in vivo* to possess significant antiplaque activity (Matsumoto et al 2004).

### Antitussive

It has been suggested that theobromine, a methylxanthine derivative present in cocoa, may form the basis for a new class of antitussive drugs, as it has been shown to effectively inhibit citric acid-induced cough in guinea pigs *in vivo*, as well as suppress capsaicin-induced cough in a human double-blind trial (Usmani et al 2005). The observation that theobromine inhibits capsaicin-induced sensory nerve depolarisation of the guinea pig and human vagus nerve suggests that its antitussive action may be mediated peripherally through an inhibitory effect on afferent nerve activation.

### Skin antiageing and photoprotection

Cocoa and, more specifically, cocoa-derived flavanols have multiple beneficial effects on skin integrity, according to several clinical trials.

Long-term cocoa ingestion appears to lead to an increased resistance to UV-induced erythema and a lowered transepidermal water loss. In a crossover design study in 10 healthy women, a single dose of cocoa rich in flavanols (329 mg) was found to enhance dermal blood flow by 1.7-fold and elevate oxygen saturation of haemoglobin at 1 mm skin depth 1.8-fold 2 hours after consumption, while there was no effect seen after consumption of low-flavanol cocoa (27 mg) (Neukam et al 2007).

In a study using a model of *ex vivo* human skin explants, cocoa polyphenols were seen to exhibit a positive action on several indicators of skin elasticity and skin tonus, and an enhancing effect of cocoa butter on activity of cocoa polyphenol was observed (Gasser et al 2008).

There is evidence to suggest that dietary flavanols from cocoa contribute to endogenous photoprotection, improve dermal blood circulation and affect cosmetically relevant skin surface and hydration variables in women. A 12-week RCT, comparing high-flavanol (326 mg/day containing epicatechin [61 mg/day] and catechin [20 mg/day]) and low-flavanol (27 mg/day containing 6.6 mg epicatechin and 1.6 mg catechin) cocoa consumption found that high-flavanol consumption led to significantly reduced ultraviolet-induced erythema (by 15% and 25%, after 6 and 12 weeks of treatment). The high-flavanol group also experienced increased skin density, skin hydration and skin thickness along with increased blood flow in cutaneous and subcutaneous tissues, and significantly decreased skin roughness and scaling, compared with no change in the low-flavanol group (Heinrich et al 2006).

### Antineurodegenerative

The major flavonoids of cocoa, epicatechin and catechin, protected cellular membrane from amyloid

beta-protein-induced neurotoxicity *in vitro*, suggesting that cocoa may have antineurodegenerative effects (Heo & Lee 2005). This is supported by a study that found that 1-year administration of a cocoa polyphenolic extract (Acticoa powder) affects the onset of age-related cognitive deficits, urinary free dopamine levels and lifespan in old Wistar-Unilever rats (Bisson et al 2008a, 2008b). Daily oral administration of Acticoa powder was also seen to protect rats from cognitive impairments after heat exposure by counteracting the overproduction of free radicals (Rozaan et al 2007). A 2012 human study confirms that the effects are also seen clinically. The study of 90 elderly men and woman with mild cognitive impairment identified that the consumption of 520–990 mg cocoa flavanols daily for 8 weeks improved the outcome of cognitive function assessments, including verbal fluency test and the trail-making test compared to those taking low (45 mg daily) flavanols (Desideri et al 2012).

### OTHER ACTIONS

Acticoa powder has been observed to protect rats from prostate carcinogenesis (Bisson et al 2008a) and prostate hyperplasia as well as improve established prostate hyperplasia in an animal model (Bisson et al 2007). The clinical significance of these findings is yet to be determined.

### CLINICAL USE

Cocoa consumption is not only highly pleasurable for many people, it is also correlated with reduced health risks of cardiovascular diseases, hypertension, atherosclerosis and cancer (Kim et al 2014). These benefits are mainly mediated by a range of cocoa-derived phytochemicals.

### Cardiovascular disease

There is evidence to support that the flavanols in cocoa can be absorbed, are bioactive and may be responsible for the cardiovascular benefits associated with regular cocoa consumption. Several mechanisms have been proposed to explain this positive influence, including metabolic, antihypertensive, anti-inflammatory and antioxidant effects, along with decreased platelet activation and function, effects on serum lipids, insulin sensitivity, immune function and vascular endothelial function (Ding et al 2006, Eo 2008, Lippi 2008).

A 2012 Cochrane review performed a meta-analysis of 20 studies involving 856 mainly healthy adults, and found that flavanol-enriched cocoa exhibited a small but statistically significant blood pressure-lowering effect compared to controls in short-term trials of 2–18 weeks' length (Reid et al 2012).

Additionally, two recent systematic reviews and meta-analyses on the effects of chocolate, cocoa and flavanols on major cardiovascular disease risk factors found benefits on markers of vascular function, insulin resistance and cholesterol (Hooper et al 2012, Shrime et al 2011). In addition to significant

antihypertensive benefits, these reviews reported significant effects on LDL ( $-0.07$  mmol/L; 95% confidence interval (CI)  $-0.13, 0.00$  mmol/L) and HDL ( $+0.03$  mmol/L; 95% CI  $0.00, 0.06$  mmol/L), cholesterol (Hooper et al 2012) and insulin resistance ( $-0.94$  points; 95% CI  $-0.59, -1.29$ ) (Shrime et al 2011).

The impact of other chocolate constituents must be considered when evaluating the effects of chocolate on cardiometabolic health. An animal study found that the chronic supplementation of two chocolate preparations with equivalent composition aside from fibre and polyphenol content resulted in significant differences in systemic inflammatory markers, liver weight and endothelial activation markers (Yakala et al 2013).

Of the epidemiological studies conducted thus far, inverse associations between dietary polyphenols and mortality from coronary heart disease have also been identified. Small, short-term intervention studies have indicated that cocoa-containing foods may provide many cardiovascular benefits, including reducing blood pressure, inhibiting platelet function, preventing lipid oxidation, reducing LDL, increasing HDL, improving endothelial function, increasing insulin sensitivity, reducing insulin resistance and reducing inflammation.

A meta-analysis of 133 trials on flavonoid-rich foods and cardiovascular risk found that chocolate increased flow-mediated dilation after acute (3.99%; 95% CI 2.86, 5.12; six studies) and chronic (1.45%; 0.62, 2.28; two studies) intake and reduced systolic ( $-5.88$  mmHg;  $-9.55, -2.21$ ; five studies) and diastolic ( $-3.30$  mmHg;  $-5.77, -0.83$ ; four studies) blood pressure (Hooper et al 2008, Innes et al 2003). A 2006 systematic review of 136 experimental, observational and clinical studies on cocoa products and the risk of cardiovascular disease concluded that stearic acid may be neutral, while flavonoids are likely to be protective against cardiovascular mortality. The review found that multiple short-term, randomised feeding trials suggest cocoa and chocolate may exert beneficial effects on cardiovascular risk, with a meta-analysis finding that flavonoids may lower risk of cardiovascular mortality (relative risk = 0.81; 95% CI 0.71–0.92), comparing highest and lowest tertiles (Ding et al 2006).

While there are no published long-term RCTs or prospective intervention studies of cocoa with hard clinical end points (Hooper et al 2008, Maron 2004), the cardiovascular benefits of cocoa are evident in a 15-year epidemiological study of 470 elderly men, which found that cocoa intake was inversely associated with blood pressure and 15-year cardiovascular and all-cause mortality. This study found a 50% reduction in cardiovascular-related death and all-cause mortality in men with the highest tertile of cocoa intake compared to the lowest tertile, suggesting that the pharmacological actions described for cocoa do, in fact, translate into reduced cardiovascular risk and other positive clinical outcomes (Buijsse et al 2006).

## Hyperlipidaemia

While the lipid content of chocolate is relatively high, around one-third of the lipid in cocoa butter is composed of the fat, stearic acid, which exerts a neutral cholesterolaemic response in humans by an unknown mechanism (Kris-Etherton et al 1993, Steinberg et al 2003). Cocoa butter, however, is considered a high-calorie fat because it has a high digestibility with a digestible energy value of 37 kJ/g in humans (Shahkhalili et al 2000). The results of a randomised, double-blind, crossover design supplementation study suggest that the addition of calcium to chocolate can significantly reduce the absorption of cocoa butter, thus reducing the absorbable energy value of the chocolate by approximately 9% while at the same time reducing the plasma LDL cholesterol level and leaving the plasma HDL cholesterol level and taste of the chocolate unchanged (Shahkhalili et al 2001).

A systematic review and meta-analysis of 10 clinical trials ( $n = 320$ ) found that dark chocolate significantly reduced serum LDL by 5.90 mg/dL (95% CI  $-10.47, -1.32$  mg/dL) and total cholesterol levels by 0.35 mmol/L (95% CI  $-0.64, -0.05$  mmol/L) compared to low or nil cocoa control (Tokedo et al 2011). No statistically significant effects on HDL or triglycerides were found (difference in means [95% CI]  $-0.04$  mmol/L [ $-0.16, 0.08$ ], and  $-0.28$  mmol/L [ $-0.75, 0.18$ ], respectively).

Since then, a double-blind RCT of 152 healthy adults (aged 40–70 years) reported that 850 mg theobromine, a non-flavonoid constituent of cocoa, independently increased serum HDL concentrations by 0.16 mmol/L compared to placebo (Neufingerl et al 2013). In this study, the use of cocoa in addition to theobromine supplementation (total 1000 mg theobromine) did not have a significant effect on HDL.

Cocoa bran may also have a use in hypercholesterolaemia, as well as constipation, because this low-fat, high-fibre material has been shown in a randomised, controlled, double-blind study to increase faecal bulk similarly to wheat bran and reduce the LDL/HDL cholesterol ratio, with no effect on LDL cholesterol oxidation (Jenkins et al 2000).

## Blood pressure

A 2012 Cochrane review of 20 studies involving 856 mainly healthy adults found that flavanol-enriched chocolate supplementation over 2–18 weeks reduced mean systolic blood pressure by 2.77 mmHg (95% CI  $-4.72, -0.82$ ) and mean diastolic blood pressure by 2.20 mmHg (95% CI  $-3.46, -0.93$ ;  $n = 19$ ) (Reid et al 2012). These modest effects for flavanol-containing dark chocolate have been observed in various populations, including normotensive people with mild hypercholesterolaemia (Erdman et al 2008), overweight adults (Davison et al 2008, Faridi et al 2008), patients with newly diagnosed essential hypertension (Grassi et al 2005b),

patients with untreated upper-range prehypertension and stage 1 hypertension without concomitant risk factors (Taubert et al 2007a) and healthy people (Grassi et al 2005a, Vlachopoulos et al 2007), including male soccer players (Fraga et al 2005).

While cocoa appears to have mild antihypertensive actions, this is complemented by positive effects on other cardiovascular risk factors, such as serum lipids, blood glucose and vascular function. These benefits are evident from the results of various clinical trials. For example, an RCT using 100 g of dark chocolate containing approximately 500 mg of polyphenol consumed daily for 15 days found reductions in diastolic blood pressure by  $-11.9 \pm 7.7$  mmHg, decreases in serum LDL cholesterol from 3.4 to 3.0 mmol/L, improvements in flow-mediated dilation and reductions in insulin resistance and increased insulin sensitivity in patients with newly diagnosed essential hypertension (Grassi et al 2005b). An 8-week double-blind, placebo-controlled crossover study found that consumption of a cocoa flavanol-containing dark chocolate bar with added plant sterols lowered serum lipids and blood pressure in a normotensive population with elevated cholesterol (Allen et al 2008). Yet another study found that 12 weeks of supplementation with high-flavanol cocoa led to reduced insulin resistance, diastolic blood pressure and mean arterial blood pressure and improved endothelial function independently of exercise in overweight and obese subjects (Davison et al 2008).

### Use in children

In children, 7 g dark chocolate once daily for 7 weeks ( $n = 124$ ) did not significantly affect blood pressure compared to controls ( $n = 70$ ), with mean systolic pressure differing by 1.7 mmHg (95% CI  $-0.6$  to 4.1) and mean diastolic pressure differing by  $-1.2$  mmHg (95% CI  $-3.6$  to 1.3) (Chan et al 2012). This study did conclude that, while providing dark chocolate appeared feasible and acceptable in a school setting, further studies would be required to clarify possible cardiovascular benefits of dark chocolate supplementation in children.

### Vascular function

In a 2008 meta-analysis it was found that acute and chronic intake of chocolate increases flow-mediated dilation (Hooper et al 2008). A 30-day double-blind RCT in 41 medicated diabetic patients which compared thrice-daily dosing of flavanol-rich cocoa with a nutrient-matched control found that vascular function was significantly improved in the cocoa-treated group, as measured by flow-mediated dilation of the brachial artery (Balzer et al 2008). More recently, a randomised, placebo-controlled crossover study found that women, but not men, also experienced significant reductions in arterial stiffness (augmentation index (AI) reduced by 83% and AI at 75 beats per minute reduced by 129%) following 4-weeks of high-flavanol cocoa and dark chocolate treatment (West et al 2014). Given that the women

in this study had higher AI at baseline, the clinical relevance of this finding is unclear.

A review of evidence from both animal and human studies suggests that human ingestion of the flavanol epicatechin is, at least in part, causally linked to the reported beneficial effects on vascular function (Schroeter et al 2006), while results from a controlled trial suggest that formation of vasodilative NO contributes to beneficial vascular effects (Taubert et al 2007b).

Improved vascular function after cocoa consumption has been demonstrated in a number of clinical trials involving congestive heart failure patients (Flammer et al 2012), hypercholesterolaemic postmenopausal women (Wang-Polagruto et al 2006), heart transplant recipients (Flammer et al 2007), diabetics (Balzer et al 2008), healthy subjects (Faridi et al 2008, Grassi et al 2012, Vlachopoulos et al 2007) and people with coronary artery disease (Horn et al 2013).

It has also been found that flavanol-rich cocoa enhanced several measures of endothelial function to a greater degree among older than younger healthy subjects, leading to the suggestion that the vascular effects of flavanol-rich cocoa may be greater among older people in whom endothelial function is more disturbed (Fisher & Hollenberg 2006).

There is evidence to suggest that the improved vascular function with flavanol-rich cocoa occurs acutely and in a sustained and dose-dependent manner, with a maximal flow-mediated dilation at 2 hours after a single-dose ingestion of flavanol-rich cocoa seen in a trial involving individuals with smoking-related endothelial dysfunction (Heiss et al 2007). Similar acute results were seen in a double-blind RCT involving 22 heart transplant recipients in which flavonoid-rich dark chocolate was seen to induce coronary vasodilation, improve coronary vascular function, decrease platelet adhesion and reduce serum oxidative stress 2 hours after consumption compared to cocoa-free control chocolate (Flammer et al 2007). Further evidence for acute effects comes from a study in which dark chocolate, but not white chocolate, was observed to significantly improve endothelial and platelet function in healthy smokers, with increased flow-mediated dilation, increased total antioxidant status and reduced shear stress-dependent platelet function seen 2–8 hours after ingestion (Hermann et al 2006).

The above findings are contrasted by a 6-week double-blind, placebo-controlled, fixed-dose, parallel-group clinical trial of 101 healthy older adults that compared consumption of a 37 g dark chocolate bar or 237 mL of artificially sweetened cocoa beverage with placebo. This study failed to demonstrate the predicted beneficial effects of short-term dark chocolate and cocoa consumption on neuropsychological or cardiovascular health-related variables (Crews et al 2008).

Whether sugar-free cocoa products have different effects to those containing sugar has also been investigated. A single-blind, crossover RCT of 45 healthy

adults suggested that endothelial function improved significantly more with sugar-free than with regular cocoa (Faridi et al 2008). Despite this, Njike et al (2011) found that both sugar-free and sugar-sweetened cocoa beverages improved endothelial function compared to sugar-sweetened placebo, in a double-blind crossover RCT of 44 healthy, overweight (BMI 25–35 kg/m<sup>2</sup>) adults. The same study found no significant changes for blood pressure, BMI, lipids or blood glucose levels for these cocoa beverages compared to placebo (Njike et al 2011).

### Cardiac ischaemia

A prospective analysis of the self-reported chocolate consumption habits of 33,372 Swedish women over a mean follow-up of 10.4 years suggested that high chocolate consumption may be associated with a lower risk of stroke (Larsson & Virtamo 2011). There is evidence suggesting that cocoa flavanols may help in reducing cardiac ischaemia, with an animal study finding that epicatechin pretreatment confers cardioprotection in the setting of ischaemia-reperfusion injury and that the effects are independent of changes in haemodynamics, sustained over time, and accompanied by reduced levels of indicators of tissue injury (Yamazaki et al 2008). Human studies suggest that cocoa consumption may have clinical benefits for cerebrovascular ischaemic syndromes, including dementias and stroke with dietary intake of flavanol-rich cocoa being associated with a significant increase in cerebral blood flow velocity in 34 healthy elderly humans (Sorond et al 2008). It is further suggested that the prospect of increasing cerebral perfusion with cocoa flavanols is extremely promising, with implications for stroke and dementia (Fisher et al 2006).

### Premenstrual syndrome

Magnesium deficiency may contribute to premenstrual syndrome symptoms, which may be improved by chocolate or cocoa powder, which contain a high concentration of magnesium (≈100 mg/100 g in chocolate and 520 mg/100 g in cocoa powder). There is also some evidence to suggest that serotonin levels are low premenstrually, and it is possible that premenstrual chocolate cravings are the body's attempt to raise central nervous system (CNS) concentrations of serotonin (Bruinsma & Taren 1999).

### Enhanced cognitive function

A recent systematic review of RCTs on the neurocognitive effects of chocolate or cocoa concluded that neither cocoa nor chocolate exerted cognitive effects in chronic or subchronic administration (Scholey & Owen 2013). Despite this, the review acknowledged that some specific physiological functions underlying cognition did appear affected, including cerebral blood flow and region-specific brain activity (Crews et al 2008, Francis et al 2006).

Previously, a double-blind study suggested that improvements in cognitive function following

chocolate consumption are due to the methylxanthine content of chocolate, with 11.6 g of cocoa powder producing identical improvements in cognitive function and the mood construct 'energetic arousal' as a mixture of caffeine (19 mg) and theobromine (250 mg) (Smit et al 2004).

A randomised, single-blinded, cross-over study determined that consuming 35 g dark chocolate (720 mg cocoa flavanols) improved visual contrast sensitivity and spatial memory and reduced time required to detect motion compared to 35 g white chocolate (trace flavanols) in a group of 30 healthy young adults (Field et al 2011).

Consumption of a 65-g chocolate bar was shown to significantly increase driving accuracy and reduce collisions compared to an equicaloric snack of cheese and biscuits or no snack in a small controlled trial of 12 volunteers (Smith & Rich 1998).

### Motor function in Parkinson's disease

A 2012 crossover study compared the effects of a single dose of dark chocolate (200 g) containing 80% cocoa with the equivalent cocoa-free white chocolate in 26 adults diagnosed with moderate non-fluctuating Parkinson's disease (Wolz et al 2012). The study found that the single dose of dark chocolate did not result in any significant improvement in Parkinson's disease motor function. As a number of cocoa components, such as xanthine derivatives, are thought to have anti-Parkinson activity, quantifying plasma concentration of these compounds in this population may help to explain the observed effects from this study.

### Colonic health and constipation

Cocoa mass has been suggested to have beneficial effects on metabolism of colonic microbiota (Mäki-vuokko et al 2007) and cocoa husk rich in dietary fibre may assist paediatric patients with idiopathic chronic constipation. This is supported by an RCT that found that benefits seem to be more evident in paediatric constipated patients with slow colonic transit time (Castillejo et al 2006). Similarly, a double-blind, crossover RCT (*n* = 22) found that daily intake of high-flavanol cocoa over 4 weeks resulted in significant increases in faecal bifidobacterial and lactobacilli microflora and reduced clostridia compared to low-flavanol cocoa (Tzounis et al 2011).

### OTHER USES

Chocolate consumption 15 minutes before exercise has been shown to enhance exercise capacity, spare glycogen stores, delay fatigue and contribute to the recovery of glycogen repletion in healthy subjects (Chen et al 1996).

Milk chocolate has also been shown to be a cheap, effective and palatable form of fatty meal for producing gallbladder contraction prior to cholecystography (Harvey 1977).

Cocoa may also be of use in lactose intolerance, with a feeding study of 35 subjects finding that the

addition of cocoa significantly reduced breath hydrogen levels, as well as bloating and cramping, with the result being independent of the presence of sucrose and carrageenan (Lee & Hardy 1989).

Cocoa butter is used in the formation of suppositories and pessaries, as well as preparations for rough or chafed skin, chapped lips, sore nipples and various cosmetics (Raintree Nutrition 1996).

There is empiric evidence indicating successful treatment of copper deficiency by adding copper-rich cocoa powder to tube-feeding formulas. It is suggested that, although there are other high-copper-containing foods such as seaweed, oyster and beans, cocoa powder is advantageous due to the ease of adding it to feeding formulas (Tokuda et al 2006, Tokuda 2007).

### DOSAGE RANGE

There is enormous variability in the polyphenol content of cocoa and chocolate and the flavanols in cocoa exist in a multitude of different stereochemical configurations, thus giving rise to a unique and complex mixture of compounds. Given this complexity, the quantitative analysis of cocoa flavanols can be challenging. It is only through the use of methods that can accurately quantify these flavanols that it will be possible to make meaningful dietary recommendations regarding the consumption of cocoa flavanol-containing foods (Kwik-Uribe & Bektash 2008).

Trials suggest that effective doses are approximately 40–100 g dark chocolate or 15–30 g cocoa powder, providing approximately 200–500 mg polyphenols. Beneficial effects are more likely to result from the use of cocoa powder or dark chocolate containing more than 50–60% cocoa mass.

### TOXICITY

Cocoa contains caffeine, which is a mild CNS stimulant that can be profoundly toxic in large doses, resulting in arrhythmia, tachycardia, vomiting, convulsions, coma and death. The caffeine content of cocoa is variable, being approximately 0.009% by weight (Kondo et al 1996), with a typical milk chocolate bar containing approximately 10 mg of caffeine, compared to a cup of coffee, which contains approximately 100 mg (Bruinsma & Taren 1999). Fatal caffeine overdoses in adults have been reported, but are rare and typically require ingestion of more than 5 g of caffeine, which would require consumption of more than 50 kg of chocolate (Kerigan & Lindsey 2005).

### ADVERSE REACTIONS

It is believed that chocolate is a trigger for migraine, yet there is inconsistent support for this. In one small double-blind, parallel-group study of 12 patients who believed that chocolate could provoke their attacks, chocolate ingestion was more likely than placebo to trigger a typical migraine episode, with the median time until the onset of the attack of 22 hours (Gibb et al 1991). Three other

double-blind, placebo-controlled trials suggest that chocolate on its own rarely precipitates migraine (Marcus et al 1997, Moffett et al 1974), with the results of one trial suggesting that chocolate was no more likely to provoke headache than was carob in typical migraine, tension-type or combined headache sufferers (Marcus et al 1997).

One case of paroxysmal supraventricular tachycardia in a healthy 53-year-old female following the consumption of 'a large amount' of chocolate has been reported (Parasramka & Dufresne 2012).

Allergy to cocoa has been documented (Taibjee et al 2004) and it has been suggested that workers employed in the processing of cocoa and flour may be at high risk for the development of allergic sensitisation and respiratory impairment (Zuskin et al 1998). One case report of cocoa aspiration causing severe aspiration pneumonitis in a 4-year-old has been documented (Lopatka et al 2004).

There is insufficient evidence to determine whether cocoa contributes to acne (Goh et al 2011, Ravenscroft 2005, Smith et al 2007). This may be due to other ingredients, such as fat and sugar content, which are known contributors to acne development and were not adequately controlled for as contributing variables (Smith et al 2007). Further studies which control for these additional factors in chocolate are required to fully evaluate the effects of cocoa on acne. The arginine content of most chocolate formulations may theoretically increase the susceptibility of consumers to cold sores (herpes simplex labialis virus). And sleep may also be adversely affected by high chocolate consumption due to its caffeine content (Lodato et al 2013).

### Practice points/Patient counselling

- Cocoa consumption is associated with reduced health risks of cardiovascular diseases, hypertension, atherosclerosis and cancer.
- Cocoa has many potential benefits for the cardiovascular system and may reduce blood pressure, improve vascular function, inhibit platelet function and improve the serum cholesterol profile, as well as having beneficial effects on insulin sensitivity. However, further research is required to confirm the benefits.
- Cocoa may act to enhance cognitive function in a similar way to coffee, albeit with one-tenth the caffeine content.
- The most active agents in cocoa are the polyphenols, which are present in high amounts in dark chocolate, with lesser amounts in milk chocolate and minimal amounts in white chocolate.
- Cocoa powder contains minimal fat while dark chocolate contains less fat and sugar than milk or white chocolate. Beneficial effects are more likely to result from the use of cocoa powder or dark chocolate containing more than 50–60% cocoa mass.

## SIGNIFICANT INTERACTIONS

Polyphenols may reduce iron absorption, with a cocoa beverage containing 100–400 mg total polyphenols per serving having been shown to reduce iron absorption by approximately 70% (Hurrell et al 1999).

### PREGNANCY USE

Cocoa and chocolate can be considered safe to use in pregnancy.

### PATIENTS' FAQs

#### What will this herb do for me?

Cocoa is a nutritious food that appears to have beneficial effects on blood pressure, cholesterol, blood clotting and psychological wellbeing.

#### When will it start to work?

Psychological effects of dark chocolate consumption may be evident immediately, whereas beneficial effects on blood pressure and cholesterol may be evident after 2–4 weeks.

#### Are there any safety issues?

Cocoa powder and dark chocolate are extremely safe and are unlikely to precipitate migraine, acne or dental caries or produce adverse effects from the caffeine content.

## Coenzyme Q10

### OTHER NAMES

Ubiquinone, ubidecarenone, ubiquinol

### BACKGROUND AND RELEVANT PHARMACOKINETICS

Coenzyme Q10 (CoQ10) is an endogenous enzyme cofactor produced in humans from tyrosine through a cascade of reactions that itself requires eight

vitamin coenzymes: tetrahydrobiopterin, vitamins B<sub>6</sub>, C, B<sub>2</sub>, B<sub>12</sub>, folic acid, niacin and pantothenic acid (Folkers et al 1990). CoQ10 is also a fat-soluble antioxidant vitamin that plays an indispensable role in intracellular energy production.

Absorption occurs in the small intestine and tends to be poor, and is influenced by the presence of food and drink. CoQ10 is better absorbed in the presence of a fatty meal and is primarily bound to

VLDL and LDL cholesterol and transported to the systemic circulation via the lymphatic system. As such, serum levels of CoQ10 depend mostly on the amount of CoQ10-containing lipoproteins in circulation.

After incorporation into lipoproteins in the liver, CoQ10 is subsequently concentrated in various tissues, including the adrenal glands, spleen, kidneys, lungs and myocardium. Physical activity markedly reduces muscle tissue levels of CoQ10, which do not correlate to serum levels, suggesting that they are independently regulated (Laaksonen et al 1995, Overvad et al 1999).

## CHEMICAL COMPONENTS

The basic structure of ubiquinones is a benzoquinone head and terpinoid tail. The number of isoprenoid units in the tail portion varies among coenzymes. CoQ10 contains one quinone group and 10 isoprenyl units (Overvad et al 1999). Ubiquinones have been found in microorganisms, plants and animals but the CoQ10 form is the most common type found in mammals and humans.

## FOOD SOURCES

Meat and fish products are the most concentrated sources of CoQ10, although lesser quantities are found in boiled broccoli, cauliflower, nuts, spinach and soy. Dietary intake of CoQ10 is approximately 3–5 mg per day (Potgieter et al 2013).

## DEFICIENCY SIGNS AND SYMPTOMS

No recommended daily intake (RDI) levels have been established, but there has been some speculation as to possible deficiency signs and symptoms. These include fatigue, muscle aches and pains and chronic gum disease.

Based on biopsy and/or serum samples, it has been observed that relative CoQ10 deficiency is associated with:

- congestive heart failure (Sole & Jeejeebhoy 2002, Spigset 1994a, Molyneux et al 2008)
- cardiomyopathy (Mortensen et al 1990, Senes et al 2008)
- hypertension (Karlsson et al 1991)
- ischaemic heart disease (Karlsson et al 1991, Lee et al 2012a, 2012b, 2012c)
- hyperthyroidism (Bianchi et al 1999)
- breast cancer (Folkers et al 1997)
- cystic fibrosis (Laguna et al 2008)
- pancreatic insufficiency (Laguna et al 2008)
- depression (Maes et al 2009)
- fibromyalgia (Cordero et al 2012, Miyamae et al 2013)
- septic shock (Dupic et al 2011, Donnino et al 2011)
- chronic fatigue syndrome (Maes et al 2009)
- mitochondrial myopathy (Sacconi et al 2010).

At this stage, it is still unclear whether an observation of relative deficiency in a particular disease state can be interpreted as part of the aetiology of that disease, or whether lowered levels are a consequence of disease.

A deficiency state may result from:

- impaired or reduced synthesis due to nutritional deficiencies, advancing age or medication use.
- interactions with drugs — there is clinical evidence that lovastatin, pravastatin and simvastatin reduce CoQ10 status in humans, which may, in part, explain the incidence of side effects, particularly myopathy, associated with their use (Bargossi et al 1994a, 1994b, Folkers et al 1990, Mortensen et al 1997). Clinical evidence also suggests that use of gemfibrozil and other fibric acid derivatives reduce CoQ10 levels (Aberg et al 1998). The clinical significance and long-term consequences of decreased CoQ10 synthesis due to chronic use of lipid-lowering drugs remains to be tested.

In vitro evidence suggests that other drugs, such as clonidine, hydralazine, hydrochlorothiazide, methyldopa, metoprolol and propranolol, may also decrease endogenous production of CoQ10 (Kishi et al 1975). Other sources cite tricyclic antidepressants as further medicines that can reduce CoQ10 status (Pelton et al 1999). Whether this evidence translates to significant clinical outcomes, remains to be seen.

- inadequate intake or biosynthesis to meet increased requirements resulting from illness or excess physical exertion.
- genetic defects — deficiencies of CoQ10 have been associated with four major clinical phenotypes: (1) encephalomyopathy characterised by a triad of recurrent myoglobinuria, brain involvement and ragged-red fibres; (2) infantile multisystemic disease, typically with prominent nephropathy and encephalopathy; (3) cerebellar ataxia with marked cerebellar atrophy; and (4) pure myopathy (Quinzii et al 2008).

## MAIN ACTIONS

### Antioxidant

CoQ10 is a powerful antioxidant that buffers the potential adverse consequences of free radicals produced during oxidative phosphorylation in the inner mitochondrial membrane (Young et al 2007). It also binds to a site in the inner mitochondrial membrane that inhibits the mitochondrial permeability transition pore (MPTP).

Being a vital electron and proton carrier, CoQ10 supports adenosine triphosphate (ATP) synthesis in the mitochondrial inner membrane and stabilises cell membranes, preserving cellular integrity and function. It also reconstitutes vitamin E into its antioxidant form by transforming vitamin E radicals to their reduced (active) form (Kaikkonen et al 2002).

### Cardioprotective

CoQ10 supplementation offers myocardial protection during cardiac surgery, as indicated by clinical trials that observed improved postoperative cardiac function and reduced myocardial structural damage with presurgery administration of CoQ10. Studies with animal models have found that CoQ10

**Clinical note — Improving bioavailability**

Absorption of compounds from the gastrointestinal tract is one of the important determinants of oral bioavailability. The absorption of oral CoQ10 is slow and limited due to its hydrophobicity and large molecular weight (Ochiai et al 2007). Research indicates that intestinal absorption of CoQ10 is enhanced when taken with food. To further improve bioavailability, specialty formulations have been produced by various manufacturers. Ochiai et al (2007) report that an emulsified form of CoQ10 had superior intestinal absorption and achieved a higher peak concentration than for a suspension formulation. Zmitek et al (2008) found that the water solubility and bioavailability of CoQ10 was increased significantly with the use of an inclusion complex with beta-cyclodextrin. This complex is widely used as Q10Vital in the food industry. PureSorb-Q40 (water-soluble type CoQ10 powder) is reported in single-dose human and rat studies to have a greater absorption rate and absorbed volume of CoQ10, even taken post-prandially, than those of regular CoQ10, which is lipid-soluble and generally taken in the form of soft gel capsules (Nuku et al 2007). Ullmann et al (2005) tested the bioavailability of DSM Nutritional Products Ltd (Kaiseraugst, Switzerland). CoQ10 10% TG/P (all-Q), a new tablet-grade formulation, with CoQ10 Q-Gel Softules based on the Bio-Solv technology (Tishcon Corp., Salisbury, MD; marketed by Epic4Health, Smithtown, NY) and Q-SorB (Nature's Bounty, Bohemia, NY). They conducted a crossover study, which showed a bioequivalence between Q-Gel and all-Q, and both preparations were found to have better bioavailability properties than Q-SorB.

Recently, CoQ10 producers in Kaneka, Japan, have synthesised ubiquinol (the reduced form of CoQ10) in an attempt to achieve better bioavailability and higher plasma concentrations with lower oral doses. This form is now available in Australia for over-the-counter use. Single-blind, placebo-controlled studies with healthy subjects testing single oral doses of 150 or 300 mg/day and longer term (4 weeks) oral administration of 90, 150 or 300 mg/day confirmed significant absorption of ubiquinol from the gastrointestinal tract (Hosoe et al 2007). Additionally, no safety concerns were noted on standard laboratory tests for safety or on assessment of adverse events for doses of up to 300 mg for up to 2 weeks after treatment completion.

improves preservation of mitochondrial ATP-generating capacity after ischaemia and reperfusion (Pepe et al 2007). Treated animals demonstrate improved myocardial contractile function, increased coronary flow, reduced release of creatine kinase and malondialdehyde in the cardiac effluent. Recent

RCTs have found supplementation of 150 mg daily of CoQ10 reduced the inflammatory marker interleukin-6 by 14% (Lee et al 2012a), reduced lipid peroxidation (plasma malondialdehyde) and increased endogenous antioxidant activity (superoxide dismutase and catalase) in patients with coronary heart disease (Lee et al 2012a, 2012b). However, it did not have any effect on homocysteine or highly sensitive C-reactive protein (Lee et al 2012c). Recently, *in vitro* evidence has suggested CoQ10 protects LDL cholesterol from oxidation, which may have benefits in atherosclerosis (Ahmadvand et al 2013).

**Doxorubicin — induced cardiotoxicity**

Irreversible oxidative damage to cardiac mitochondria is believed to account for the dose-related cardiomyopathy induced by anthracyclines. Tests in animal models have demonstrated that CoQ10 protects against doxorubicin cardiotoxicity, possibly via antioxidant activity and protection of mitochondrial function (Combs et al 1977, Folkers et al 1978). Clinical studies provide some support for the use of oral CoQ10 and indicate that adjunctive treatment provides protection against cardiotoxicity or liver toxicity during cancer therapy; however, further studies are required to prove this association conclusively and confirm safety (Roffe et al 2004).

**Antihypertensive**

In the 1970s, Yamagami et al (1975, 1976) observed a deficiency in CoQ10 in patients with hypertension and suggested that correction of the deficiency could result in hypotensive effects. Small studies were initially conducted with hypertensive patients identified as CoQ10-deficient.

Since then, numerous studies have been conducted. In 2007, a meta-analysis was published which evaluated 12 clinical trials ( $n = 362$ ) and found that oral CoQ10 has the potential in hypertensive patients to lower systolic blood pressure by up to 17 mmHg and diastolic blood pressure by up to 10 mmHg without significant side effects (Rosenfeldt et al 2007). Interestingly, most trials fail to identify the subjects' baseline CoQ10 plasma levels and determine whether oral administration restored levels to within the normal range. It has been suggested that CoQ10 supplementation is associated with a decrease in total peripheral resistance, possibly because of action as an antagonist of vascular superoxide, either scavenging or suppressing its synthesis (McCarty 1999).

More specifically, suspected mechanisms of action include: increased antioxidant activity reducing free-radical damage to the endothelial lining and increasing nitric oxide bioavailability (Graham et al 2009); increasing superoxide dismutase-1 which scavenges superoxide anion, which reacts with nitric oxide impairing endothelium-derived relaxation (Kedziora-Kornatowska et al 2010), reduced aldosterone secretion (Louis et al 1965), improved angiotensin II-induced oxidative stress and endothelial dysfunction and reduced angiotensin II-induced

upregulation of intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1) (Tsuneki et al 2013).

### Immunostimulant activity

Several models of immune function have demonstrated the immunostimulant activity of CoQ10 (Folkers & Wolaniuk 1985), and immunomodulatory activity of CoQ10 (Bessler et al 2010).

### Endothelial function

The vascular endothelium is the interface between the blood and vascular smooth muscle in arteries and is easily damaged by oxidative stress, resulting in impaired endothelial function. Substances with antioxidant and anti-inflammatory activity, such as CoQ10, have been studied for beneficial effects on endothelial function. A recent meta-analysis ( $n = 194$ ) found CoQ10 supplementation (150–300 mg/daily) taken for 4 to 12 weeks was associated with a significant improvement in endothelial function compared to placebo, as assessed peripherally by flow-mediated dilation (FMD) of the brachial artery (Gao et al 2012). The improvement measured by FMD was a clinically significant 1.7%, which may translate to 10–25% reduction in residual cardiovascular risk for these patients. FMD is designated as an endothelium-dependent process that reflects vasorelaxation. CoQ10 supplementation was not found to improve nitrate-mediated dilation, suggesting no effect on endothelium-independent vasorelaxation. Of the study participants, 33% were women, 44% had diabetes, 34.5% had hypertension and 28% had established coronary artery disease, indicating activity in patients with and without overt cardiovascular disease. The studies included in this meta-analysis were Watts et al 2002, Tiano et al 2008, Hamilton et al 2009 and Dai et al 2011.

Recently, several *in vitro* studies have examined the mechanisms of CoQ10 on endothelial function using human umbilical vein endothelial cells. CoQ10 was found to prevent the oxidative stress and subsequent endothelial dysfunction induced by angiotensin II (Tsuneki et al 2013) and by the expression of oxidised low-density lipoprotein receptor (via suppressing NADPH oxidase activation) (Tsai et al 2011). In another study examining CoQ10 on the effects of oxidised LDL cholesterol on endothelial dysfunction, it was found to suppress inflammation and oxidative damage by protecting the activity of superoxide dismutase and catalase, reducing the increase in intracellular calcium and attenuating changes to nitric oxide synthase (Tsai et al 2012).

### Neuroprotective

Oxidative stress, resulting in glutathione loss and oxidative DNA and protein damage, has been implicated in many neurodegenerative disorders, including Alzheimer's disease, Parkinson's disease and Huntington's disease (Young et al 2007). Of relevance in Alzheimer's disease, CoQ10 inhibits

the formation of beta-amyloid protein *in vitro* (Ono et al 2005) and clinically, lower levels of CoQ10 have been found in the cortex of the brain in Parkinson's patients (Hargreaves et al 2008). Experimental studies in animal models suggest that CoQ10 may protect against neuronal damage that is produced by ischaemia, atherosclerosis and toxic injury. Though most have tended to be pilot studies, there are published preliminary clinical trials showing that CoQ10 may offer promise in many brain disorders.

### Regulates genomic expression

CoQ10 targets the expression of multiple genes, especially those involved in cell signalling, intermediary metabolism and transport (Groneberg et al 2005, Pepe et al 2007) and inflammation (Schmelzer et al 2008, Sohet et al 2009). These mechanisms may account for some of the pharmacological effects observed with CoQ10 supplementation.

### OTHER ACTIONS

#### Tissue protection

A protective effect of coenzyme Q10 against acute paracetamol hepatotoxicity, mostly via antioxidant, anti-inflammatory and antiapoptotic effects, has been demonstrated *in vivo* (Fouad & Jresat 2012). Additionally, pretreatment of test animals with coenzyme CoQ10 for 6 days protected against acute cisplatin nephrotoxicity, reducing the induced adverse effects on antioxidant defences, lipid peroxidation, tumour necrosis factor- $\alpha$  and nitric oxide concentration (Fouad et al 2010).

CoQ10 affects the transport activity of P-gp according to an *in vitro* test, although the clinical significance of this remains to be established (Itagaki et al 2008).

Recently, a possible antidepressant activity was identified for CoQ10 *in vivo*. Test animals treated with CoQ10 (25, 50, 100 and 150 mg/kg/day, for 3 weeks) found CoQ10 reduced the hippocampal DNA damage induced by chronic restraint stress in an experimental model of depression, possibly via antioxidant mechanisms and activity within the mitochondria (Aboul-Fotouh 2013).

### CLINICAL USE

#### Cardiovascular diseases

In 1972, Folkers and Littaru from Italy documented a deficiency of CoQ10 in human heart disease (Ernster & Dallner 1995). Since those early reports, a steady stream of research articles has been published and clinical experience in its use as an adjunct to conventional treatment in various forms of heart disease has accumulated. Data from laboratory studies have also accumulated and generally provide a supportive basis for its use.

A review by Langsjoen and Langsjoen of over 34 controlled studies and additional open studies concluded that CoQ10 supplementation goes beyond the correction of a simple deficiency state with

strong evidence to show that it has the potential to reduce the risk of cardiovascular disease by the maintenance of optimal cellular and mitochondrial function in cardiomyocytes.

Although investigation into specific cardiovascular diseases has been undertaken, the results of an open study of 424 patients suggested that CoQ10 may have widespread benefits. The study found that CoQ10 supplementation produced clinically significant improvements in cardiac function and reduced medication requirements in patients with a range of cardiovascular disorders, including ischaemic cardiomyopathy, dilated cardiomyopathy, primary diastolic dysfunction, hypertension, mitral valve prolapse and valvular heart disease (Langsjoen et al 1994).

A review by Langsjoen & Langsjoen (1999) of more than 34 controlled studies and additional open studies concluded that CoQ10 supplementation goes beyond the correction of a simple deficiency state, with strong evidence to show that it has the potential to reduce the risk of cardiovascular disease by the maintenance of optimal cellular and mitochondrial function in cardiomyocytes. Furthermore, a recent meta-analysis confirms that CoQ10 supplementation is associated with a significant improvement in endothelial function as measured by FMD, which may translate to 10–25% reduction in residual cardiovascular risk in people both with and without established cardiovascular disease (Gao et al 2012).

### Congestive heart failure (CHF)

The potential of CoQ10 as a therapeutic agent is of great interest because it is a safe and well tolerated supplement and CHF causes significant morbidity and mortality and currently has no known cure. CoQ10 has been reported to improve symptoms of congestive heart failure (CHF) and quality of life (QOL), and to reduce hospitalisation, and is used as standard therapy for CHF in some parts of Europe, Russia and Japan.

At the cellular level, oxidative stress, mitochondrial dysfunction and energy starvation are believed to play important roles in the aetiology of CHF (Overvad et al 1999). As such, it has been suggested that low CoQ10 levels identified in patients with CHF may play a role in disease development (Jeejeebhoy et al 2002), and that restoring myocyte nutrition with vitamin supplementation, including CoQ10, produces significant improvement (Sole & Jeejeebhoy 2002). Furthermore, an inverse relationship has been found between the severity of CHF and CoQ10 levels in blood from endocardial biopsies. Some evidence suggests that decreased myocardial function is associated with decreased CoQ10 myocardial tissue concentrations and observational studies have reported that the plasma CoQ10 concentration was an independent predictor of mortality in patients with CHF (Fotino et al 2013).

Recently, the CORONA study by McMurray et al (2010) showed that while low coenzyme Q10 was a marker of greater disease severity, it is very unlikely to have utility as a clinically important

prognostic biomarker in heart failure. They observed that people with lower baseline serum coenzyme Q10 levels were found to have risk factors associated with more advanced disease and poorer prognosis such as being older, more severe heart failure (higher NYHA functional class), lower EF and lower estimated glomerular filtration rate; however, multivariate analysis did not find serum coenzyme Q10 to be an independent prognostic variable (McMurray et al 2010). These results are in contrast to those published by Molyneux et al (2008), who had previously identified that plasma CoQ10 concentration in people with CHF was an independent predictor of mortality.

### Clinical studies

A meta-analysis of studies published prior to 2012 examined whether CoQ10 supplementation could improve the ejection fraction (EF) and/or New York Heart Association (NYHA) classification of people with congestive heart failure (Fotino et al 2013). The analysis included 13 placebo-controlled clinical trials (seven crossover and six parallel-arm) involving a total of 395 subjects, with several additional studies not included in an earlier meta-analysis (Berman et al 2004). The included studies had a duration of 4–28 weeks, testing a dose of CoQ10 from 60–300 mg daily. Importantly, baseline EF ranged from 22% to 46% and the baseline NYHA functional class ranged from 2.3 to 3.4.

From the limited number of studies available, the changes in EF for CoQ10 compared with placebo ranged from –3.0% to 17.8% (mean 3.67%) and the pooled mean net change in NYHA classification was –0.30, which meant a slight, but non-significant improvement in NYHA heart failure classification. Additional post hoc analysis by a subgroup found positive effects in crossover trials, study duration less than 12 weeks, conducted prior to 1994 (which tended to include less sick patients) using doses less than 100 mg daily, and in those with a milder stage of CHF (baseline EF  $\geq$  30%). The authors stated that due to the small number of studies with NYHA classification, use of various different CoQ10 formulations and doses and lack of information about adjunctive medications used and comorbidities, results should be viewed cautiously and the study may have been under-powered to detect a true effect.

The finding regarding changes to EF largely supports the conclusion made in an earlier meta-analysis (Sander et al 2006). The primary outcome measure was EF and secondary outcome measures were cardiac output (CO), cardiac index (CI), stroke volume (SV) and stroke index (SI). The analyses used data from 11 eligible trials (randomised, double-blind, placebo-controlled) and CoQ10 doses ranging from 60 to 200 mg/day with treatment periods ranging from 1 to 6 months. Overall, there was a significant 3.7% net improvement in EF ( $P < 0.00001$ ). Interestingly, more profound effects on EF were observed for patients not receiving angiotensin-converting enzyme inhibitors (6.74% net improvement). To put the degree of EF

improvement into perspective, the beta-blocker drug, metoprolol, is associated with an average increase in EF of 7.4% (range 3–16%), whereas carvedilol is associated with an increase of 5% (3–11%). CoQ10 also significantly increased the cardiac output by an average of 0.28 L/min. When a less conservative meta-analysis model was used, cardiac index, stroke volume and stroke index were also significantly improved. Sander et al (2006) used data from clinical trials by Hofinan-Bang et al 1995, Judy et al 1986, Keogh et al 2003, Khatta et al 2000, Langsjoen et al 1985, Morisco et al 1994, Munkholm et al 1999, Permanetter et al 1992, Pogessi et al 1991, Serra et al 1991 and Watson et al 1999.

The largest controlled trial in adult cardiomyopathy and CHF was reported in 1993 and not included in the 2013 meta-analysis (Morisco et al 1993). It involved 641 patients with CHF New York Heart Association (NYHA) classes III and IV. The double-blind, placebo-controlled study used a dose of 2 mg CoQ10 per kg daily over 1 year and found that active treatment significantly improved arrhythmias and episodes of pulmonary oedema, as well as reducing the number of hospitalisations and overall mortality rate. The same researchers conducted a smaller double-blind, crossover study that again produced positive results. Oral CoQ10 (150 mg/day) taken for 4 weeks significantly improved EF, stroke volume and cardiac output in chronic heart failure patients (Morisco et al 1994).

Although CoQ10 is generally studied in heart failure patients (NYHA class II and III), a double-blind, placebo-controlled, randomised study published in 2004 (Berman et al) describes its effects in end-stage heart failure among patients awaiting heart transplantation. The study of 32 subjects compared Ultrasmol CoQ10 (60 mg/day) to placebo over 3 months as an adjunct to conventional therapy. Significant improvements in functional status, clinical symptoms and QOL were reported for CoQ10; however, no significant changes in the echocardiography parameters (dimensions and contractility of cardiac chambers) or atrial natriuretic factor and tumour necrosis factor (ANF and TNF) blood levels were observed.

While the overall body of evidence generally supports the use of CoQ10 in mild heart failure, not every trial has produced positive results. One theory proposes that the most profound effects on myocardial function occur when supplementation is given shortly after the diagnosis of CHF and before the development of irreversible myocyte loss and fibrosis. Some commentators have suggested that the sample sizes, severity and duration of disease, treatment dose and duration of treatment may have contributed to the inconsistent results observed (Langsjoen 2000). An important issue that often fails to be considered is the measurement of plasma and myocyte CoQ10 concentrations and whether supplementation has achieved levels that are within the range likely to produce clinical results.

Langsjoen and Langsjoen (2008) reported that patients with CHF, NYHA class IV, often fail to

achieve adequate plasma CoQ10 levels on supplemental ubiquinone at dosages up to 900 mg/day. These patients often have plasma total CoQ10 levels of less than 2.5 microgram/mL and limited clinical improvement. Interestingly, the 2013 meta-analysis reported that CHF patients had a baseline blood CoQ10 concentration ranging from 0.61 to 1.01 mcg/mL and those receiving CoQ10 supplementation had a pooled mean net increase in blood CoQ10 concentration of 1.4 mcg/mL, suggesting some may have had plasma levels at less than the optimal range (Fotino et al 2013).

One theory proposed to explain this discrepancy is that critically ill patients have intestinal oedema, which reduces oral CoQ10 absorption. To test this hypothesis, seven patients with advanced CHF were identified (mean EF 22%) with subtherapeutic plasma CoQ10 levels with mean level of 1.6 microgram/mL on an average dose of 450 mg of ubiquinone daily (150–600 mg/day) (Langsjoen & Langsjoen 2008). The doses of all patients were increased by an average of 580 mg/day of ubiquinol (450–900 mg/day) with follow-up plasma CoQ10 levels, clinical status and EF measurements by echocardiography. At these higher doses, mean plasma CoQ10 levels increased from 1.6 microgram/mL (0.9–2.0 microgram/mL) up to 6.5 microgram/mL (2.6–9.3 microgram/mL) with a subsequent mean improvement in EF from 22% (10–35%) to 39% (10–60%). Substantial clinical improvements were also reported with higher dosing as patients' NYHA class improving from a mean of IV to a mean of II (I–III).

Stocker and Macdonald make the observation that a major change in the treatment of CHF in the mid-1990s with the increase in prescription of  $\beta$ -blockers may account for the less impressive results obtained in CoQ10 studies conducted after this period compared to earlier ones (as reported by Fotino et al 2013). They suggest it is possible that there is an incremental benefit of CoQ10 when added to treatment that includes angiotensin-converting enzyme inhibitors but no or less incremental benefit of CoQ10 in addition to angiotensin-converting enzyme inhibitors plus  $\beta$ -blockers (Stocker & Macdonald 2013). To test the theory, a future study utilising CoQ10 with adjunctive beta-blockade would be necessary, but as they point out, funding such an expensive study without patent protection for CoQ10 will be near impossible.

### Mortality and CHF

Ultimately, whether CoQ10 has a significant effect on EF or NYHA classifications is relatively less important than whether it affects mortality. To this end, the Q-SYMBIO trial has been conducted, a randomised, double-blind, multicentre trial with CoQ10 as adjunctive treatment of CHF, with focus on SYMptoms, BIOMarker status and long-term outcome (hospitalisations/mortality) (Stocker & Macdonald 2013). Most recently, the preliminary results were presented at the 7th International Coenzyme Q10 Association Meeting in Seville,

Spain (SA Mortensen, unpublished data, 2012 reported by Stocker and Macdonald). At completion, 422 patients with CHF were recruited and those receiving CoQ10 (2 mg/kg/day) experienced a significantly reduced all-cause mortality at 2 years compared with placebo. This important trial makes a major addition to the evidence base supporting a role of CoQ10 in the management of CHF.

### Paediatric myopathy

The potential role of CoQ10 in paediatric idiopathic dilated cardiomyopathy has been investigated in a small double blind RCT. Thirty-eight subjects (<18 years) using standard treatment were given additional placebo or 2 mg/kg/daily of CoQ10 in divided doses which were increased to the maximum dose of 10 mg/kg/daily or until side effects occurred. After 6 months of treatment, those receiving CoQ10 supplementation had improved cardiac performance with t-ejection fraction, heart rate and grading of diastolic dysfunction (measured by electrocardiogram) reaching statistical significance. Additionally, the cardiac failure index score was reduced in those receiving treatment compared to the controls and CoQ10 was well tolerated (Kocharian et al 2009).

### Haemodialysis

In a prospective, double-blind, placebo-controlled, crossover study, haemodialysis patients were given CoQ10 200 mg/day during 8 weeks, with a 4-week washout period. There was no significant improvement in left ventricle diastolic functions compared with placebo; however, it did improve left ventricle hypertrophy (Turk et al 2013).

### IN COMBINATION

A randomised, double-blind, placebo-controlled trial the addition of a supplement containing water-soluble CoQ10 (320 mg) terclatrate and creatine (340 mg) on exercise tolerance and health-related quality of life in 67 patients with stable chronic heart failure was examined. After 8 weeks, exercise tolerance measured by peak oxygen consumption and health-related quality of life (physical component) were significantly improved compared to placebo (Fumagalli et al 2011).

### Hypertension

CoQ10 has been studied both as stand-alone and adjunctive treatment in hypertension. In 2007, a meta-analysis was published which evaluated 12 clinical trials ( $n = 362$ ) consisting of three randomised controlled trials, one crossover study and eight open label studies (Rosenfeldt et al 2007). In the randomised controlled trials ( $n = 120$ ), systolic blood pressure in the treatment group decreased by 16.6 mmHg (12.6–20.6,  $P < 0.001$ ), with no significant change in the placebo group. Diastolic blood pressure in the treatment group was also significantly reduced after treatment by 8.2 mmHg (6.2–10.2,  $P < 0.001$ ), with no significant change in the placebo group. In the crossover study ( $n = 18$ ),

systolic blood pressure decreased by 11 mmHg and diastolic blood pressure by 8 mmHg with no significant change in the placebo group. In the open label studies ( $n = 214$ ), mean systolic blood pressure decreased by 13.5 mmHg (9.8–17.1,  $P < 0.001$ ) with active treatment and mean diastolic blood pressure significantly decreased by 10.3 mmHg (8.4–12.3,  $P < 0.001$ ). Previously, a review of eight studies concluded that supplemental CoQ10 results in a mean decrease in systolic blood pressure of 16 mmHg and in diastolic blood pressure of 10 mmHg (Rosenfeldt et al 2003). The effect on blood pressure has been reported within 10 weeks of treatment at doses usually starting at 100 mg daily.

A 2009 Cochrane review of CoQ10 in the treatment of essential hypertension reported that despite a clinically significant greater reduction in blood pressure in the treatment group receiving 100–120 mg daily for 4–12 weeks (systolic by 11 mmHg and diastolic by 7 mmHg) compared to the placebo group, caution is needed in interpreting the findings due to the limited available data and the possibility of bias (Ho et al 2009). The review analysed results from one crossover study and two RCTs which met the inclusion criteria ( $n = 96$ ) (Digiesi 1994, Singh 1999, Yamagami 1976) and were also included in the earlier meta-analysis by Rosenfeldt et al (2007).

### In conjunction

The effect of CoQ10 in patients with metabolic syndrome and inadequately controlled hypertension ( $n = 30$ ) was examined in a randomised, double blind, placebo-controlled, crossover trial. Subjects received either 100 mg CoQ10 twice daily or placebo for 12 weeks in addition to their antihypertensive medication, and were then changed over to the alternative treatment following a 4-week washout period. Plasma levels of CoQ10 increased 3.7 fold following treatment, however, there was no significant reduction in clinic or 24-hour ambulatory blood pressure compared to placebo, though there was a non-statistically significant trend towards reduction in 24-hour blood pressure, and a reduction in daytime diastolic blood pressure loads (the proportion of 24-hour blood pressure readings increased above 90 mmHg and  $\geq 85$  mmHg in diabetics) (Young et al 2012).

### Cardiac surgery

The use of CoQ10 supplementation before cardiac surgery has been studied since the early 1980s. Since that time, growing evidence has suggested that CoQ10 can reduce reperfusion injury after coronary artery bypass surgery, reduce surgical complications, accelerate recovery times and, possibly, shorten hospital stays (Chello et al 1996, Chen et al 1994, Judy et al 1993, Rosenfeldt et al 2002, Taggart et al 1996, Tanaka et al 1982, Zhou et al 1999). In general, the studies that achieved positive results had provided supplements for 1–2 weeks prior to surgery. One study observed that

continuing to administer CoQ10 for 30 days after surgery hastened the recovery course to 3–5 days without complications, compared with a 15–30-day recovery period for a control group, which did experience complications (Judy et al 1993, Rosenfeldt et al 2002).

A randomised, double-blind trial investigated the effects of preoperative high-dose CoQ10 therapy (300 mg/day) in patients undergoing elective cardiac surgery (mainly coronary artery bypass graft surgery (CABG) or valve replacement) (Rosenfeldt et al 2005). Approximately 2 weeks of active treatment resulted in significantly increased CoQ10 levels in the serum, atrial myocardium and mitochondria compared with placebo, but no significant change in the duration of hospital stay. Active treatment also improved subjective assessment of physical QOL (+13%) compared with placebo; however, the authors point out that physical QOL does not necessarily indicate improved cardiac pump function and further studies are required with larger sample sizes to clarify the role of CoQ10 in QOL.

More recently, a prospective, randomised trial involving patients undergoing CABG compared coenzyme Q10 supplementation (150–180 mg/day) taken for 7 to 10 days prior to surgery as an adjunct to standard care to a cohort receiving standard care only. Compared to the control group, those receiving CoQ10 experienced shorter hospital stays (7.1 vs 10.3 days) and better clinical outcomes, such as fewer reperfusion arrhythmias, greater spontaneous return of heartbeat and normal sinus rhythm after clamping, lower total inotropic medication requirements (dopamine and adrenaline). Interestingly, no significant difference in plasma levels of total antioxidants was observed between the groups until 24 hours after aortic clamp release, where it was significantly higher than baseline ( $P < 0.05$ ) for CoQ10 treatment (Makhija et al 2008).

The use of CoQ10 as preoperative treatment may hold special significance for older patients, who generally experience poorer recovery of cardiac function after cardiac surgery than their younger counterparts. One explanation gaining support is that the aged myocardium has less homeostatic reserve and so is more sensitive to both aerobic and physical stress and less well equipped to deal with cardiac surgery. Two studies have confirmed this theory, demonstrating an age-related deficit in myocardial performance after aerobic and ischaemic stress and the capacity of CoQ10 treatment to correct age-specific diminished recovery of function (Rosenfeldt et al 1999).

Besides improving cardiac resilience, CoQ10 has been found to reduce skeletal muscle reperfusion injury after clamping and declamping by reducing the degree of peroxidative damage (Chello et al 1996).

#### IN COMBINATION

CoQ10 supplementation has been utilised as part of a multi-component metabolic treatment in a double-blind,

randomised, placebo-controlled trial of 117 elective CABG and valve surgery patients at The Alfred Hospital (Melbourne, Australia) (Leong et al 2010). Treatment was commenced while on the waiting list for surgery (approximately 2 months) and continued for 1 month after surgery. Active treatment consisted of CoQ10 (Blackmore's CoQ10; 300 mg/day), magnesium orotate, alpha lipoic acid, omega-3 EFAs and selenium which was taken for a mean of  $76 \pm 7.5$  days and resulted in increased antioxidant levels preoperatively so that the adverse effect of surgery on redox status was attenuated. Active treatment also reduced plasma troponin I, 24 hours postoperatively from 1.5 (1.2–1.8) mcg/L, to 2.1 (1.8–2.6) mcg/L ( $P = 0.003$ ) and shortened the mean length of postoperative hospital stay by 1.2 days from 8.1 (7.5–8.7) to 6.9 (6.4–7.4) days ( $P = 0.004$ ) and reduced associated hospital costs.

As a result of these positive findings, the Integrative Cardiac Wellness Program was established at The Alfred Hospital in 2008, whereby metabolic therapy is provided to all elective cardiothoracic patients prior to surgery. Metabolic therapy consists of: CoQ10 225 mg/day; R,S alpha-lipoic acid 225 mg/day; magnesium orotate 1500 mg/day (as FIT Bioceuticals' Cardionutrients) and omega-3 EFAs 3000 mg/day (as FIT Bioceuticals' UltraClean). Supplements are commenced after visiting the surgery pre-admission clinic, continued until the day before surgery and resumed on the ward, once solids are recommenced. A clinical audit of 337 elective cardiothoracic surgical patients in the program was recently undertaken, which found that coronary artery bypass patients had a relative reduction of 42% for positive inotropic requirements post-surgery compared to controls ( $P < 0.001$ ) and valve repair/replacement patients, a 40% relative reduction ( $P = 0.02$ ). Multivariate analysis was used to compare them to a historical control group receiving standard care only in the previous 3 years at the same hospital (Braun et al 2013).

#### Angina pectoris

Based on the observation of relative CoQ10 deficiency in patients with ischaemic heart disease, and in animal models showing that it prevents reperfusion injury, several randomised clinical trials have been performed in angina pectoris. The doses used have varied from 60 mg to 600 mg daily, and the time frames for use varied from 4 days to 4 weeks. Overall, CoQ10 appears to delay signs of oxygen deficiency in the myocardium, increases patients' stamina on a treadmill or during exercise and delays the onset of angina (Overvad et al 1999), as well as reducing glyceryl trinitrate consumption (Kamikawa et al 1985).

#### Statin drug use

The mechanism of action of the statin group of drugs is inhibition of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, an enzyme involved in the biosynthesis of cholesterol from

acetyl-CoA. Inhibition of this enzyme also adversely affects the intrinsic biosynthesis of CoQ10, as demonstrated in laboratory animals and humans and reduces plasma and myocardial levels of CoQ10 (Bargossi et al 1994b, Folkers et al 1990, Rosenfeldt et al 2005).

This fact, plus the role of CoQ10 in mitochondrial energy production, which is required in muscle function, has prompted the hypothesis that statin-induced CoQ10 deficiency is involved in the pathogenesis of statin myopathy and long-term statin use may actually impair cardiac function.

At least nine observational studies and six RCTs have demonstrated that statins reduce plasma/serum levels of CoQ10 by 16–54% (Marcoff & Thompson 2007). This could be related to the fact that statins lower plasma LDL levels, and CoQ10 is mainly transported in LDL; however, a decrease is also found in platelets and in lymphocytes of statin-treated patients and, therefore, it could truly depend on inhibition of CoQ10 synthesis (Littarru & Langsjoen 2007). Additionally, studies have also demonstrated that co-administration of oral CoQ10 can still effectively raise serum levels when taken together with statin drugs (Bargossi et al 1994, Silver et al 2004).

Reduced muscle CoQ10 concentrations are of greater concern because they may be associated with impaired cardiac function and, theoretically, increased risk of myopathy and possibly side effects such as physical fatigue. The results obtained by Folkers et al (1990), Silver et al (2004) and Paiva et al (2005) provide support for an association between statin use and reduced intramuscular CoQ10 levels, whereas other studies find no change to intramuscular CoQ10 concentrations (Laaksonen et al 1994, 1995, 1996), increased risk of cardiovascular disease or impaired left ventricular systolic or diastolic function in hypercholesterolaemic subjects (Colquhoun et al 2005, Stocker et al 2006). Further investigation is required to determine whether long-term reductions of CoQ10 as a result of chronic statin therapy increases the risk of myopathy and whether subpopulations at risk, such as patients with familial hypercholesterolaemia, heart failure or who are over 65 years of age, may benefit from CoQ10 supplementation (Levy & Kohlhaas 2006).

### Statin-induced myalgia

The decreased formation of coenzyme Q10 (CoQ10) within the body due to statin use is suspected of contributing to the incidence of statin-associated muscle pain (myalgia), one of the possible side effects of statins. The question of whether supplemental CoQ10 can help prevent or treat statin myopathy is regularly asked by clinicians.

In recent years, several intervention studies have been performed whereby CoQ10 supplementation has been tested in volunteers also taking statin medication and experiencing myalgia.

A 2012 study examined the effect of CoQ10 supplementation (Q max 30 mg twice daily) on

statin-associated myopathy in 28 patients. After 6 months, serum CoQ10 levels had substantially increased (194%), subjective muscle pain reduced by almost 54% and muscle weakness by 44% (Zlatohlavek et al 2012). Similarly, positive results were obtained in a controlled double-blind randomised trial, which demonstrated 100 mg CoQ10 daily produced a 40% reduction in pain severity and 38% in pain interference with daily activities compared to a control group receiving 400 IU of vitamin E (Caso et al 2007).

In contrast, a 3-month placebo-controlled, randomised trial found no difference in the reduction of muscle pain between CoQ10 (60 mg twice daily) or placebo in patients who had developed myalgia within 2 months of starting or increasing statins. Interestingly, both the groups demonstrated significant reduction in pain after one month, suggesting a substantial placebo effect. The endpoints measured in this trial were the 10 cm visual analogue scale and the McGill pain questionnaire (Bookstaver et al 2012). Additionally, Young et al (2007) found no change in the myalgia score compared to placebo in a group receiving 200 mg CoQ10 for 12 weeks (Caso et al 2007).

It is difficult to explain the reasons for these inconsistent results; however some of the following factors should be considered. As there was no measurement of CoQ10 levels (serum or muscle) at baseline or at the end of treatment it is not possible to know if there were any differences between the study groups at baseline, if there was any change in levels by the end of the study, and therefore if the bioavailability or dose of CoQ10 used may have been factors.

There is another placebo controlled study currently being conducted in the USA to test whether CoQ10 supplementation is beneficial for reducing pain intensity in statin-induced myalgic patients (Parker et al 2013). In practice, a 3-month trial of supplemental CoQ10 can be safely considered for patients with fatigue, mild muscle soreness or slightly impaired concentration while taking long-term statins and with other risk factors for low CoQ10, such as advanced age, low meat intake or multi-system diseases.

### Statin-induced cognitive impairment

Cognitive problems are also identified among some patients reporting statin adverse events. Brain tissue shares with muscle tissue a high mitochondrial vulnerability and both are the dominant organs clinically affected in CoQ10-deficiency mitochondrial syndromes (Golomb & Evans 2008). Whether the cognitive side effects reported by statin users are due to CoQ10 depletion or responds to CoQ10 treatment is not well explored. To date, a study with aged dogs that had undergone long-term statin use demonstrated significant cognitive deficits with statin use compared to age-matched controls. In addition, poorer cognition was associated with lower parietal cortex CoQ10, and statin use was associated with a significant reduction in serum

CoQ10 (Martin et al 2011). Human trials are now warranted to determine whether CoQ10 supplementation improves cognitive function in long-term statin users.

### Statin use and CoQ10 supplementation

Overall, whether supplementation is effective as a treatment in statin-associated myalgia remains unclear because test results are inconsistent. Due to the low risk nature of CoQ10, a 3-month trial is worth considering in people presenting with statin-associated myalgia or generalised muscle pain and who cannot be satisfactorily treated with other agents.

It is also worth considering for people reporting fatigue, poor concentration and headaches in association with long-term statin use. Particularly consider it for those with a family history of heart failure, elevated cholesterol levels, and who are over 65 years of age and taking statin drugs long-term (Levy & Kohlhaas 2006). A trial of therapy may also be worthwhile in patients reporting fatigue, malaise, cognitive impairment and headaches as possible side effects to statin treatment.

### Arrhythmias

A small open study of 27 volunteers showed that CoQ10 exerts antiarrhythmic effects in some individuals (Fujioka et al 1983).

### Hypercholesterolemia

Oral CoQ10 reduces cholesterol levels, according to two clinical trials. One small 10-week open study of 26 subjects with essential hypertension study found that an oral dose of 50 mg CoQ10 taken twice daily also reduced total serum cholesterol levels with a modest increase in serum HDL cholesterol (Digiesi et al 1994). A reduction in total cholesterol was also seen in a 2013 randomised, double-blind, placebo-controlled study of 64 people with type 2 diabetes. A dose of CoQ10 (200 mg/day) significantly reduced total cholesterol, LDL-cholesterol and improved glycaemic control compared to placebo in the 12-week trial (Kolahdoust et al 2013).

### Sports supplement/ergogenic aid

Because CoQ10 is essential for energy metabolism and reduces oxidative stress, researchers have speculated that it may improve athletic performance. Clinical studies investigating the effects of CoQ10 supplementation on physical capacity generally show negative results. One theory as to the differences in study results is due to great variations in serum CoQ10 levels resulting from differences in dosage and also individual responses to treatment. Nine earlier studies used test doses of CoQ10 which varied from 60 mg to 150 mg daily over time periods of 28 days to 8 weeks. Of these eight studies, only two produced positive results. One was a double-blind, crossover trial which produced positive results on both objective and subjective parameters of physical performance (Ylikoski et al 1997).

In that study 94% of athletes felt that CoQ10 had improved their performance and recovery times, compared with the 33% receiving placebo. Most recently, another double-blind, placebo-controlled, crossover study of healthy people found that oral CoQ10 (300 mg/day) taken for 8 days improved subjective fatigue sensation and physical performance during fatigue-inducing workload trials (Mizuno et al 2008).

Of the others, one study found that 150 mg CoQ10 taken over 2 months had no effect on maximal oxygen consumption, lactate thresholds or forearm blood flow, although it did improve the subjective perceived level of vigour (Porter et al 1995). Another study demonstrated that CoQ10 did not alter physiological or metabolic parameters measured as part of cardiopulmonary exercise testing; however, it did extend the time and the workload required to reach muscular exhaustion (Bonetti et al 2000). Five further clinical trials produced negative results.

One retrospective study found that muscle CoQ10 levels were positively related to exercise capacity and/or marathon performance, suggesting that runners with the highest levels performed better than those with lower levels (Karlsson et al 1996).

More recent studies also demonstrate mixed results, though the majority of studies are negative. Whether negative results are due to insufficient dose or treatment time frames or differences in baseline CoQ10 levels remains to be clarified.

In another double-blind RCT of trained and untrained subjects, a single dose of CoQ10 (200 mg) resulted in raised plasma levels and significantly correlated with higher muscle CoQ10 levels, maximal oxygen consumption and treadmill time to exhaustion. After supplementation for 2 weeks, there was an increase in plasma CoQ10 levels and a non-significant trend towards increased time to exhaustion (Cooke et al 2008). In a study where 18 elite kendo athletes were given either 300 mg CoQ10 or placebo for 20 days, the active treatment group had reduced exercise-induced muscular injury with lower levels of creatine kinase, myoglobin and lipid peroxides compared with the corresponding values in the placebo group (Kon et al 2008). Similarly, the increase in lipid peroxidation induced by repeated bouts of supramaximal exercises was partially prevented following 8 weeks of CoQ10 supplementation (100 mg) in a randomised, double-blind, crossover study involving 15 sedentary men (Gul et al 2011). Recently, a small, randomised, double-blind, crossover study involving 15 healthy sedentary men found supplementation with 100 mg CoQ10 increased mean power during repeated bouts of supramaximal exercises, suggesting possible benefits in performance; however, while fatigue indexes decreased, they did not significantly differ from placebo (Gokbel et al 2010). A study by Ostman et al (2012) also failed to show any benefit from 8 weeks of supplemental CoQ10 (90 mg) daily on exercise capacity, muscle damage or oxidative stress in a small randomised, double-blind,

controlled study involving moderately trained healthy men.

#### Postpolio syndrome

One randomised, double-blind study tested whether adding oral CoQ10 to resistance training would further improve muscle strength and endurance as well as functional capacity and health-related quality of life (Skough et al 2008). All 14 patients (8 women and 6 men) with postpolio syndrome in the 12-week study undertook muscular resistance training 3 days/week and were randomised to receive either CoQ10 200 mg/day or placebo. For all patients, muscle strength, muscle endurance and quality of life regarding mental health increased statistically significantly, but there was no significant difference between the CoQ10 and placebo groups.

#### Chronic obstructive pulmonary disease (COPD)

Patients with COPD have increased oxidative stress, which increases further during periods of exacerbation, so the investigation of supplements with antioxidant activity has been of interest in this cohort (Tanrikulu et al 2011). At least two clinical trials have investigated the use of CoQ10 supplementation in COPD (Fujimoto et al 1993, Satta et al 1991). In one study, 20 patients with COPD were randomly assigned CoQ10 (50 mg) or placebo as part of their pulmonary rehabilitation program (Satta et al 1991). Treatment resulted in a 13% increase in maximum oxygen consumption and a 10% increase in maximum expired volume — both significant improvements. A dose of CoQ10 (90 mg) daily over 8 weeks was studied in a smaller trial of patients with COPD (Fujimoto et al 1993). Significantly elevated serum CoQ10 levels were associated with improved hypoxaemia at rest, but pulmonary function was unchanged.

#### IN COMBINATION

A double-blind, placebo-controlled study found that supplementation of CoQ10 (Q-Ter) and creatine in COPD patients with chronic respiratory failure (in long term O<sub>2</sub> therapy) during the stable phase of the disease significantly increased lean body mass, exercise tolerance as measured by the 6-minute walk test, reduced severity of dyspnoea, improved quality of life and decreased exacerbations. Treatment consisted of Creatine 340 mg + 320 mg Coenzyme Q-Ter (Eufortyn), Scharper Therapeutics SRL taken for 2 months while diet and lifestyle remained unchanged and the study involved 55 volunteers (Marinari et al 2013).

#### Cystic fibrosis

Pancreatic insufficiency and a diminished bile acid pool cause malabsorption of important essential nutrients and other dietary components in cystic fibrosis (CF) (Papas et al 2008). Of particular significance is the malabsorption of fat-soluble antioxidants such as carotenoids, tocopherols and CoQ10.

Despite supplementation, CF patients are often deficient in these compounds, resulting in increased oxidative stress, which may contribute to adverse health effects. Papas et al (2008) conducted a pilot study to evaluate the safety of a novel micellar formulation (CF-1) of fat-soluble nutrients and antioxidants, which included CoQ10 (30 mg/10 mL), alpha-tocopherol (200 IU), beta-carotene (30 mg), gamma tocopherol (94 mg), vitamin D<sub>3</sub> (400 IU) and other tocopherols (31 mg). Ten CF subjects aged 8–45 years were given 10 mL of the formulation orally daily for 56 days after a 21-day washout period in which subjects stopped supplemental vitamin use, except for a standard multivitamin. No serious adverse effects, laboratory abnormalities or elevated nutrient levels (above normal) were identified for the treatment. Supplementation with CF-1 significantly increased CoQ10, beta-carotene and gamma tocopherol from baseline in all subjects and improvements in antioxidant plasma levels were associated with reductions in airway inflammation in CF patients.

#### Periodontal disease

Dry mouth is associated with ageing and may also contribute to diseases such as periodontal disease. CoQ10 is used both topically and internally for the treatment of chronic periodontal disease. Topical application has been shown to improve adult periodontitis (Hanioka et al 1994) and a small open study has shown that oral CoQ10 supplementation can produce dramatic results within 5–7 days, making location of baseline biopsy sites impossible (Wilkinson et al 1975).

Supplemental CoQ10 (100 mg ubiquinol or ubiquinone) taken for 1 month was found to significantly increase salivary secretion and salivary CoQ10 concentration in patients with dry mouth compared to placebo. The authors suggest the effects were due to improving the decreased energy production and reducing oxidative stress in salivary glands (Ryo et al 2011).

#### Parkinson's disease

Parkinson's disease (PD) is a neurodegenerative disorder characterised by progressive loss of dopaminergic neurons within the substantia nigra pars compacta. The pathogenesis of PD remains obscure, but there is increasing experimental and clinical data that points to a defect of the mitochondrial respiratory chain, oxidative damage and inflammation as major pathogenetic factors in PD, inducing degeneration of nigrostriatal dopaminergic neurons (Beal 2003, Ebadi et al 2001, Gotz et al 2000, Storch 2007).

It has been theorised that restoration of mitochondrial respiration and reduction of oxidative stress by CoQ10 could induce neuroprotective effects against the dopaminergic cell death in PD and could also enhance dopaminergic dysfunction (Storch 2007). As a result, CoQ10 might exert both neuroprotective and symptomatic effects in PD.

Current data from controlled clinical trials are not sufficient to answer conclusively whether CoQ10 is neuroprotective in PD or has significant symptomatic effects, as results are inconsistent. The data are presented here.

A number of preclinical studies using *in vitro* and *in vivo* models of PD have demonstrated that CoQ10 can protect the nigrostriatal dopaminergic system, and levels of CoQ10 have been reported to be decreased in blood and platelet mitochondria from subjects with PD (Shults 2005, Mischley et al 2012), as well as reduced brain CoQ10 status (Hargreaves 2008).

As a result, several clinical intervention studies have been conducted to determine whether CoQ10 supplementation can provide benefits for people with PD. An early randomised, placebo-controlled, double-blind study compared three different doses of CoQ10 (300 mg, 600 mg or 1200 mg) with placebo in 80 subjects with early PD. After 9 months of treatment, subjects taking 1200 mg CoQ10 daily experienced significant improvements in disability compared with the placebo group. CoQ10 was also well tolerated at the dosages studied (Shults et al 2002). In 2003, results were published of a double-blind, placebo-controlled study, which showed that even a relatively low dose of CoQ10 (360 mg/day) taken for a short period (4 weeks) produced a significant mild benefit on PD symptoms and significantly improved visual function compared with placebo (Muller et al 2003).

The safety and tolerability of high-dose CoQ10 in subjects with PD was investigated in an open study of 17 patients (Shults et al 2004). The study used an escalating dosage of 1200, 1800, 2400 and 3000 mg/day administered together with vitamin E (alpha-tocopherol) 1200 IU/day and failed to identify any serious adverse effects with CoQ10 administration. It also identified that plasma CoQ10 levels reached a plateau at 2400 mg/day, suggesting that higher treatment doses are not required.

In 2007, a multicentre, randomised, double-blind, placebo-controlled, stratified, parallel-group, single-dose trial was conducted which used nanoparticulate CoQ10, as it has been shown to provide symptomatic effects in patients with mid-stage PD without motor fluctuations (Storch et al 2007). The study of 131 volunteers with PD without motor fluctuations and a stable anti-parkinsonian treatment were randomly assigned to receive placebo or nanoparticulate CoQ10 (100 mg three times a day) for a treatment period of 3 months. This form and dose of CoQ10 led to plasma levels similar to 1200 mg/day of standard formulations; however, no significant changes to the Unified Parkinson's Disease Rating Scale (UPDRS) were observed with CoQ10 after stratification for L-dopa dosing in this group of people with mid-stage PD.

More recently, a 2011 Cochrane review examined the efficacy and safety of coenzyme Q10 in patients with early and midstage Parkinson's disease. Four randomised, double-blind, placebo-controlled

trials (Muller 2003, Shults 2002, Storch 2007, The NINDS NET-PD 2007) involved a total of 452 patients, with CoQ10 doses ranging from 300 mg to 2400 mg/day. Positive effects were identified in activities of daily life in Unified Parkinson's Disease Rating Scale and the Schwab and England scale for Q10 at 1200 mg/day for 16 months versus placebo. There were no differences in the withdrawals from adverse effects between treatment and placebo groups, although there was a mildly increased relative risk ratio for pharyngitis and diarrhoea (Liu et al 2011).

A large phase III trial comparing placebo and 1200 and 2400 mg of CoQ10 daily was recently published that found no effect for oral CoQ10 supplementation on slowing the progression of disease (Beal et al 2014).

Another form of parkinsonism is progressive supranuclear palsy. A short-term double-blind, randomised, placebo-controlled, phase II trial was conducted in patients with progressive supranuclear palsy, a disease which causes down-gaze palsy with progressive rigidity and imbalance. Impairment of mitochondrial ETC complex I activity is thought to play a role in its pathogenesis suggesting a possible role for CoQ10 in its treatment. Twenty-one patients received either CoQ10 at a dose of 5 mg/kg/day or placebo. After 6 weeks, magnetic resonance spectroscopy showed a statistically significant increase in oxidative phosphorylation in the occipital cortex with an increase in the ratio of high-energy to low-energy phosphates, and an increase in motor and neuropsychological dysfunction measured by the PSP rating scale and the Frontal Assessment Battery (Stamelou et al 2008).

### Alzheimer's dementia

Similar to Parkinson's disease, mitochondrial dysfunction and oxidative damage appear to play a role in the pathogenesis of Alzheimer's dementia and, therefore, CoQ10 supplementation has been investigated as a possible treatment. Currently, evidence is limited to test tube and animal studies and is far from definitive.

CoQ10 was shown to inhibit beta-amyloid formation *in vitro* (Ono et al 2005) and in an animal model of AD (Dumont et al 2011, Choi et al 2012, Yang et al 2008, Yang et al 2010), activate the phosphatidylinositol 3-kinase pathway involved in neuronal cell survival and adult neurogenesis (Choi et al 2013), and protect against brain mitochondrial dysfunction induced by a neurotoxic beta-peptide in a study using brain mitochondria isolated from diabetic rats (Moreira et al 2005). McDonald et al (2005) conducted two studies with test animals and found that supplemental CoQ10 (123 mg/kg/day) taken with alpha-tocopherol acetate (200 mg/kg/day) improved age-related learning deficits; however, supplementation of CoQ10 alone at this dose, or higher doses of 250 or 500 mg/kg/day, failed to produce comparable effects.

## Haemodialysis

Increased oxidative stress is associated with various complications in haemodialysis (HD) patients (Sakata et al 2008). Due to its antioxidant activity, CoQ10 was administered for 6 months to 36 HD patients. Treatment was found to partially reduce oxidative stress as measured by a decrease of oxygen radical absorbing capacity (ORAC) and Trolox equivalent antioxidant capacity (TEAC).

## Migraine

There is now good supportive evidence to recommend the use of CoQ10 supplementation as a preventive treatment for migraine headache. Due to its relatively good safety profile when compared to pharmaceutical migraine treatments, a 3-month trial can be considered for prevention.

Research began over a decade ago to determine whether CoQ10 could affect the course of migraine attacks and reduce their frequency, largely because migraine was starting to become known as a disorder with an underlying mitochondrial dysfunction component.

An open-labelled trial investigated the effects of oral CoQ10 supplementation (150 mg/day) over 3 months in 32 volunteers with a history of episodic migraine with or without aura. CoQ10 significantly reduced both the frequency of attacks and the number of days with migraine after 3 months' treatment (Rozen et al 2002). In 2005, Sandor et al investigated the effects of CoQ10 (300 mg/day) taken over 3 months in 42 migraine subjects in a double-blind, randomised, placebo-controlled study; 47.6% of CoQ10-treated patients responded to treatment compared with 14.4% for placebo, experiencing a (50% or less) reduction in migraine frequency (number needed to treat, 3). Active treatment was superior to placebo for reducing attack frequency, headache days and days with nausea in the third treatment month and was well tolerated.

In 2007, Hershey et al assessed 1550 paediatric patients (mean age  $13.3 \pm 3.5$ , range 3–22 yrs) attending a tertiary care centre with frequent headaches for CoQ10 deficiency (Hershey et al 2007). Of these patients, 32.9% were below the reference range. Patients with low CoQ10 were recommended to start 1 to 3 mg/kg/day of CoQ10 in liquid gel capsule formulation as part of their multidisciplinary treatment plan. Those patients who returned for follow-up (mean, 97 days) demonstrated significantly increased total CoQ10 levels and significant improvements for headache disability and headache frequency ( $19.2 \pm 10.0$  to  $12.5 \pm 10.8$ ). In a subsequent, placebo-controlled, double-blind, crossover, add-on trial, 120 paediatric and adolescent migraine patients were given either CoQ10 (100 mg/day) or placebo for 32 weeks. Migraine frequency, severity and duration improved in both groups by the end of the study; however, the treatment group had significant early improvement in frequency in the first 4 weeks (Slater et al 2011).

In 2012, the Canadian Headache Society made a strong recommendation for the use of CoQ10 supplementation as a preventive treatment in migraine (Pringsheim et al 2012). This was based on a comprehensive search strategy to identify randomised, double-blind, controlled trials of drug treatments for migraine prophylaxis and relevant Cochrane reviews and then grading the evidence according to criteria developed by the US Preventive Services Task Force.

## Fibromyalgia

Fibromyalgia presents with a range of symptoms including chronic pain, allodynia, fatigue, joint stiffness and migraines. Oxidative stress and mitochondrial dysfunction are thought to play a role in its pathogenesis, with some academics suggesting CoQ10 deficiency as part of the pathophysiology of fibromyalgia (Alcocer-Gomez et al 2013). This theory has gained momentum as a result of the observation that, compared to healthy controls, several studies have identified lower levels of CoQ10 in fibromyalgia patients (Cordero et al 2009, 2012, Miyamae et al 2013), as well as increased levels of oxidative stress and decreased ATP production (Cordero et al 2009, 2012). Cordero et al identified a significant correlation between high oxidative stress (measured as low CoQ10 or catalase levels, and high levels of lipid peroxidation) with headache symptoms experienced by fibromyalgia subjects.

Furthermore, in fibromyalgia subjects given CoQ10 (300 mg/day for 12 weeks), the level of oxidative stress decreased to similar levels to the controls, and the levels of CoQ10, ATP and catalase significantly increased, although they were still lower than controls. Supplementation also improved clinical symptoms and headaches measured by tender points, Fibromyalgia Impact Questionnaire, visual analogue scales and the Headache Impact Test scores (Cordero et al 2012). A small case series involving four patients who met the American College of Rheumatology (ACR) Diagnostic Criteria of 1990 and 2010 for FM found that all were CoQ10-deficient. Treatment with CoQ10 resulted in an improvement in clinical symptoms as assessed by three different methods (Alcocer-Gomez et al 2013).

In a study involving young patients with fibromyalgia ( $14.7 \pm 2.9$  years), CoQ10 100 mg/day for 12 weeks similarly increased CoQ10 levels and decreased the ratio of ubiquinone-10 to total coenzyme Q10. Cholesterol metabolism was also improved with treatment (decreased free cholesterol and cholesterol esters) as well as fatigue (measured by the Chalder Fatigue Scale); however, subjective pain intensity (assessed by VAS) and health-related QOL did not change (Miyamae et al 2013).

Further investigation with doubled-blind, placebo-controlled clinical trials is warranted.

## Male infertility

Several studies have recently examined the role of coenzyme Q10 in the treatment of male infertility,

with most reporting positive results. Potentially beneficial mechanisms include its role as an antioxidant, improving mitochondrial activity and energy production, all of which influence spermatogenesis and motility.

The level of seminal plasma coenzyme Q10 and oxidative stress was examined in patients with different types of male infertility in a case-controlled study. Compared to the age-matched healthy controls, those with infertility had lower seminal levels of CoQ10 and lower CoQ10 was associated with higher levels of oxidative stress (measured by malondialdehyde (MDA) (Abdul-Rasheed et al 2010). A randomised, placebo-controlled study examined the seminal levels and antioxidants effects of CoQ10 in infertile men with idiopathic oligoasthenoteratozoospermia. After 3 months of 200 mg CoQ10 supplementation daily, the levels of CoQ10 increased in the treatment group, as did the activity of seminal antioxidants catalase and superoxide dismutase while the marker of oxidative stress, seminal plasma 8-isoprostane, decreased. There was significant correlation found between the reduction in seminal oxidative stress and improved sperm morphology (Nadjarzadeh et al 2013).

Several clinical trials have suggested treatment with CoQ10 improves sperm parameters and may increase the pregnancy rate in those with male infertility. In a placebo-controlled, double-blind, randomised trial, men with idiopathic infertility receiving 200 mg/day of CoQ10 for 6 months had significantly increased seminal plasma and sperm levels of CoQ10 and increased sperm motility. The greatest response was seen in those with the lowest baseline CoQ10 and sperm motility levels (Balercia et al 2009). Similarly, in a study by Safarinejad et al (2009) involving 212 infertile men (aged 21–42 years) with idiopathic oligoasthenoteratozoospermia, 300 mg/day of CoQ10 for 26 weeks led to a significant increase in sperm density (increase of 21.5% versus 1.3%) and motility (increase of 30.7% versus 2%), as well as a decrease in serum follicle-stimulating hormone (suggesting better spermatogenesis) and increase in inhibin B (reflecting better Sertoli's cell function); however, there was no difference in the pregnancy rate compared to placebo. Interestingly, at the 56 week follow-up (30 weeks post-treatment) sperm count, motility and morphology were still higher in the CoQ10 treated group compared to placebo, although it was not statistically significant. More recently, Safarinejad has conducted two additional studies. Using the same study design as above, 200 mg ubiquinol/day was given to 114 infertile men with idiopathic oligoasthenoteratozoospermia for 26 weeks. Compared to the placebo group ( $n = 114$ ), active treatment improved several sperm parameters including sperm density, sperm motility (35.8% versus 25.4%) and sperm morphology (17.6% versus 14.8%). As in the 2009 study, serum follicle-stimulating hormone decreased while inhibin B levels increased. Sperm parameters had decreased again at the 12-week follow-up post-treatment; however, there was still a statistically significant

improvement from the placebo group for sperm density and motility (Safarinejad et al 2012b). An open label prospective study was conducted with 287 infertile men with idiopathic oligoasthenoteratozoospermia who had previously undergone at least two failed infertility treatments. They received CoQ10 300 mg (Nutri Q10) twice daily for 12 months. Compared to baseline, blood and seminal CoQ10 levels increased at 3 months and remained steady for the remainder of the study. Sperm parameters significantly increased concentration by 114%, progressive motility by 105%, and morphology by 79%. There was also a pregnancy rate of 34.1% achieved within a  $8.4 \pm 4.7$  months (Safarinejad 2012).

In contrast, a double-blind, placebo-controlled clinical trial ( $n = 47$ ) found 200 mg CoQ10 for 3 months did not significantly change sperm concentration, motility and morphology in infertile men with idiopathic oligoasthenoteratozoospermia, although total antioxidant capacity of seminal plasma significantly increased (Nadjarzadeh et al 2011). As this study was shorter than those reporting positive results, the shorter treatment timeframe may have been a factor.

## OTHER USES

### Cancer

Currently, controlled studies are not available to determine the clinical effectiveness of CoQ10 in cancer; however, there have been several case reports of CoQ10 (390 mg/day) successfully reducing metastases or eliminating tumours entirely (Lockwood et al 1994, 1995). This supports numerous recent *in vitro* and animal studies that also suggest a protective role for CoQ10 against cancer development (Bahar et al 2010, Fouad et al 2012, Kim & Park 2010, Mizushima et al 2008). An *in vivo* study found that CoQ10 enhances the effects of immunotherapy (Kokawa et al 1983).

Studies investigating the plasma level of CoQ10 in those with cancer have reported variable correlation. In postmenopausal women, higher CoQ10 levels were found to be associated with an increased risk of breast cancer (Chai et al 2010), while a moderate amount was associated with reduced risk of prostate cancer in men (Chai et al 2011). Furthermore, compared to placebo, supplementation with CoQ10 for 12 weeks significantly lowered PSA levels from baseline in men with PSA levels below 2.5 ng/L, and there was a strong correlation between serum CoQ10 and PSA (Safarinejad et al 2012a).

### Reducing cardiotoxic effects of anthracyclines

There is some evidence that CoQ10 supplementation protects the mitochondria of the heart from anthracycline-induced damage. A systematic review of six studies (three randomised), in which patients in five of the six studies received anthracyclines, concluded that CoQ10 provides some protection against cardiotoxicity or liver toxicity during cancer

treatment; however, weaknesses in design and reporting made it difficult to reach a definitive conclusion (Roffe et al 2004). Despite the high level of heterogeneity, it appeared that CoQ10 had a stabilising effect on the heart. Importantly, CoQ10 was not shown to interfere with standard treatments in the clinical trials reviewed and no adverse effects were reported in any single study for CoQ10 administration.

Sample sizes in the studies ranged from 19 to 88 patients and one study included children. The methods researchers used to measure patient tolerance to anthracyclines and other cancer treatments were heart function and toxicity in five studies, and hair loss and liver enzymes in one study. The dose of CoQ10 investigated in the trials ranged from 90 mg/day to 240 mg/day. The lack of adverse effect by CoQ10 on cytotoxicity of doxorubicin was also supported by a recent *in vitro* study using breast cancer cell lines treated with doxorubicin at a range of CoQ10 concentrations (Greenlee et al 2012).

### Reducing side effects of tamoxifen

Tamoxifen is a common treatment used by those with breast cancer and is associated with some adverse effects, such as increasing oxidative stress and causing hypertriglyceridaemia. A study examining the effects of Coenzyme Q10 (100 mg) supplementation in addition to tamoxifen in breast cancer patients found it counteracted the effects of tamoxifen on raising triglycerides and increasing angiogenesis (increasing potential tumour metastasis) (Sachdanandam 2008). Similarly, in a study examining postmenopausal women with breast cancer treated with tamoxifen, the addition of CoQ10 combined with niacin and riboflavin for 90 days reduced oxidative stress and improved antioxidant status.

Several animal and *in vitro* studies have suggested a protective effect of CoQ10 from chemotherapy-induced organ toxicity (Celebi et al 2013, da Silva Machado et al 2013, El-Sheikh et al 2012, Sato et al 2013).

### Mitochondrial myopathy

An open multicentre study involving 44 volunteers with mitochondrial myopathies showed that treatment with CoQ10 (2 mg/kg daily) over 6 months decreased post-exercise lactate levels by at least 25% in 16 patients. Of those responding, a further 3 months' treatment with either CoQ10 or placebo produced no significant differences (Bresolin et al 1990). A more recent randomised, double-blind, crossover trial involving 30 patients with mitochondrial disease (mostly due to MELAS, chronic external progressive encephalopathy and mitochondrial DNA deletions) tested a high dose of oral CoQ10 (1200 mg/day). After 60 days of treatment, plasma CoQ10 levels were increased 5.5-fold, the post-exercise rise in lactate was reduced and the cycle aerobic capacity (measured by oxygen consumption

in lean body mass) was increased. There was no effect on other measurements including grip strength, or resting lactate production during a non-ischaemic isometric forearm exercise protocol (Glover et al 2010).

### Age-related macular degeneration (in combination)

Mitochondrial dysfunction is likely to play a role in the pathophysiology of age-related macular degeneration (Littarru & Tiano 2005). The level of CoQ10 in the retina has been shown to decrease with age by approximately 40% and the reduction in antioxidant protection and ATP synthesis may contribute to age-associated eye diseases, such as macular degeneration (Qu et al 2009). Further potential benefits of CoQ10 for eye health include *in vitro* evidence of its ability to protect lens epithelial cells from light-induced damage (Kernt et al 2010) and retinal cells from radiation-induced apoptosis (Lulli et al 2012a, Lulli et al 2012b). As a result, researchers are investigating therapeutic agents, such as CoQ10, which affect mitochondrial function.

Metabolic therapy consisting of a combination of omega-3 fatty acids, CoQ10 and acetyl-L-carnitine may have potential benefits as a treatment for early age-related macular degeneration by improving mitochondrial dysfunction, specifically improving lipid metabolism and ATP production in the retinal pigment epithelium, improving photoreceptor turnover and reducing generation of reactive oxygen species (Feher et al 2007). According to a pilot study and a randomised, placebo-controlled, double-blind clinical trial, both central visual field and visual acuity slightly improved after 3–6 months of treatment with the metabolic combination; however, the difference was not statistically significant when compared to the baseline or to controls. Treatment produced an improvement in fundus alterations as the drusen-covered area decreased significantly compared to baseline readings or controls, and was most marked in the less-affected eyes. Interestingly, a prospective case study on long-term treatment confirmed these observations. Visual function remained stable and, generally, drusen regression continued for years and for some intermediate and advanced cases, significant regression of drusen was found with treatment.

### Friedreich's ataxia

Decreased mitochondrial respiratory chain function and increased oxidative stress and iron accumulation play significant roles in the disease mechanism of Friedreich's ataxia (FRDA), raising the possibility that energy enhancement and antioxidant therapies may be an effective treatment (Cooper & Schapira 2007). Therapeutic avenues for patients with FRDA are beginning to be explored; in particular, targeting antioxidant protection, enhancement of mitochondrial oxidative phosphorylation and iron chelation. The use of quinone therapy (ubiquinone and

idebenone) has been the most extensively studied to date, with clear benefits demonstrated using evaluations of both disease biomarkers and clinical symptoms (Mariotti et al 2003).

A 4-year follow-up on 10 Friedreich's ataxia patients treated with CoQ10 (400 mg/day) and vitamin E (2100 IU/day) showed a substantial improvement in cardiac and skeletal muscle bioenergetics and heart function, which was maintained over the test period and some clinical feature of disease (Hart et al 2005). Comparison with cross-sectional data from 77 patients with FRDA indicated the changes in total International Cooperative Ataxia Rating Scale and kinetic scores over the trial period were better than predicted for seven patients, but the posture and gait and hand dexterity scores progressed as predicted.

In a more recent pilot study involving 50 subjects, the potential for high dose CoQ10 and vitamin E to modify the clinical progression of Friedreich's ataxia was investigated. Patients were randomly assigned to either high- or low-dose CoQ10 and vitamin E. At baseline, both groups had low serum CoQ10 and vitamin E, which significantly increased in both groups over the course of the 2-year trial. There was improvement in the International Cooperative Ataxia Rating Scale (ICARS) in 49% of patients when compared to cross-sectional data, but the response did not differ between the high- and low-dose groups. Serum CoQ10 levels were the best predictor of positive clinical response to treatment with CoQ10/vitamin E (Cooper et al 2008).

### Tinnitus and hearing loss

CoQ10 has been considered in hearing impairment due to its ability to act as an antioxidant and inhibit oxidative stress in the inner ear and reduce damage induced by noise (Hirose et al 2008).

In patients with a low plasma CoQ10 concentration, CoQ10 supply may decrease the tinnitus expression in chronic tinnitus aurium according to a 16-week prospective, non-randomised clinical trial ( $n = 20$ ) (Khan et al 2007). CoQ10 was tested in this population because of its antioxidant activity.

### IN COMBINATION

A controlled prospective study ( $n = 120$ ) examined the effects of CoQ10 in addition to steroid treatment in patients diagnosed with sudden sensorineural hearing loss. The CoQ10 was administered at a dose of 200 mg three times daily for 5 days and then 100 mg three times daily for another 10 days. After 3 months, the CoQ10 group had a non-statistically-significant additional benefit in hearing improvement compared to the steroid treatment alone (78.3% compared to 71.7%), but had a significantly better improvement in speech discrimination (Ahn et al 2010). This was supported by a more recent study in patients with presbycusis, a disorder with progressive bilateral symmetrical age-related

sensorineural hearing loss. Patients ( $n = 60$ ) were given either a water-soluble form of CoQ10 (Q-TER, 160 mg), vitamin E (50 mg) or placebo for 30 days. All patients receiving the CoQ10 had improvement in hearing, which was significant at most frequencies compared to the vitamin E group. No differences were found in those receiving the placebo treatment (Salami et al 2010).

### Myelodysplastic syndromes

The myelodysplastic syndromes (MDS) are a collection of haematopoietic disorders with varying degrees of mono- to trilineage cytopenias and bone marrow dysplasia. In recent years, much progress has been made in the treatment of MDS and there are now several therapeutic compounds used with varying levels of success; however, side effects make them unattractive for patients (Galili et al 2007).

Galili et al tested CoQ10 supplementation in MDS patients with low- to intermediate-2-risk disease. A variety of responses were observed in 7 of 29 patients. Sequencing mitochondrial DNA (mtDNA) from pretreatment bone marrows showed multiple mutations, some resulting in amino acid changes, in 3 in 5 non-responders, 1 in 4 responders and in two control samples. Based on these observations, it appears that CoQ10 may be of clinical benefit in a subset of MDS patients, but responders cannot be easily preselected on the basis of either the conventional clinical and pathological characteristics or mtDNA mutations.

### Huntington's chorea

A randomised, double-blind study involving 347 patients with early Huntington's chorea showed that a dose of CoQ10 (600 mg/day) taken over 30 months produced a trend towards slow decline as well as beneficial trends in some secondary measures; however, changes were not significant at this dosage level (Huntington's Study Group, 2001).

In a more recent 20-week open-label study by the same group, the effect on blood levels and safety of high dose CoQ10 supplementation was tested. Subjects (8 healthy and 20 with Huntington's disease) were supplemented with 1200 mg CoQ10 for 4 weeks, with the dose increasing by 1200 mg every 4 weeks to the maximum of 3600 mg/day. Blood levels of CoQ10 increased steadily from baseline  $1.26 \pm 1.27$  mcg/mL to a peak of  $7.49 \pm 4.09$  mcg/mL at a dose of 3600 mg at 12 weeks, and then declined again to  $6.78 \pm 3.36$  mcg/mL at the same dose at week 20. The most common adverse effects reported were gastrointestinal symptoms. Most symptoms developed at the initial dosage of 1200 mg/day, with no new symptoms occurring at the 2400 mg dose although two new cases occurred at the 3600 mg dose. It is possible that a smaller initial dose may reduce initial symptoms. The authors suggest that 2400 mg provides the best balance between increased blood levels and tolerability (Huntington Study Group, 2010).

## Preeclampsia

Teran et al (2009) conducted a randomised, double-blind, placebo-controlled trial involving 235 pregnant women at increased risk of preeclampsia. Women who received 100 mg of CoQ10 twice daily from week 20 until delivery had significantly reduced risk of developing preeclampsia compared to the placebo group (14.4% versus 25.6%). Possible mechanisms of action include reducing oxidative stress and improving endothelial function, but further research is required to clarify the outcomes.

## Diabetes

In 2009, the observation was made that plasma CoQ10 was significantly lower in a cohort of 28 people with type 2 diabetes compared to healthy controls and there was a negative correlation between plasma CoQ10 and glycosylated haemoglobin (El-ghoroury et al 2009). Soon after, a small open-label study found that volunteers with type 2 diabetes given 200 mg ubiquinol daily for 12 weeks, in addition to their existing hypoglycaemic medication, improved their glycosylated haemoglobin readings. No significant differences were seen for blood pressure, lipid profile, oxidative stress or inflammatory markers. Furthermore, five healthy volunteers who received 200 mg ubiquinol daily for 4 weeks had improved insulinogenic index and ratio of proinsulin to insulin, suggesting that CoQ10 may improve glucose control via increasing insulin secretion (Mezawa et al 2012). In 2013, a randomised, double-blind, placebo-controlled study of 64 people with type 2 diabetes, CoQ10 (200 mg/day) significantly reduced total cholesterol, LDL-cholesterol and improved glycaemic control compared to placebo (Kolahdouz et al 2013). Treatment was taken for 12 weeks, resulting in serum HbA<sub>1c</sub> concentration decreasing in the CoQ10-treated group (8 ± 2.28% vs 8.61 ± 2.47%) with no significant changes seen for placebo.

## Peyronie's disease

Peyronie's disease is an acquired idiopathic localised fibrosis of the penis which causes the penis to curve and associated sexual dysfunction. Safarinejad et al investigated the effects of CoQ10 supplementation in the treatment of early chronic Peyronie's disease in 186 patients. Treatment with CoQ10 300 mg/day for 24 weeks significantly reduced plaque size and penile curvature, improved erectile function (International Index of Erectile Function increasing by 117.1 versus 8.6%) and slowed disease progression compared to the placebo group (Safarinejad 2010).

## DOSAGE RANGE

### According to clinical studies

- Generally 100–150 mg/day has been used for conditions such as congestive cardiac failure (Mortensen et al 1990), hypertension, neurological disease, performance enhancement, periodontal disease (Wilkinson et al 1975).

- As preparation for cardiac surgery: 100–300 mg/day for 2 weeks before surgery followed by 100–225 mg/day for 1 month after surgery has been used (Judy et al 1993, Rosenfeldt et al 2002, 2005, Braun et al 2013).
- Adjunct to chemotherapy (anthracyclines) 90–240 mg/day, but evidence is not definitive.
- Angina pectoris: 60–600 mg daily.
- Chronic obstructive pulmonary disease: 50–90 mg daily.
- Cholesterol lowering: 200 mg daily (in type 2 diabetes).
- Congestive heart failure: 60–200 mg/day or 2 mg/kg/day for reducing mortality.
- Dry mouth: 100 mg/day.
- Fibromyalgia: 100–300 mg/day.
- Huntington's chorea: 600 mg daily.
- Hypertension: 100–120 mg/day.
- Male infertility: 200–600 mg/day.
- Migraine: 150–300 mg daily.
- Parkinson's disease: 1200 mg/day.
- Peyronie disease: 300 mg/day.
- Type 2 diabetes: 200 mg daily ubiquinol for improved glycosylated Hb levels.
- Sports supplement: 60–300 mg/day — inconsistent results.
- Statin-associated myalgia: 60–200 mg/day — inconsistent results.

## ADVERSE REACTIONS

CoQ10 appears relatively safe and non-toxic and is extremely well tolerated. Dizziness, nausea, epigastric discomfort, anorexia, diarrhoea, photophobia, irritability and skin rash occur in less than 1% of patients. This tends to occur with higher doses (> 200 mg/day).

## SIGNIFICANT INTERACTIONS

When controlled studies are not available, interactions are based on evidence of pharmacological activity, case reports and other evidence and are largely theoretical.

### Beta-adrenergic antagonists

Induces CoQ10 depletion — beneficial interaction with co-administration (Stargrove et al 2008).

### Doxorubicin

Tests in animal models have demonstrated that CoQ10 protects against doxorubicin cardiotoxicity (Combs et al 1977, Folkers et al 1978) and clinical studies provide some support for the use of oral CoQ10, and indicate that adjunctive treatment provides some protection against cardiotoxicity or liver toxicity during cancer therapy; however, further studies are required to prove this association conclusively (Roffe et al 2004). Furthermore, in vivo results indicate that CoQ10 has no significant effect on the pharmacokinetics of doxorubicin and the formation of the cytotoxic metabolite, doxorubicinol (Combs et al 1977, Zhou & Chowbay 2002) — potentially beneficial interaction with co-administration under professional supervision.

### Phenothiazines

CoQ10 reduces adverse effect this drug class has on CoQ10-related enzymes, NADH oxidase and succinoxidase — beneficial interaction with co-administration (Stargrove et al 2008).

### Statin drugs

Currently, it is still not clear whether CoQ10 supplementation should be considered a necessary adjunct to all patients taking statin drugs; however, there are no known risks to this supplement and there is some anecdotal and clinical trial evidence of its effectiveness (Marcoff & Thompson 2007). Consequently, CoQ10 can be tested in patients requiring statin treatment, who develop statin myalgia, headache, fatigue or malaise as statin-induced side effects. It may also prove useful for patients considered at risk of deficiency, in particular, patients with a family history of heart failure, elevated cholesterol levels and who are older than 65 years and taking statin drugs long term (Levy & Kohlhaas 2006) — possible beneficial interaction with co-administration, particularly with the antioxidant effects of superoxide dismutase (Okello et al 2009).

### Sulfonylureas

CoQ10 reduces adverse effect this drug class has on CoQ10-related enzymes, NADH oxidase and low CoQ10 levels have been observed in people with diabetes — beneficial interaction with co-administration (Stargrove et al 2008).

### Tamoxifen

Concomitant use of CoQ10 reduced triglyceride levels in one study — potentially beneficial.

### Theophylline

An animal study suggests significant changes to the pharmacokinetics of theophylline, such as time to peak concentration, half-life and distribution following treatment with CoQ10. While there is very limited research, there may be possible interactions (Baskaran et al 2008).

### Timolol

Eye drops — oral CoQ10 reduced the vascular side effects of timolol without affecting eye pressure (Takahashi 1989) — beneficial interaction with co-administration.

### Tricyclic antidepressants

CoQ10 reduces adverse effect this drug class has on CoQ10-related enzymes, NADH-oxidase and succinoxidase — beneficial interaction with co-administration (Stargrove et al 2008).

### Warfarin

There are three case reports suggesting that CoQ10 may decrease the international normalised ratio (INR) in patients previously stabilised on anticoagulants (Spigset 1994b). However, a double-blind crossover study involving 24 outpatients on stable

long-term warfarin found that oral CoQ10 (100 mg) daily had no significant effect on INR or warfarin levels (Engelson et al 2003). One observational study suggested an increase in minor bleeding events but not INR (Shalansky et al 2007). Observe patients using high CoQ10 doses and taking warfarin.

### Vitamin E

Reconstitutes oxidised vitamin E to its unoxidised form — beneficial interaction with co-administration.

#### CONTRAINDICATIONS AND PRECAUTIONS

Insufficient reliable evidence — unknown.

#### PREGNANCY USE

Since this is an endogenously produced substance that has been tested in preeclampsia without serious negative outcomes, it is likely to be safe in this population during the final trimester.

#### Practice points/Patient counselling

- CoQ10 is a safe antioxidant vitamin used in supplement form for a wide range of diseases.
- Meta-analyses provide support for its use in congestive heart failure and hypertension.
- Clinical evidence further supports the use of presurgical supplementation in cardiac surgery, as it improves recovery and has cardioprotective activity.
- Clinical evidence supports its use in the prevention of migraine headache.
- There is also some clinical evidence suggesting a role in fibromyalgia, dry mouth, type 2 diabetes, Huntington's chorea, mitochondrial myopathy, COPD, periodontal disease, haemodialysis, Friedreich's ataxia, tinnitus, age-related macular degeneration, cystic fibrosis, male infertility and reducing cardiotoxicity and liver toxicity associated with anthracyclines, although further research is required.
- Whether CoQ10 may slow the progression of PD is unclear.
- Several common medicines, such as statins, have been found to reduce serum CoQ10 status. It is still unclear whether CoQ10 should be considered a necessary adjunct to statin drugs; however, there are no known risks to this supplement and there is some anecdotal and clinical trial evidence of its effectiveness. In particular, it may be useful in patients who develop statin myalgia, headache, fatigue or malaise and those considered at risk of deficiency, such as people of advanced age and vegetarians..

## ! PATIENTS' FAQs

### What will this vitamin do for me?

CoQ10 is an antioxidant vitamin used in every cell of the body. It is necessary for healthy function and can improve heart function, lower blood pressure and reduce angina. Taken before cardiac surgery, it has been shown to reduce complications and hasten recovery in some studies. It may also provide benefits in preventing migraine headache, Huntington's chorea, mitochondrial myopathy, COPD, type 2 diabetes, chronic obstructive airways disease, periodontal disease, haemodialysis, Friedreich's ataxia, tinnitus, age-related macular degeneration, cystic fibrosis and reducing cardiotoxicity and liver toxicity associated with anthracyclines, although further research is required to definitively confirm effect. Whether it is helpful in Parkinson's disease is not clear. People taking statin drugs long term and experiencing mild side effects could safely take a 3-month trial of CoQ10 and see whether it helps them.

### When will it start to work?

This depends on the indication. For heart conditions and to reduce migraine, 10–12 weeks may be required. To delay the progression of PD, one study found that effects started after 9 months' use.

### Are there any safety issues?

Medical monitoring is required in patients taking warfarin and starting high-dose CoQ10 supplements; however, even high-dose supplements are well tolerated and considered safe.

## Colostrum

### **Clinical note — Hyperimmune bovine colostrum**

Bovine colostrum contains a variety of Ig, but the specific Ig present varies and is influenced by previous immune system challenges. Hyperimmune BC, in which the concentration of specific antibodies is raised, can be produced by immunising cows with either specific pathogens or their antigens. For example, BC from cows exposed to rotavirus might contain a relatively high neutralising Ig titre against the virus (as well as many other pathogenic microorganisms), whereas BC collected from cows never exposed to rotavirus is less likely to have specific neutralising Ig against rotavirus. This is an important distinction, because much of the research on BC as prophylaxis or treatment for infectious disease has focused on products that are, as a consequence of specific immune provocation, immunologically unique (Kelly 2003).

### **BACKGROUND AND RELEVANT PHARMACOKINETICS**

Colostrum is the milk produced by female mammals towards the end of pregnancy and secreted from the mammary gland in the first 2 days after giving birth. It is a very complex fluid, rich in nutrients, antibodies, growth factors, vitamins and minerals (Uruakpa et al 2002). The antibodies provide passive immunity to the newborn, and the growth factors stimulate development of the gastrointestinal tract. In contrast to humans, where immunoglobulins are transferred in utero via the placenta, newborn calves are wholly dependent on colostrum to provide passive immunity via intestinal absorption of immunoglobulins, which do not cross the placenta in cattle. This provides a highly concentrated immunoglobulin-rich substance (Rathe et al 2014).

### **CHEMICAL COMPONENTS**

Colostrum contains macronutrients, such as protein and carbohydrate, micronutrients, such as vitamins and minerals, together with cytokines, including IL-1-beta, IL-6, trypsin inhibitors, protease inhibitors and oligosaccharides. It also contains growth factors,

such as insulin-like growth factor (IGF)-1 and -2, transforming growth factor-alpha and -beta, lactoferrin, epidermal growth factor and others. High amounts of insulin-like growth factors (IGF-1 and IGF-2) are present and are heat and acid stable, able to withstand dairy processing, and the acid conditions of the GIT (Rathe et al 2014). Several different antimicrobial factors are also present, such as immunoglobulin (Ig) A, secretory IgA, IgG-1, IgG-2 and IgM, lactoferrin, lactoperoxidase and lysozyme, which produce both specific and non-specific bacteriostatic and bacteriocidal effects on many pathological microorganisms, including bacteria, viruses and fungi. IgG-1 is the principal immunoglobulin type in colostrums, and IgM, IgA and IgG-2 are present in lower amounts (Mach & Pahud 1971). Colostrum is the only natural source of two major growth factors: transforming growth factors alpha and beta, and high amounts of insulin-like growth factors 1 and 2. These growth factors have significant muscle and cartilage repair characteristics (Uruakpa et al 2002). The presence of fibroblast growth factors and platelet-derived growth factor is thought to be instrumental in tissue repair and wound healing. Transforming growth factor- $\beta$  has anti-inflammatory effects and is implicated in tissue proliferation and repair, while transforming growth factor- $\alpha$  has a role in maintenance of epithelial function and integrity (Rathe et al 2014).

Evidence for stability of bioactive substances in GIT transit has been documented for bovine immunoglobulin; however, other constituents such as cytokines may be less resilient to changes in conditions related to collection and administration, which may account for variable effects (Rathe et al 2014).

### **FOOD SOURCES**

Bovine colostrums (BC) are derived from cows, and hyperimmune BC is derived from cows that have been exposed to organisms that can cause disease in humans.

### **MAIN ACTIONS**

In a recent systematic review, Rathe et al (2014) suggest that while methodological quality of clinical trials has been generally less than robust, the main

benefits of bovine colostrums are provided in gastrointestinal and immunological effects. Further, more robust studies are required to confirm findings to date in humans, and animal model studies may help to elucidate the biological mechanisms underlying any observed effect and the best methods for dosage and administration.

### Imparts passive immunity and stimulates growth of the neonatal gastrointestinal tract

Just as the immunoglobulins of human colostrum impart passive immunity to the newborn child, so too BC provides protection against microbial infections and confers passive immunity to the newborn calf until its own immune system matures (Korhonen et al 2000). Studies with targeted hyper-immune BC suggest that passive immunity may prevent or treat infectious diseases that affect the entire length of the gastrointestinal tract (Pacyna et al 2001).

In contrast, two studies examining the effects of BC on short bowel syndrome in both children (Aunsholt et al 2014) and adults (Lund et al 2012) found that the inclusion of BC to the diet did not improve intestinal function in either population.

Rathe et al (2014) reviewed research that suggests that the antimicrobial effect of bovine colostrum lies in its constituent elements that contain numerous proteins and peptides that are attributable to both the innate and the acquired immune systems (Stelwagen et al 2009).

### Immunomodulatory activity

An animal study found that BC has a Th1-promoting activity, which may be helpful in treating various infectious diseases, including influenza (Biswas et al 2007, Yoshioka et al 2005). When BC was administered to weaned piglets, this intervention increased total serum IgA levels, stimulated ileal Peyer's patch (PP) and both Th1 and Th2 cytokine production (Boudry et al 2007). Further research would be needed to assess if BC increases Th1 in already high Th1 profiles or simply modulates the immune function where there is dysfunction.

Uchida et al (2012) demonstrated in their study that skimmed and concentrated bovine late colostrum (SCBLC) activates the immune system and protects against the influenza (flu) virus infection. Activity of natural killer (NK) cells of PP cells significantly increased following oral administration of SCBLC to mice. This was seen in splenocytes and lung cells, indicating that oral administration of SCBLC activates systemic cellular immunity and also local cellular immunity, such as in the respiratory tract, and that activation of cellular immunity is one of the mechanisms of amelioration of flu infection.

In an analysis of human colostrum and breast milk, Marcuzzi et al (2013) confirmed the presence of high levels of cytokines, cytokine receptors and chemokines. The concentrations of these were significantly higher in colostrum, including the

presence of IL-9, which was first described by these researchers. Of the cytokines investigated, IL-1 $\beta$ , IL-2, IL-4, IL-5, IL-7 and MIP-1 $\alpha$  were present in colostrum only. The presence of these substances is indicative of the influence on the development of the immune system of the newborn.

For children aged 1–10 years, with non-organic failure to thrive, Panahi et al (2010) found that daily supplementation with 40 mg oral BC significantly improved the Gomez index for weight status after 3 months. One hundred and twenty children with mild to moderate non-organic failure to thrive were randomised to routine treatment or to 40 mg oral BC plus routine treatment. The mean Gomez index significantly improved in the oral BC group, but height status, as measured by the Waterlow I index, was no different between the groups.

In contrast, a clinical study found no significant effect on immune parameters for healthy volunteers aged 40–80 years who received BC concentrate 1.2 g/day. The researchers suggested that improving immune function in people with healthy immune responses is difficult, thereby explaining why no significant effect was observed (Wolvers et al 2006).

Jensen et al (2012), however, investigated the effects of bovine colostrum low-molecular weight fraction (CLMWF) on aspects of innate immune function in healthy adults. In a double-blind, placebo-controlled, randomised crossover study, a single dose of CLMWF resulted in a rapid increase in phagocytic activity of monocytes at 1 hour and polymorphonuclear cells at 1 hour and 2 hours. The relative increase of NK cells suggested that new NK cells were mobilised into action following the interaction of CLMWF with immune cells in the gut mucosa. Local immune events in the gut are triggered acutely, with systemic consequences. This is reiterated by Rathe et al (2014), suggesting that BC constituents may contribute to systemic immunological events following contact with gut mucosa, as well as localised direct antimicrobial and endotoxin-neutralising effects throughout the GIT. Further, the authors suggested other growth-stimulating factors may be at work, indicated by suppression of gut inflammation and the promotion of mucosal integrity and tissue repair in the context of injury (Rathe et al 2014).

### Antibacterial and antiviral effects

Targeted hyperimmune BCs have proven effective in prophylaxis against various human infectious diseases caused by organisms such as rotavirus, *Shigella flexneri*, *Escherichia coli*, *Clostridium difficile*, *Streptococcus mutans*, *Cryptosporidium parvum* and *Helicobacter pylori* (Korhonen et al 2000). Hyperimmune BC from cows previously immunised with a vaccine of 17 strains of pathogenic diarrhoea bacteria was shown to inhibit in vitro growth of the same pathogens by destroying cell walls and agglutinating with bacteria (Xu et al 2006).

It is suspected that colostrum may modulate the interaction of *H. pylori* and other adhesin-expressing

**Clinical note — Ovine colostrum and colostrum proline-rich polypeptides**

There is new research appearing in the literature regarding colostrum from ewes, mostly using a product called Colostrin, which is a proline-rich, polypeptide complex from mammalian colostrum. In vitro, in vivo and clinical trials using this product have gained attention as having possible therapeutic benefit in the treatment of mild or moderate Alzheimer's disease (AD) by improving cognitive symptoms and delaying the disease process. Two mechanisms have been proposed to explain these benefits — an antioxidant mechanism which reduces oxidative stress and prevention of beta-amyloid aggregation (Bilikiewicz & Gaus 2004, Boldogh & Kruzel 2008, Stewart 2008). The anti-inflammatory action of this substance may also have an effect on decreasing IgE/IgG-1 production, which could prevent or reduce allergic responses (Boldogh et al 2008). It seems that bovine colostrum proline-rich polypeptides have also displayed some potential in this anti-allergenic arena. Ovine colostrum, Colostrin and colostrum proline-rich polypeptides are products to watch and would benefit from broader clinical trials to confirm their potential therapeutic uses.

pathogens with their target tissues, chiefly due to phosphatidylethanolamine and its derivatives, rather than to an antibody response (Bitzan et al 1998).

Benson et al (2012) evaluated the effects on the innate immune system in the mouse model after exposure to a low-molecular weight fraction (CLMWF) of immunoglobulin-depleted bovine colostrum whey. Reduced bacterial (*Streptococcus*) and viral (influenza) loads were observed in lungs within 24 hours when product is introduced across mucosal membranes. The results are confirmed by Jensen et al (2012), with a follow-up human study linking a rapid and immediate increase in phagocytic activity of monocytes with a subsequent triggering of new natural killer cells into systemic circulation.

**Improves gut permeability**

Studies with agents known to disrupt gut permeability indicate that BC has a preventive effect that is likely to be a result of more than one growth factor present in the colostrum (Mir et al 2010, Playford et al 1999, 2000, Rathe et al 2014).

**Reduces NSAID-induced intestinal damage**

Defatted BC had major beneficial effects in preventing non-steroidal anti-inflammatory drug (NSAID)-induced gut injury in a variety of well-validated in vivo and in vitro models (Kim et al 2005a, 2005b, Playford et al 1999, 2001). BC improves the integrity of intestinal villi and prevents NSAID-induced increases in small intestine permeability. More specifically, the studies indicate that it stimulates both

cell migration and proliferation, thereby enhancing the natural repair mechanisms that occur during acute mucosal injury. One of the studies, by Kim et al (2005a), identified that when BC is administered together with glutamine, gastrointestinal protection is greater than when either agent is used alone. Further, the other study found that the overgrowth of enteric aerobic bacteria seen with NSAID administration did not occur to the same extent with BC (Kim et al 2005b).

**OTHER ACTIONS**

The high nutritional content of BC makes it an excellent source of many macro- and micronutrients.

**Antioxidant activity**

BC given to intestinal ischaemia/reperfusion-injured rats experienced reduced oxidative stress and reduced nitric oxide (NO) overproduction in the lungs, which reduced lung injury. Superoxide dismutase and glutathione peroxidase levels were significantly increased and myeloperoxidase and malondialdehyde were significantly reduced in lung tissue, indicating an overall reduction in oxidative stress (Choi et al 2007). The same research team went on to show that BC may reduce damage in brain ischaemia/reperfusion-injured rats (Choi & Ko 2008). Following this, the same research team (Choi et al 2009) demonstrated that BC may have beneficial effects in treating and preventing intestinal barrier damage, bacterial translocation and the related systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS) in an intestinal ischaemia/reperfusion (I/R)-injured rat model.

**CLINICAL USE**

The use of BC as a dietary supplement has increased substantially over the past two decades. Unlike other dietary supplements, the composition of BC is not precisely defined and varies greatly according to the breed and health status of the donor animal feeding practices, previous exposure to infectious organisms and time collected postparturition (Kelly 2003).

**Prevention and treatment of infection**

Targeted hyperimmune BC products have proven effective in prophylaxis against various infectious diseases in humans, such as URTI, influenza and shigella (Rathe et al 2014, Tacket et al 1992).

**Infectious diarrhoea****Rotavirus infection**

The clinical evidence available suggests that hyperimmune BC is a promising agent in the prophylaxis and treatment of infectious diarrhoea caused by rotavirus. One Australian study using BC containing high titres of antibody to all four human rotavirus serotypes found that administration successfully prevented symptomatic infection in 100% of children treated with the preparation (Davidson et al 1989). It also reduced the duration of rotavirus

excretion, which may have implications for preventing cross-infection. A double-blind study of 75 boys aged 6–24 months with rotavirus diarrhoea compared ordinary BC to hyperimmune BC (100 mL three times daily for 3 days) from cows immunised with four serotypes of human rotavirus (Mitra et al 1995). Diarrhoea ceased within 48 hours in 50% of children receiving hyperimmune BC, whereas 100% of children receiving ordinary BC continued to have diarrhoea. Total stool output (g/kg) between admission and cessation of diarrhoea was also reduced in the group receiving hyperimmune BC compared with ordinary BC. Another double-blind study also found that treatment with antirotavirus immunoglobulin of BC origin is effective in the management of children with acute rotavirus diarrhoea (Sarker et al 1998).

A double-blind study of children aged 6–30 months found that treatment with hyperimmune BC (100 mL solution four times daily for 4 days) leads to improved weight gain, decreased duration of diarrhoea and resulted in fewer stools, although the differences were not statistically significant compared to ordinary colostrum or placebo (Ylitalo et al 1998).

Studies using hyperimmune BC in young children have identified rotavirus antibodies as early as 8 hours after ingestion and up to 72 hours after consumption has ceased, with a strong relation between the titre of rotavirus antibody administered and the level of antibody activity detected in the faeces (Pacyna et al 2001). This suggests that passive immunity is imparted to the entire length of the gastrointestinal tract.

### Shigella infection

According to one small study, hyperimmune BC with a high titre of anti-*Shigella flexneri* 2a lipopolysaccharide prevented the incidence of shigella infection in 10 of 10 volunteers, whereas 5 of 11 volunteers administered a control substance went on to develop the infection (Tacket et al 1992).

### HIV-induced diarrhoea

BC has also been investigated as a potential treatment in HIV-induced diarrhoea, a symptom that occurs in most patients infected with AIDS. A BC product (Lactobin, Biotest, Dreieich, Germany) containing high titres of antibodies against a wide range of bacterial, viral and protozoal pathogens, as well as against various bacterial toxins, was tested in a multicentre pilot study involving 29 HIV-infected patients (Rump et al 1992). An oral dose of 10 g/day produced a transient (10 days) or long-lasting (>4 weeks) normalisation of the stool frequency in 21 patients. Mean daily stool frequency decreased from 7.4 to 2.2 at the end of the treatment. Some success was also obtained 1 year later in a prospective, open, uncontrolled study of 25 HIV patients with chronic refractory diarrhoea and either confirmed cryptosporidiosis ( $n = 7$ ) or absence of demonstrable pathogenic organisms ( $n = 18$ ) (Plettenberg et al 1993). An oral dose of 10 g/day

of an immunoglobulin preparation from BC over a period of 10 days led to complete remission of cryptosporidiosis infection in three of seven subjects and two had partial remission. Complete remission was also seen in seven of 18 patients with diarrhoea and negative stool culture and a further four had partial remission. Of those subjects not responding to treatment, doubling of the dose to 20 g/day led to partial remission in four more patients and complete remission in one.

A BC product designed for slow passage through the gastrointestinal tract (ColoPlus) was tested over 4 weeks in an open-label study of 30 people with HIV-associated diarrhoea (Floren et al 2006). Treatment resulted in a dramatic decrease in daily stool evacuations (from  $7.0 \pm 2.7$  to  $1.3 \pm 0.5$ ), a mean increase of 7.3 kg of body weight, a 125% increase in CD4<sup>+</sup> count and a substantial decrease in self-estimated fatigue. However, in a 2011 study by Byakwaga et al researchers found that the administration of neither raltegravir nor hyperimmune bovine colostrum (HIBC) for 24 weeks resulted in any significant change to CD4<sup>+</sup> count.

### Reducing incidence of upper respiratory tract infections (URTIs)

There is good evidence that daily supplementation with bovine colostrum for a number of weeks (and preliminary evidence for acute effects after a single dose) can maintain intestinal barrier integrity, immune function and reduce the chances of suffering URTI or URT symptoms in athletes or those undertaking heavy training (Davison 2012). IgA is found in saliva and acts as a major barrier preventing pathogens entering the body via the oral route. As such, the level of secretory IgA has been found to correlate with resistance to some viral infections. According to two clinical studies, BC (20 g/day) increases salivary IgA levels, a factor that could feasibly increase the host's resistance to infection (Crooks et al 2006, Mero et al 2002). In the study by Crooks et al, secretory IgA levels were elevated by 79% after 12 weeks of BC administration in athletes. The presence of numerous immune factors in BC further provides a theoretical basis for its use; however, little clinical investigation has been conducted to confirm its preventive effects.

In 2003, results of a randomised, double-blind, placebo-controlled trial were published, providing some support for its use as a prophylactic agent (Brinkworth & Buckley 2003). The study of 174 physically active young males compared colostrum powder (60 g/day; intact, Numico Research Australia Pty Ltd) to concentrated whey powder over 8 weeks. During the test period, a significantly smaller proportion of subjects taking BC reported URTI symptoms than the control group; however, BC did not alter the duration of URTI once infection was established. Due to the self-reporting method used in this study, results should be viewed as preliminary and require further confirmation. An open study with 605 children in India achieved exceptional results as a prophylactic in preventing

recurrent episodes of upper respiratory tract infections and diarrhoea. The children received a BC (PediMune) for 12 weeks, which reduced the incidence of URTI by 91% and diarrhoea by 86% (Patel & Rana 2006). This was an open study, and more rigorous clinical trials are needed to confirm these findings.

### Influenza prophylactic

Colostrum may reduce the incidence of influenza according to a trial which compared a colostrum supplement, given over 2 months, with an influenza vaccination and a combination of the two, for the prevention of flu. Over the next 3 months, the group receiving colostrum treatment only had the lowest number of flu episodes (13), with the next highest in the colostrum and vaccination group (14), then the vaccination only (41), highest in non-treated subjects (57). The study was repeated with 65 high-risk cardiovascular patients, which once again produced positive results, as the incidence of hospital admissions and complications was higher in those who received only the vaccination compared to people receiving colostrum. Overall, colostrum supplementation was considered at least three times more effective than vaccination for flu prevention (Cesarone et al 2007). Benson et al's (2012) mouse model study, followed by the Jensen et al (2012) human study, suggests reduced bacterial (*Streptococcus*) and viral (influenza) load observed in the lungs within 24 hours of administration of a consumable low-molecular weight fraction (CLMWF) bovine colostrum whey is the result of a rapid immediate increase in phagocytic activity of monocytes with a subsequent triggering of new natural killer cells into systemic circulation.

### Improved physical performance and preservation of muscle mass

BC has been used by athletes mainly as a natural source of IGF-1 because it has an anabolic effect and is involved in the regulatory feedback of growth hormone. It is taken with the belief that protein catabolism will be reduced during intense training periods and physical performance will improve.

A double-blind, crossover study of nine male athletes confirmed that ingestion of BC (125 mL/day; Bioenergie, Viable Bioproducts) resulted in elevated concentrations of IGF-1; however, no significant effects were reported for serum IgG or saliva IgA concentrations (Mero et al 1997). Several years later in a larger study of athletes, under double-blind study conditions, researchers confirmed that BC ingestion produced significant increases in serum IGF-1 (Mero et al 2002). The dose of 20 g/day of BC (dynamic supplement) was used during a 2-week training period in this study, which further found that saliva IgA levels increased with this particular treatment.

In a more recent trial, 29 cyclists were randomly assigned to take either 10 g/day of a BC protein concentrate or a placebo consisting of 10 g/day of

whey protein during normal training over 5 weeks. Performance tests showed that BC treatment improved results in a 40-km time trial during a high-intensity training regimen and also maintained ventilatory threshold (Shing et al 2006). The same researchers also found that the supplement modulated immunity before and after training and prevented postexercise reductions in serum IgG2 at the end of the high-intensity training period. A trend towards fewer upper respiratory tract illnesses was also detected (Shing et al 2007). In 2013, these same researchers undertook a pilot study ( $n = 10$ ) to examine the effects of bovine colostrum protein concentrate (CPC) (10 g per day) supplementation on salivary hormones, salivary IgA and heart rate variability (HRV) over consecutive days of competitive cycling, compared with a control group receiving whey protein concentrate (10 g per day). They found that bovine CPC supplementation was associated with maintained salivary testosterone concentration and modulated autonomic activity (HRV) over consecutive days of competitive cycling. No differences were found in salivary IgA between groups. Implications for improved recovery is implied for endurance athletes in this pilot study, and further research is warranted (Shing et al 2013).

Conversely, in a study by Carol et al (2011), BC was investigated for its effect in post exercise immune modulation after short-term intense exercise in nine male athletes. No significant effect was found for BC in preventing post-exercise immune suppression. Similarly, a study by Crooks et al (2010) on the effect of BC on mucosal defence in the respiratory tracts of athletes and a non-exercising control group found no measurable effect on either saliva or plasma immunoglobulin levels in the BC group or the control group.

However, a trial by Davison and Diment (2010), designed to model stress-induced immunodepression by examining exercise-induced immunodepression, found that while previous research had focused primarily on salivary IgA levels, a more useful measure may be to examine the exercise-induced changes in innate immunity as measured by neutrophil function and salivary lysozyme, in addition to salivary IgA. They found that there were significant increases in these stress markers in both groups, but that over time there were observed differences in neutrophil function and salivary lysozyme concentration and release. Significant exercise-induced decreases were observed in these parameters, but the BC group had a more speedy recovery of the neutrophil function and prevention of the decrease in salivary lysozyme, as measures of innate immunity. Therefore, the authors suggest that BC supplementation limits the immunodepressive effects induced by an acute prolonged physical stressor.

Appukutty et al (2011) found in a 6-week intervention of bovine colostrum in active adolescent boys that supplementation resulted in modulated interferon- $\gamma$  activity.

The review by [Rathe et al \(2014\)](#) suggest that collectively, results from studies of athletes, and GIT re-activity to BC, confirm systemic effects, which follow immunological events triggered by contact with gut mucosa.

### Gastrointestinal protection against NSAID-induced damage

BC has also been investigated in a small, randomised, crossover study as prophylaxis against NSAID-induced gastrointestinal damage ([Playford et al 2001](#)). A spray-dried, defatted colostrum (125 mL three times daily) was co-administered with indomethacin (50 mg three times daily) for 5 days in the first phase, then the effect of 7 days treatment with the colostrual solution on gut permeability was determined in subjects taking NSAID long-term. Indomethacin (150 mg/day) caused a threefold increase in gut permeability after 5 days, whereas no change was observed when colostrum was co-administered, suggesting a protective effect. In contrast, no protective effect was seen in subjects who had been using NSAIDs long-term and then administered colostrum for 1 week. Various animal and human studies suggest the protective effect of BC on the gut against NSAID exposure ([Rathe et al 2014](#)).

### Antidiabetic

It has been suggested that BC may have an effect on blood glucose levels. A small, randomised study of 16 patients with type 2 diabetes tested the effects of BC (10 g/day) over 4 weeks. Total cholesterol and triglyceride levels decreased significantly with active treatment, and a reduction in blood glucose levels and ketones were observed, which suggests a potential role for BC in diabetes management ([Kim et al 2009](#)). Larger clinical studies are warranted to confirm this finding.

[Hammon et al \(2013\)](#) state that BC affects intestinal growth and function and is likely to enhance the absorptive capacity of the GIT, and therefore improve the glucose status in neonatal calves by increasing glucose absorption and elevating post-prandial plasma glucose concentrations. This is thought to occur by improved glucose absorption and therefore storage in the liver, enhancing availability in the postprandial state ([Hammon et al 2013](#)). In a study by [Tozier \(2013\)](#), neonatal admissions to the intensive care unit (NICU) for glucose stabilisation decreased following the initiation of routine colostrum feeds for newborns of diabetic mothers, replacing routine formula supplementation for this population. Rates of exclusive breastfeeding were also increased, in line with best practice recommendations from the WHO. [Marinelli et al \(2012\)](#) note that the high protein content of colostrum helps with glucose stabilisation and promotion of ketogenesis.

### Wound healing

In a small study by [Doillon et al \(2011\)](#), a complex compound (immune ('IM') fraction) from colostrum-

derived whey was investigated for potential wound-healing capabilities. In vitro, the compound was able to significantly inhibit the contraction of collagen gel while fibroblast density remained similar to control gels, and did not exhibit evidence of stress fibres. This effect was dose-dependent. In vivo studies of guinea pig models demonstrated significantly delayed wound closure by contraction, resulting in minimised residual scarring, and the wound covered a significantly larger surface area, with unchanged collagen deposition. The mechanism of action may reflect a contraction rate modulation and wound remodelling.

### OTHER USES

Due to its effects on gut permeability, BC is used in a variety of other conditions, such as inflammatory bowel disease, coeliac disease, food allergies, intestinal infection and inflammatory joint diseases. It has also been used to restore normal gut permeability in people using chemotherapy. In some instances, it is used with glutamine for these indications ([Kim et al 2005a](#)).

### DOSAGE RANGE

#### According to clinical studies

- Diarrhoea due to rotavirus: 100 mL three times daily for 3 days of BC from cows immunised with the four serotypes of human rotavirus.
- HIV-induced diarrhoea: 10 g/day (Lactobin, Biotest, Dreieich, Germany).
- Prevention of URTI: 60 g/day (intact, Numico Research Australia Pty Ltd).
- Increasing serum IGF-1 levels: 125 mL/day (Bio-energie, Viable Bioproducts) or 20 g/day (Dynamic supplement).
- Prevention of NSAID-induced gastrointestinal damage: 125 mL three times daily of spray-dried, defatted BC.
- For improving performance in high-intensity training and reducing exercise-induced URTI: 10 g/day.

### TOXICITY

Not known.

### ADVERSE REACTIONS

Not known.

### SIGNIFICANT INTERACTIONS

Not known.

### CONTRAINDICATIONS AND PRECAUTIONS

Only BC products produced under strict quality control guidelines should be used. They typically contain lactose, so should be avoided by people with lactose intolerance.

### PREGNANCY USE

Likely to be safe.

**Practice points/Patient counselling**

- Colostrum is a very complex fluid that is rich in nutrients, antibodies, growth factors, vitamins and minerals.
- Targeted hyperimmune BC products have proven effective in prophylaxis against various infectious diseases in humans, notably infectious diarrhoea.
- BC is a popular supplement among athletes and used mainly as a natural source of IGF-1 because it has an anabolic effect and is involved in the regulatory feedback of growth hormone.
- Preliminary evidence suggests that BC may prevent NSAID-induced gastrointestinal damage and improve gut permeability.
- Most studies use hyperimmune BC in which the concentration of specific antibodies is raised.
- Preliminary evidence shows some potential for BC in flu prevention and upper respiratory tract infections.

**! PATIENTS' FAQs****What will this supplement do for me?**

Bovine colostrum contains nutrients, antibodies, growth factors, vitamins and minerals, and has a variety of effects on the gastrointestinal tract, immune function and the ability to fight some infections, and may possibly reduce muscle catabolism. It also may reduce the risk of developing an upper respiratory tract infection.

**When will it start to work?**

Studies with infectious diarrhoea have reported benefits within 3–4 days, and improvement in gut permeability within 5 days.

**Are there any safety issues?**

Bovine colostrum produced under quality control guidelines is a safe substance; however, it should be avoided by people with lactose intolerance.

## Coriolus versicolor

**HISTORICAL NOTE** In traditional medical practices of China and Japan, *Coriolus versicolor* or Yun Zhi mushroom was harvested, dried, ground and made into tea. It has an established history of use in these cultures and is included in the Chinese Materia Medica, being widely prescribed for cancer and infection. Not surprisingly, the healing properties of coriolus has been further investigated in clinical trials, mainly by Chinese and Japanese scientists. The dose of the active polymers in the traditional tea was similar to that used in modern clinical practice. Of the mushroom-derived therapeutics, polysaccharopeptides (PSP) obtained from *Coriolus versicolor* are commercially available and are of most interest. In addition to its medical applications, *C. versicolor* is widely used to degrade recalcitrant organic pollutants such as pentachlorophenol (Cui et al 2003).

### COMMON NAME

Coriolus, Yun Zhi

### OTHER NAMES

*Agaricus versicolor*, *Boletus versicolor*, champignon coriolus, Krestin, *Polyporus versicolor*, *Polystictus versicolor*, *Poria versicolor*, *Trametes versicolor*, Yun Zhi (Chinese), Kawaratake (Japanese), polysaccharide-K, polysaccharide Krestin, PSK

In North America, *C. versicolor* is commonly known as 'turkey tail' mushroom.

### BOTANICAL NAME/FAMILY

*Coriolus versicolor* (family Agaricaceae)

### PLANT PART USED

Fruiting body

### CHEMICAL COMPONENTS

*Coriolus versicolor* consists of saccharide, protein, polyphenol and triterpenoid components, with PSP and polysaccharide-K (PSK, krestin) being the most noteworthy fractions (Cui & Chisti 2003, Hsu et al 2013). The protein-bound polysaccharides and their polypeptide moieties are rich in aspartic acid and glutamic acid and also contain the amino acids: alanine, tyrosine, threonine, cysteine, phenylalanine, serine, valine, tryptophan, methionine, lysine, proline, isoleucine and histidine, glycine, leucine and

arginine (Yeung & Or 2012). The polysaccharide component contains the sugars mannose, xylose, galactose, arabinose, glucose and rhamnose (Yeung & Or 2011).

## MAIN ACTIONS

Studies exploring the mechanisms of action for coriolus have utilised various different extracts and also isolated constituents, but mainly focused on PSK (krestin) and PSP, which are chemically similar and display similar activities. In vitro and in vivo tests reveal an extremely broad range of pharmacological activity and physiological effects for coriolus, PSK and PSP.

### Immunomodulatory activity

The ability to influence immune regulation via anti-inflammatory and cell-signalling pathways is well documented in experimental literature. Overall, polysaccharides from coriolus have been shown to activate various types of immune effector cells, such as B lymphocytes, T lymphocytes, cytotoxic T cells, macrophages, polymorphonuclear cells, natural killer cells, lymphokine-activated killer cells and tumour-infiltrating lymphocytes (Wong et al 2004).

PSP from *Coriolus* has also been shown to regulate gene expression and cytokine secretion related to Toll-like receptor signalling pathway in human peripheral blood mononuclear cells (PBMCs) (Li et al 2010).

### Anticancer

Research into the anticancer properties of coriolus has largely focused on the effects of the mushroom to strengthen the immune response of cancer patients. Additionally, direct anticancer activity has been demonstrated for both PSK and PSP in vitro and in vivo for several cancers.

A dose-dependent cytotoxic activity was demonstrated in vitro for a standardised aqueous ethanol extract of coriolus. The extract was shown to suppress the proliferation of Raji, NB-4 and HL-60 cells by more than 90%, with ascending order of IC50 values. It was also found that it did not exert any significant cytotoxic effect on normal liver cell line WRL when compared with a chemotherapeutic anticancer drug, mitomycin C, confirming the tumour-selective cytotoxicity (Lau et al 2004). In a rat model PSP enhanced the cytotoxic effect of cyclophosphamide on a cancer cell line in vitro and altered the pharmacokinetics of cyclophosphamide (Chan et al 2006b). A methanol extract exerted pronounced antimelanoma activity, both directly through antiproliferative and cytotoxic effects on tumour cells and indirectly through promotion of macrophage antitumour activity in vitro. The methanol extract treatment was also shown to inhibit tumour growth in C57BL/6 mice inoculated with syngeneic B16 tumour cells. Moreover, peritoneal macrophages collected 21 days after tumour implantation from methanol extract-treated animals exerted

stronger tumouristatic activity ex vivo than macrophages from control melanoma-bearing mice (Harhaji et al 2008).

*Coriolus versicolor* polysaccharide-B was also shown to inhibit proliferation and enhance apoptosis of oesophageal cancer cell lines (Wang et al 2012), and, in a double-blind, pilot randomised controlled trial (RCT), high-dose PSP significantly delayed the progression of metastases and afforded the longest survival times reported in canine haemangiosarcoma (Brown et al 2012). Other studies show that coriolus extract dose-dependently suppressed the proliferation of HL-60 cells, with increased nucleosome production from apoptotic cells. Expression of proapoptotic protein Bcl-2-associated X protein was significantly upregulated in HL-60 cells treated with the coriolus extract, especially after 16 and 24 hours, and expression of antiapoptotic protein Bcl-2 was concomitantly downregulated, as reflected by the increased Bcl-2-associated X protein:Bcl-2 protein ratio and markedly, but transiently, promoted the release of cytochrome c from mitochondria to cytosol after 24-hour incubation and may be useful in the treatment of some forms of human leukaemia (Ho et al 2006).

### Analgesic activity

Analgesic activity has been demonstrated in several animal models and found to be dose-dependent for polysaccharopeptide (Ng et al 1997, Chan et al 2006a). The activity appears to be partly mediated by interleukin-2 (IL-2), which is activated by polysaccharopeptide and interacts with IL-2 receptors in the mediobasal hypothalamus, as demonstrated in mice (Gong et al 1998).

### Antioxidant

A direct antioxidant effect of Yun Zhi against oxidant challenge on the DNA of lymphocytes was evidenced in vitro and the active component in Yun Zhi is thought likely to be membrane-permeable (Szeto et al 2013).

## OTHER ACTIONS

### Anti-inflammatory

The anti-inflammatory effects of *Coriolus versicolor* can be explained by its ability to inhibit certain proinflammatory cytokines, as was seen in a study of male mice with experimentally-induced ulcerative colitis. There was a significant reduction in the expression of STAT1 and STAT6 molecules, thereby leading to lower interferon- $\gamma$  and IL-4 expression (Lim et al 2011).

### Anti-HIV

The inhibitory effect of polysaccharopeptide from *Coriolus versicolor* on HIV-1 reverse transcriptase and alpha-glucosidase was enhanced after chemical modification with chlorosulfonic acid (Wang et al 2001). In a series of in vitro assays it demonstrated inhibition of the interaction between HIV-1 gp 120 and

immobilised CD4 receptor (IC50 150 mcg/mL) and potent inhibition of recombinant HIV-1 reverse transcriptase (IC50 6.25 mcg/mL) and it inhibited a glycohydrolase enzyme associated with viral glycosylation (Collins et al 1997).

### Hepatoprotection

PSP dose-dependently decreased the binding of [<sup>14</sup>C]-paracetamol to microsomal proteins in vitro. When PSP was given to rats subchronically for 7 days, the subsequent microsomes obtained also showed a 25% decrease in covalent binding to [<sup>14</sup>C]-paracetamol, suggesting that PSP interacted with the microsomal proteins rather than the chemically reactive metabolite of paracetamol (Yeung et al 1994).

### CLINICAL USE

Preparations containing coriolus and PSK and PSP have been extensively used in Japan and China in the last 30 years, mainly as adjuvant treatment in various cancers to improve patient survival.

### Cancer

Both PSP and PSK are considered a new type of biological response modifier which appears to counter the immunosuppressive effect of standard cancer treatments, improve appetite and liver function, enhance the pain threshold and, according to a 2012 meta-analysis, provide a significant survival advantage when used together with standard anticancer treatments compared with standard conventional anticancer treatments alone (Cui & Chisti 2003, Eliza et al 2012, Wong et al 2004). PSK is a Japanese product, while PSP is a Chinese product, and both are approved as adjuvant agents of cancer treatment in Japan and China (Eliza et al 2012).

The 2012 meta-analysis was conducted on 13 RCTs in which coriolus or its extracts (PSP or PSK) were compared to placebo or standard therapy in cancer patients ( $n = 2587$ ) (Eliza et al 2012). Importantly, no language restrictions limited access to RCTs and trials using coriolus in combination with other herbs were excluded. The overall 5-year survival rate compared was defined as the common end point and was used to assess the differences between the Yun Zhi and standard conventional anticancer treatment groups. The authors identified 22 RCTs that met inclusion criteria; however data were only available from 13 RCTs in a form that could be used for meta-analysis. All RCTs compared Yun Zhi or its extracts (PSK or PSP) with conventional anticancer treatment with or without placebo, using a dose range of 1–3.6 g daily, and the duration of therapy was 1–36 months.

Coriolus treatment or its extracts produced a highly significant difference in overall survival at 5 years when compared to patients solely receiving standard oncology treatment ( $P < 0.00001$ ; relative risk = 1.14; 95% confidence interval = 1.09, 1.20). More specifically, in the patients randomised to

receive coriolus preparations, there was a 9% absolute reduction in 5-year mortality, resulting in one additional patient alive for every 11 patients treated. The increase in 5-year survival was most evident for people with breast cancer, gastric cancer or colorectal cancer who were also treated with chemotherapy, according to the RCTs that were assessed.

This is not to assume that coriolus is ineffective in other cancers. Eliza et al (2012) stated they could not be sure whether people with oesophageal cancer were responders from the data available.

The possibility that PSK and PSP could be effective adjuvant treatments in people with cancer is not new. In Japanese trials since 1970, PSK significantly extended survival at 5 years or beyond in cancers of the stomach, colon/rectum, oesophagus, nasopharynx and lung (non-small-cell types), and in an HLA B40-positive breast cancer subset. PSP was subjected to phase II and III trials in China. In double-blind trials, PSP significantly extended 5-year survival in oesophageal cancer. PSP significantly improved quality of life, provided substantial pain relief and enhanced immune status in 70–97% of patients with cancers of the stomach, oesophagus, lung, ovary and cervix. PSK and PSP boosted immune cell production, ameliorated chemotherapy symptoms and enhanced tumour infiltration by dendritic and cytotoxic T cells. Their extremely high tolerability, proven benefits to survival and quality of life and compatibility with chemotherapy and radiation therapy make them well suited for cancer management regimens (Kidd et al 2000). A study to evaluate the effects of 28-day administration of PSP in 34 patients with non-small-cell lung carcinoma showed a significant improvement in blood leucocyte and neutrophil counts, serum immunoglobulin G (IgG) and IgM, and percentage of body fat among the PSP, but not the control, patients. Although the evaluable PSP patients did not improve in non-small-cell lung carcinoma-related symptoms, there were significantly fewer PSP patients withdrawn due to disease progression than their control counterparts. There was no reported adverse reaction attributable to the trial medications (Tsang et al 2003).

#### **Clinical note — PSP and PSK successful development of traditional medicine**

PSK was the first polysaccharide to be commercialised from coriolus. It was tested extensively in clinical trials and approved for use in Japan in 1977. Within a decade it was ranked 19th in the world's most commercially successful drug list and annual sales grew to \$357 million in Japan in 1987. About 10 years after the development of PSK, PSP was commercialised by the Chinese (Cui & Chisti 2003).

## OTHER USES

### Immunomodulatory

#### IN COMBINATION

The regular oral consumption of Yun Zhi together with a Chinese herb known as Danshen is able to promote immunological function in the posttreatment period of breast cancer patients, according to a study in 82 patients. Results showed that the absolute counts of T-helper lymphocytes (CD4<sup>+</sup>), the ratio of T-helper (CD4<sup>+</sup>):T suppressor and cytotoxic lymphocytes (CD8<sup>+</sup>) and the percentage and absolute counts of B lymphocytes were significantly elevated in patients with breast cancer after taking Yun Zhi-Danshen capsules, while plasma-soluble receptors for IL-2 concentration were significantly decreased (Wong et al 2005). Similarly, multiple effects on immune function were reported in a study of healthy subjects, where oral consumption of Yun Zhi-Danshen capsules significantly elevated PBMC gene expression of IL-2 receptor, increased the percentage and absolute counts of T-helper cell and ratio of CD4<sup>+</sup> (T-helper):CD8<sup>+</sup> (T-suppressor and cytotoxic T) cell, and significantly enhanced the ex vivo production of typical Th1 cytokine interferon-gamma from PBMCs activated by a lectin found in plants, called phytohaemagglutinin and lipopolysaccharide. Such consumption had no adverse effects on liver or renal function (Wong et al 2004).

### DOSAGE RANGE

2–6 g daily

### TOXICITY

The oral lethal dose of *Coriolus versicolor* water extract is more than 5000 mg/kg and no observed adverse effect level of the extract for both male and female rats is 5000 mg/kg per day for 28 days (Hor et al 2011).

### ADVERSE REACTIONS

The use of *Coriolus versicolor*, PSK and PSP has not been associated with any serious adverse reactions. No toxicity has been observed and serious adverse effects have not been reported in clinical trials. Doses of the extract up to 15 g daily over a long period have not been linked with any side effects (Kidd et al 2000).

### SIGNIFICANT INTERACTIONS

In sarcoma-bearing mice, PSK, a protein-bound polysaccharide from *Coriolus versicolor*, was not found to affect microsomal enzymatic activities and, when administered concomitantly, is predicted to not cause changes in the pharmacokinetics of drugs (Fujita et al 1988).

### Immunosuppressant medication

The use of *C. versicolor* polysaccharopeptides is contraindicated when immune suppression is desired. Polysaccharopeptides reduce the potency of immunosuppressants such as cyclosporin — avoid.

### CONTRAINDICATIONS AND PRECAUTIONS

People with cancer choosing to use coriolus treatment or its polysaccharides should seek professional guidance when doing so, to ensure safety and monitor for response.

Given its immune-stimulating action *Coriolus versicolor* should be used with caution by people with autoimmune diseases as well as people who are organ transplant recipients, particularly in the case of bone marrow transplant (Chu et al 2002).

### PREGNANCY USE

PSP did not produce adverse effects on female reproductive or embryonic development in mice treated intraperitoneally, suggesting safety in pregnancy (Ng et al 1997).

### Practice points/Patient counselling

- Coriolus is a medicinal mushroom which is used extensively in China and Japan as adjuvant treatment in cancer
- Clinical trials show that coriolus and the derived polysaccharides PSK and PSP increase the chances of 5-year survival when used as adjuvant treatment with chemotherapy in several cancers — current evidence supports its use in breast, gastric and colorectal cancer, but it may also have benefits in other cancers.
- It improves immune function, has direct anti-cancer effects, reduces liver toxicity, decreases pain and stimulates appetite.
- Coriolus, PSK and PSP may counteract immunosuppression therapy and should be used with caution by people with autoimmune disease.
- The treatment is well tolerated and can be used long-term.

### PATIENTS' FAQs

#### What will this supplement do for me?

Clinical studies show that coriolus and the derived polysaccharides PSK and PSP increase the chances of 5-year survival when used as adjuvant treatment with chemotherapy in several cancers. To date the evidence most strongly supports use in breast, gastric and colorectal cancer, but it may also have benefits in other cancers.

#### When will it start to work?

It is usually used long-term by people with cancer and studies use frames lasting from 1 month to 36 months; there do not appear to be any safety issues associated with long-term use.

#### Are there any safety issues?

Coriolus, PSP and PSK are well tolerated and safe. They should not be used by people taking immunosuppressive medicines or organ transplant recipients due to their immunostimulating effects. People

with autoimmune disease should use this treatment with caution.

# Cranberry

**HISTORICAL NOTE** Native American Indians used cranberries as both a food and a treatment for bladder and kidney diseases. In the mid-1800s, German scientists suggested that cranberry juice had antibacterial activity, supporting its use as a treatment for bladder infections. Recent investigation has confirmed its usefulness in the prevention of urinary tract infections.

## OTHER NAMES

Kronsbeere, marsh apple, moosbeere, preisselbeere

## BOTANICAL NAME/FAMILY

*Vaccinium oxycoccus*, *Vaccinium macrocarpon* (family Ericaceae)

## PLANT PART USED

Fruit

## CHEMICAL COMPONENTS

Catechin, flavone glycosides, fructose, organic acids, proanthocyanidins, vitamin C. Cranberry has a high flavonol content (100–263 mg/kg) (Hakkinen et al

1999) — higher than commonly consumed fruits and vegetables.

## MAIN ACTIONS

### Bacteriostatic and antiadhesive activity

The adhesion of pathogenic organisms to a tissue surface is required to initiate most infectious diseases (Sharon & Ofek 2002). Various in vitro and in vivo studies have identified that cranberry has antiadhesion properties relevant to several different strains of bacteria, including *Escherichia coli*, *Staphylococcus aureus*, *Helicobacter pylori*, *Streptococcus pneumoniae* and *Streptococcus mutans*.

The proanthocyanidins in cranberry are potent inhibitors of *E. coli* adhesion, thereby influencing the initiation of disease without exerting bactericidal activity. One in vitro study found that cranberry juice inhibited adhesion of 46 different *E. coli* isolates by 75% (Sobota 1984): when administered to mice for 14 days, adherence of *E. coli* to uroepithelial cells was inhibited by 80%. Significant inhibition of adherence was also observed in samples of human urine 1–3 hours after subjects drank a cranberry drink. A water-soluble extract was found to be most effective in its antimicrobial inhibition of seven bacterial strains, including *E. coli*, *Listeria monocytogenes* and *Salmonella typhimurium* (Côté et al 2011).

The morphology of *E. coli* is changed when grown in the presence of cranberry juice or extract (Johnson et al 2008). It appears that the antiadhesion effects are a result of irreversible inhibition of the expression of P-fimbriae of *E. coli* (Ahuja et al 1998). Electron micrographic evidence suggests that cranberry juice acts either on the cell wall, preventing proper attachment of the fimbrial subunits, or as a genetic control, preventing the expression of normal fimbrial subunits, or both (Gupta et al 2007). Of the cranberry constituents, it appears that the sugars in conjunction with organic acids cause osmotic stress and the anthocyanins and phenolics lead to the disintegration of the outer membrane when tested against *E. coli* (Lacombe et al 2010). Furthermore, cranberry juice has been shown to disrupt bacterial ligand-uroepithelial cell receptor binding (Liu et al 2008). This inhibitory effect has been seen with *Staphylococcus aureus* (Magarinos et al 2008, Su et al 2012), *E. coli* and uroepithelial tissues, but also in the adhesion of *Helicobacter pylori* to human gastrointestinal cells (Burger et al 2002) and in the co-aggregation of oral bacteria and *Streptococcus mutans* counts in saliva (Sharon & Ofek 2002, Weiss et al 1998).

New research on human bronchial cells found a 90% adhesion inhibition for *Streptococcus pneumoniae* (a common cause of pneumonia, meningitis and otitis media) with cranberry juice (Huttunen et al 2011). Two studies have looked at the effect of cranberry extracts on biofilm production, which can cause infections with catheter use and corneal infections caused by contact lens use. Both studies found a reduction in growth of biofilm with Gram-positive bacteria, specifically *Staphylococcus* spp. (LaPlante et al 2012, Leshem et al 2011).

### Antioxidant

Cranberries consistently rank highly among common fruits with antioxidant activity. In particular, the polyphenolic compounds in cranberry display substantial antioxidant capacity. In vitro tests with whole fruit and isolated flavonol glycosides found in cranberry showed free radical scavenging activity comparable or superior to that of vitamin E (Yan et al 2002). In vivo studies demonstrate that cranberry juice increases plasma antioxidant status (Villarreal et al 2007). A small human trial demonstrated

that a single 240-mL serving of cranberry juice increased plasma antioxidant capacity significantly greater than controls receiving an equivalent amount of vitamin C in solution (Vinson et al 2008).

### Increases excretion of oxalic acid and uric acid

According to an open study, a dose of 330 mL cranberry juice can increase the excretion of oxalic acid and uric acid (Kessler et al 2002).

### Alterations to urinary pH

Earlier hypotheses that cranberry juice prevents urinary tract infection (UTI) by acidification of urine or by its hippuric acid content have not been substantiated. Results from human studies are contradictory, but overall suggest no significant change in urinary pH at doses less than 330 mL daily. A crossover study of 27 patients with indwelling urinary catheters and chronic bacteriuria showed no change in urinary pH (Nahata et al 1982); the results of a double-blind study of 153 women were the same (Avorn et al 1994). One small, open study involving 12 healthy subjects found that 330 mL of cranberry juice reduced the urinary pH (Kessler et al 2002).

### Chemoprotective

Studies employing mainly in vitro tumour models show that cranberry extracts and compounds inhibit the growth and proliferation of several types of tumour, including lymphoma, bladder, breast, colon, prostate, ovaries, oesophageal, lung, oral squamous cell carcinoma and gastric cancer cells (Chatelain et al 2008, Ferguson et al 2006, Hochman et al 2008, Kim et al 2012, Kresty et al 2008, Liu et al 2009, MacLean et al 2011, Prasain et al 2008, Singh et al 2009, Sun & Hai Liu 2006, Vu et al 2012). The flavonoid components may act in a complementary fashion to limit carcinogenesis by inducing apoptosis in tumour cells (Neto et al 2008).

### Cytochromes

Although some studies with animal models have suggested effects on various cytochromes, human studies have found that cranberry juice has no significant effect on CYP 2C9, 1A2 or 3A4 (Greenblatt et al 2006, Grenier et al 2006, Lilja et al 2007, Mohammed Abdul et al 2008, Ushijima et al 2009).

Before we can definitively conclude that cranberry juice has no effect on CYP3A4, it must be noted that a human study testing five commercial cranberry juices has identified substantial interbrand variations in ability to inhibit intestinal (but not hepatic) CYP3A, ranging from 34% to abolishment (Ngo et al 2009). Further testing indicates that three triterpenes are able to inhibit CYP3A in humans, suggesting it may be the natural variation in concentration of these constituents between products which is responsible for the inconsistent results seen between in vivo and clinical trials to date (Kim et al 2011a).

## OTHER ACTIONS

Preliminary research with in vitro tests and those using animal models are identifying many different actions which are worthy of further exploration.

### Antiviral activity

A non-specific antiviral effect has been demonstrated in vitro for a commercially produced cranberry fruit juice drink (Lipson et al 2007).

### Antifungal activity

A recent in vitro study of cranberry proanthocyanidin fractions on human fungi, *Candida* spp. and *Cryptococcus neoformans* reported antifungal activity (Patel et al 2011).

### ACE inhibitor

Cranberry powders have been shown in vitro to have a limited inhibitory activity on alpha-amylase and to significantly impact angiotensin 1-converting enzyme (ACE) (Pinto Mda et al 2010).

### Lipid lowering and anti-inflammatory

According to a rat study, cranberry powder may modify serum lipids and reduce inflammatory markers (Kim et al 2011b).

## CLINICAL USE

### Prevention of UTI

A number of controlled clinical trials support the use of cranberry products (solid-dose form and juice) in the prevention of UTIs in women experiencing recurrent infections; however, the heterogeneity of studies makes a clear interpretation difficult. There is emerging evidence to suggest that cranberry juice with high concentrations of Type A proanthocyanidin may be more effective than other forms; however further studies are required to assess this (Afshar et al 2012).

A significant preventive effect was concluded in a 2012 systematic review and meta-analysis of 10 randomised controlled trials (RCTs) which included 1494 subjects (Wang et al 2012). Wang et al reported that, on subgroup analysis, cranberry-containing products seemed to be more effective in several subgroups, including women with recurrent UTIs (relative risk [RR] 0.53), female populations (RR 0.49), children (RR 0.33), cranberry juice drinkers (RR 0.47) and subjects using cranberry-containing products more than twice daily (RR 0.58). While the conclusion was positive, authors cautioned that the results should be interpreted in the context of substantial heterogeneity across the studies.

In contrast, a 2012 Cochrane review evaluated data from RCTs and also quasi-RCTs of cranberry products for the prevention of UTIs in all populations ( $n = 4473$ ) and concluded that there is no statistically significant difference between cranberry and placebo for the prevention of UTIs (Jepson

et al 2012). The effects of cranberry/cranberry-lingonberry juice versus placebo, juice, lactobacillus, antibiotics or water were evaluated in 13 studies (with amounts ranging from 30 mL to 1000 mL), and cranberry tablets versus placebo in nine studies (daily dose range from 400 mg to 2000 mg); one study evaluated both juice and tablets. Overall, cranberry products did not significantly reduce the incidence of UTIs at 12 months compared with placebo/control. Cranberry products showed a small benefit in some of the smaller studies for women with recurrent UTIs; however no significant benefit was seen in the elderly, pregnant women, children with recurrent UTIs, cancer patients, those with neuropathic bladder or spinal injury or people requiring catheterisation. Only one study reported a significant result for the outcome of symptomatic UTIs. One study (McMurdo et al 2009) showed that cranberry treatment was as effective as an antibiotic. Beerepoot et al (2011) did not get the same result. Gurley (2011) suggests the negative result with Beerepoot was because he used a cranberry treatment whereby the quantity of type-A proanthocyanidins used amounted to only 9 mg/g, making the amount of free proanthocyanidins reaching the urinary tract of study participants less than 1 mg/day. Side effects were common in all studies, and dropouts/withdrawals in several of the studies were high (Jepson et al 2012).

### Why the conflicting conclusions?

The systematic review and meta-analysis completed by Wang et al, also in 2012, reported conflicting results, possibly due to the significant heterogeneity of the trials, making the literature difficult to evaluate in a meaningful way. The Wang review confirmed the findings of the earlier 2008 Cochrane review, concluding that cranberry products were effective especially for women with recurrent UTIs. It excluded the Barbosa-Cesnik RCT of women with recurrent UTIs (Barbosa-Cesnik et al 2011), as they inadvertently used ascorbic acid in the placebo. As this in itself may reduce UTIs, it may have masked the effects of cranberry, especially as the authors expected the placebo arm to have 30% recurrence of UTIs and the rate was only 14%. The study also used the lowest threshold of bacteria in the urine to determine a UTI (Wang et al 2012). Gurley (2011) reports that the amount of type A procyanidin present in the test extracts needs to be of a sufficient quantity to have an effect, as they tend to have very poor bioavailability and some studies, such as Beerepoot et al (2011), use extracts with insufficient amounts.

Since these two reviews were published, further RCTs have also been published.

A clear protective effect and significant decrease in the rate of relapse were seen amongst women aged aged over 50 years taking cranberry juice in a double-blind RCT by Takahashi et al (2013). The study involved 118 women aged 20–79, given 125 mL of cranberry juice to drink daily before

going to sleep over a 24-week period. In a subgroup analysis of women aged over 50 years, relapse of UTI was observed in 16 of 55 (29.1%) patients drinking cranberry juice compared with 31 of 63 (49.2%) in the placebo group.

In 2012, an RCT of 176 premenopausal women with a history of UTIs found cranberry juice (120–240 mL/day) demonstrated a potentially protective effect with a hazard ratio for UTI of 0.68 compared with placebo, but it was not statistically significant. In addition, researchers found that the group ingesting cranberry juice had reduced infection with P-fimbriated *E. coli* strains, which suggests benefits from cranberry juice therapy are possible and confirms the antiadhesion mechanism clinically. One major limitation of this study was that it was underpowered to show a significant effect of cranberry on the cumulative rate of UTI, as they did not achieve the necessary sample size (Stapleton et al 2012).

A concentrated cranberry liquid blend (UTI-Stat with Proantinox) was tested for safety, tolerability and maximal tolerated dose in 28 women with a history of recurrent UTI and an average age of 46 years. A secondary outcome was UTI recurrence. The secondary end points demonstrated that 2 (9.1%) of 23 women reported a recurrent UTI, a rate considered superior to their historical data. At 12 weeks, there was a significant reduction in worry about recurrent infection and increased quality of life in regard to the physical functioning domain and role limitations from physical health domain, as measured by the Medical Outcomes Study short-form 36-item questionnaire ( $P = 0.0097$ ). A lower American Urological Association Symptom Index indicating greater quality of life was also significant ( $P = 0.045$ ) (Efros et al 2010).

Another RCT with 137 women aged 45 years or older, who had experienced cystitis at least twice in the past year and been treated with antibiotics, were given a 500 mg cranberry capsule (Cran-Max, Buckton Scott Health Products, UK) at bedtime for a period of 6 months or 100 mg of the antibiotic trimethoprim. Overall, 28% of women experienced a UTI during the study (25 in the cranberry group and 14 in the trimethoprim group), with median time to recurrence of 84.5 days for the cranberry group and 91 days for the trimethoprim group. Trimethoprim was more effective at reducing UTIs in older women in this study but it was not statistically significant and compared with cranberry the trimethoprim conferred only 7 extra UTI-free days. Cranberry may be a cheaper, better-tolerated option for recurrent UTI treatment in older women and does not carry the risk of antimicrobial antibiotic resistance (McMurdo et al 2009).

### Renal transplant patients

A small retrospective trial of 82 renal transplant patients receiving cranberry juice (2 × 50 mL/day) found the annual number of UTI episodes was reduced by 63.9% (Pagonas et al 2012).

### Spinal cord injuries

Patients with spinal cord injuries are a high-risk group for catheter-associated UTIs, so cranberry products are popular in this group. One double-blind, factorial-design, RCT of 305 people with spinal cord injuries showed no significant UTI-free period compared to placebo when taking 800 mg of cranberry tablets twice daily (Lee et al 2007), while another randomised, double-blind, placebo-controlled, crossover trial in 47 patients with spinal cord injury demonstrated a significant reduction in the frequency of UTIs (Hess et al 2008). An open pilot study involving 15 volunteers with spinal cord injuries showed that three glasses of cranberry juice daily significantly reduced the adhesion of Gram-negative and Gram-positive bacteria to uroepithelial cells (Reid 2002). Treatment using catheter device with proanthocyanidin solutions has also been shown to inhibit adhesion of bacteria to non-biological particles such as PVC (Eydelnant & Tufenkji 2008). While these results are promising, a 2010 review of five studies of spinal cord injury patients reported that there is limited evidence that cranberry may be helpful in preventing or treating UTIs and suggests that more rigorous research is required (Opperman 2010).

### Radiotherapy and UTI prevention

Bladder infections are a common side effect of radiotherapy for prostate cancer. This controlled trial of 370 patients who were receiving radiotherapy for prostate cancer in an Italian hospital were given a 200 mg enteric-coated tablet (VO370 or Monoselect Macrocarpon) containing standardised cranberry extract titrated as 30% proanthocyanidins. This trial took place over 6–7 weeks and a significant reduction was found in the number of UTIs and recurrent UTIs in the treatment group vs controls. Good compliance and only two gastric complaints were reported. It was also found to help reduce urinary symptoms of dysuria, nocturia, urinary frequency and urgency (Bonetta & Di Piero 2012).

### Gynaecological surgery and UTI prevention

The short-term use of cranberry capsules produced no statistically significant difference in UTI incidence in a cohort of 286 women undergoing gynaecological surgery. The treatment group received cranberry capsules for 4 days prior to surgery and 5 days postoperatively (Cadkova et al 2009).

### Children

#### Catheterisation and renal disease

Cranberry use is popular for children with renal disease. An anonymous survey of 117 parents of children seen in a hospital paediatric nephrology clinic identified that 29% gave cranberry products to their children to treat as well as prevent diverse renal problems (Super et al 2005). Most parents felt

that it was beneficial and only one reported an adverse reaction (nausea).

Two studies conducted in children managed by clean intermittent catheterisation found no clinical or statistical difference in the number of symptomatic UTIs observed in either the cranberry or the placebo group (Foda et al 1995, Schlager et al 1999). Foda et al used a dose of 5 mL/kg/day of cranberry cocktail for 6 months and the dose used by Schlager et al was 2 oz (≈55 g) of cranberry concentrate.

### Recurrent UTIs in children

There has been a recent Cochrane systematic review and a meta-analysis by Wang et al, both published in 2012 and both reporting different conclusions. The Cochrane review found no significant difference of cranberry compared to placebo in children with recurrent UTIs (RR 0.48, 95% confidence interval [CI] 0.19–1.22); whereas the Wang meta-analysis concluded benefit for children (RR 0.33; 95% CI 0.16–0.69). The Cochrane review included three studies, one RCT (Ferrara et al 2009) of 84 girls randomised to cranberry (50 mL daily), *Lactobacillus* or control for 6 months, and reported that daily cranberry drink significantly reduced recurrent UTIs in children. Also in the Cochrane review was a study by Salo et al (2012) which was a randomised placebo-controlled trial with 263 children recruited in seven hospitals in Finland reported no significant difference in the number of children with recurrent UTIs, although there was a non-significant reduction, with 20 children (16%) in the cranberry group and 28 (22%) in the placebo group experiencing a recurrent UTI (difference –6%; 95% CI –16 to 4%;  $P = 0.21$ ). The cranberry juice dose was 5 mL/kg up to 300 mL per day. Although cranberry did not significantly reduce the number of children with a UTI, the authors reported a significant reduction in the number of times a child got a UTI and also the number of days the child needed to take antibiotics.

The third study (Uberos et al 2010) mentioned in the Cochrane review was dismissed as it was unclear about whether they were testing for a UTI or just a positive culture. Uberos et al did report that cranberry syrup was equally effective to trimethoprim for recurrent UTIs in their population of 192 children.

The Wang meta-analysis included only the Ferrara study for children with recurrent UTIs and report that the current data support the use of cranberry products in children with UTIs, although suggest that more trials are needed. Overall the differences in the two meta-analyses appear to be that Wang did not include either the Salo et al (2012) or the Uberos et al (2010) trials. The difference in the individual trial results may be explained by the variety of cranberry products used and the dosage levels (for children, dosage may need to be adjusted by body weight), although in general the trend on

all the trials is towards benefit for children with recurrent UTIs.

A later RCT looked at a cranberry juice with high concentrations of proanthocyanidin and compared that to regular cranberry juice for 1 year. There were 40 children in the study and the incidence of infection in the treatment group of high proanthocyanidins was 0.4 per patient per year and 1.15 in the placebo group, showing a 65% reduction in the risk of UTIs in non-febrile children (Afshar et al 2012). This high-proanthocyanidin-containing cranberry juice shows promise and further investigation is warranted.

### Treatment of UTI

Although cranberry may be a viable adjunctive treatment in UTI when antibiotic resistance is encountered, there is no reliable evidence that it is an effective sole treatment in diagnosed UTI (Ulbricht & Basch 2005). One study of pregnant women demonstrated comparable effects of daily cranberry juice mixture to those of placebo for asymptomatic bacteriuria and symptomatic UTIs; however, the results were not statistically significant and more than one-third of participants withdrew from the study because of gastrointestinal upset (Wing et al 2008). In another study, cranberry exhibited only weak antimicrobial activity in urine specimens of symptom-free subjects after ingestion of a single dose (Lee et al 2010).

### Nephroprotection

Cranberries have an antioxidant function and may prevent infection-induced oxidative renal damage. Animal studies suggest that cranberries might be used clinically as a beneficial adjuvant treatment to prevent damage due to pyelonephritis in children with vesicoureteric reflux (Han et al 2007).

### OTHER USES

#### Gout

Cranberry juice has been used to treat gout. Evidence of increased uric acid excretion in humans provides a theoretical basis for the indication, although studies in patients with gout are not available to confirm effectiveness (Kessler et al 2002).

#### Oral hygiene

The antiadhesion effect of cranberry on oral microbial flora has been demonstrated in vitro (Bodet et al 2008, Koo et al 2006, Polak et al 2013, Yamanaka et al 2007). More specifically, cranberry polyphenol fraction significantly decreased the hydrophobicity of oral streptococci in a dose-dependent manner, suggesting that it may reduce bacterial adherence to the tooth surface (Yamanaka-Okada et al 2008). It has been shown in vitro to prevent biofilm formation and reduce adherence of *Candida albicans* and so may have a role in the prevention or treatment of oral candidiasis (Feldman et al 2012). The same research group also found the

synergy of cranberry proanthocyanidins and licochalcone A inhibited *Porphyromonas gingivalis* growth and biofilm formation, offering potential in the treatment and prevention of periodontal disease (Feldman & Grenier 2012).

### Prevention and treatment of *Helicobacter* infection

Cranberry inhibits the adhesion of *H. pylori* to human gastrointestinal cells in vitro (Matsushima et al 2008); however, very little clinical evidence is available to confirm significance in humans (Burger et al 2002). A multicentre, randomised controlled, double-blind trial found that regular intake of cranberry juice or a probiotic inhibited *H. pylori* in a trial of 295 children (Gotteland et al 2008). Another double-blind, randomised clinical study was carried out in 177 patients with *H. pylori* infection to investigate the possible additive effect of cranberry juice to triple therapy with omeprazole, amoxicillin and clarithromycin. Overall, there was no statistically significant difference; however, analysis by gender showed that the eradication rate was higher in females taking cranberry, but not in males (Shmueli et al 2007).

### Cardioprotection

Consumption of 250 mL cranberry juice daily is associated with decreasing markers of oxidative stress (Ruel et al 2008) and a significant increase in plasma high-density lipoprotein (HDL) cholesterol concentration (Ruel et al 2006). A small study of 30 abdominally obese, healthy, middle-aged men who consumed increasing doses of cranberry juice, up to 500 mL/day over 12 weeks, found a significant reduction in plasma matrix metalloproteinase-9, a substance which can accelerate atherosclerotic progression (Ruel et al 2009). The same authors recruited 35 overweight men in an RCT using an intervention of 500 mL/day of low-calorie cranberry juice or placebo juice. In a 4-week trial there was no significant difference in the cardiometabolic parameters but some benefit was noted in the augmentation index measuring arterial stiffness (Ruel et al 2013). These potential cardioprotective effects (which may be useful in reducing hypertension and atherosclerotic plaque vulnerability) need larger studies to confirm the findings. In addition, cranberry extract increases cholesterol uptake and the synthesis of low-density lipoprotein (LDL) receptors (Chu & Liu 2005), suggesting that accelerated cholesterol excretion may occur in vivo (McKay & Blumberg 2007). An oestrogen-deficient animal model found improvements in cholesterol parameters and endothelial function and suggested that cranberry juice consumption may be a useful food for postmenopausal women (Yung et al 2013).

### Type 2 diabetes

Some studies have suggested that consumption of a low-calorie cranberry juice is associated with a favourable glycaemic response (Wilson et al 2008a,

2008b). In a double-blind RCT, 60 males with type 2 diabetes, some of whom were taking oral hypoglycaemic drugs, were asked to drink one cup of cranberry juice daily for 12 weeks or placebo. A significant decrease in serum glucose and apolipoprotein B and a significant increase in serum apolipoprotein A-1 and paraoxonase 1 activity in the cranberry juice group resulted. The authors concluded that cranberry juice may assist in the management of type 2 diabetic males to reduce cardiovascular disease risk factors (Shidfar et al 2012). However, a randomised, placebo-controlled, double-blind study of 16 males and 14 females demonstrated that a 500 mg capsule of cranberry extract had a neutral effect on glycaemic control in type 2 diabetics who were on oral glucose-lowering medication. This same study found, however, that cranberry supplements are effective in reducing atherosclerotic cholesterol profiles, including LDL cholesterol and total cholesterol levels, as well as total:HDL cholesterol ratio in people with type 2 diabetes (Lee et al 2008). A study of 13 participants with type 2 diabetes, attempting to find palatable options for food choices, found that raw cranberries and sweetened dried cranberries containing less sugar and with polydextrose added as a bulking agent significantly improved glycaemic control when compared to sweetened dried cranberries alone or white bread (Wilson et al 2010).

### Prostate health

A trial of 42 men at risk of prostate disease (with negative prostate biopsy) with UTIs, elevated prostate-specific antigen (PSA) and chronic non-bacterial prostatitis were prescribed cranberry powder (1500 mg) for 6 months, with the control group receiving no treatment. The treatment group showed benefits with statistically significant improvement in International Prostate Symptom Score, quality of life, urination parameters and lower total PSA levels (Vidlar et al 2009, 2010). More research is required to confirm these promising findings.

### Urinary deodorising activity

Cranberry juice and solid-dose forms are popular in nursing homes as urinary deodorising agents in older adults with incontinence. Although no clinical study is available to confirm efficacy, numerous anecdotal reports suggest that it is useful when used on a regular basis.

### DOSAGE RANGE

#### Preventing UTI

According to clinical studies

- Adults: 120–400 mL daily or 400–500 mg capsule 1–3 times daily.
- Children: 15 mL/kg or up to 300 mL daily.

In practice, much higher doses are being used in an attempt to achieve quicker results (e.g. cranberry capsules or tablets 10,000 mg/day for prevention).

Recent studies reveal that cranberry extract regimens containing 72 mg of type-A proanthocyanidins produced significant bacterial anti-adhesion activity in human urine, therefore the dose of bioavailable type-A proanthocyanidins is important to consider (Gurley 2011).

### ADVERSE REACTIONS

At high doses (3 L or greater), gastrointestinal discomfort and diarrhoea can occur (Ulbricht & Basch 2005).

### SIGNIFICANT INTERACTIONS

The composition of bioactive components of cranberry juice can vary substantially and there is potential for drug interaction (Ngo et al 2009).

#### CYP3 A substrates

Whether cranberry juice inhibits the metabolism of drugs chiefly metabolised by CYP3A isoenzymes appears to be dependent on the concentration of three triterpenes (maslinic acid, corosolic acid and ursolic acid) in the juice (Kim et al 2011a). These have been identified as the important constituents responsible for inhibiting intestinal CYP3A and most likely explain the interbrand differences seen in various clinical and preclinical trials.

Caution — monitor patients taking high-strength cranberry preparations and medicines chiefly metabolised by CYP3A. Special care should be taken if the medicines have a narrow therapeutic index.

#### Proton pump inhibitors

Cranberry juice increases the absorption of vitamin B<sub>12</sub> when used concurrently with proton pump inhibitor medicines (Saltzman et al 1994) — beneficial interaction.

#### Warfarin

There are a small number of case reports suggesting that cranberry juice may increase the international normalised ratio (INR) in patients taking warfarin; however, clinical pharmacokinetic studies have found no clinically relevant interaction between cranberry and warfarin (Ansell et al 2008, Pham & Pham 2007), changes to the anticoagulant activity of warfarin or a significant effect on the activities of CYP2C9, CYP1A2 or CYP3A4 (Lilja et al 2007). Other clinical studies have found a daily glass of cranberry juice has no significant effect on INR compared to placebo (Ansell et al 2009) and two glasses of cranberry juice daily do not change prothrombin times (Mellen et al 2010). Ansell et al (2009) conducted an RCT with 30 patients on stable warfarin anticoagulation (international normalised ratio [INR], 1.7–3.3) and found 240 mL of CJ had no effect on plasma S- or R-warfarin plasma levels, thereby excluding a pharmacokinetic interaction.

An earlier study suggests that a pharmacodynamic interaction is more likely (Mohammed Abdul et al 2008).

### CONTRAINDICATIONS AND PRECAUTIONS

People with diabetes should take care when using commercially prepared cranberry juices because of the high sugar content.

If symptoms of UTI become more severe while cranberry is being administered, other treatments may be required and medical advice is recommended.

Cranberries contain oxalates and theoretically this could encourage kidney stone formation. People with a history of oxalate kidney stones should therefore limit their intake of cranberry juice.

### PREGNANCY USE

Women experience UTIs with greater frequency during pregnancy. A systematic review of the literature for evidence on the use, safety and pharmacology of cranberry, focusing on issues pertaining to pregnancy and lactation, found that there is no direct evidence of safety or harm to the mother or fetus as a result of consuming cranberry during pregnancy. A survey of 400 pregnant women did not uncover any adverse events when cranberry was regularly consumed. In lactation, the safety or harm of cranberry is unknown (Dugoua et al 2008). Recent trials have not shown evidence for benefit of cranberry juice in preventing UTIs in pregnant women so, although it has a good safety profile, its benefit may be limited.

#### Practice points/Patient counselling

- Cranberry preparations are widely used to prevent minor UTIs.
- Overall, clinical testing suggests that cranberry products, particularly the juice, with high concentrations of type-A proanthocyanidin may have some benefits for UTI prevention in certain populations.
- It may be more effective to take the cranberry products more than twice daily.
- Cranberry exerts bacteriostatic effects by reducing bacterial adhesion to host tissues.
- Overall, evidence suggests no significant alteration to urinary pH at doses less than 330 mL daily.
- Cranberry products have also been used to treat gout and to deodorise urine in people with incontinence.
- Preliminary research suggests a possible role in preventing conditions such as *Helicobacter pylori* infection, dental plaque formation and periodontal disease, managing glucose control in type 2 diabetes, prostate health and reducing cardiovascular risk among type 2 diabetics.
- Patients taking warfarin and regular cranberry intake should have their INR monitored.

In regard to the case reports, a systematic review concluded that the suggested drug interactions were questionable and that moderate consumption of cranberry juice was unlikely to affect coagulation (Zikria et al 2010).

Until the interaction can be better understood, patients taking warfarin with cranberry juice should continue to monitor their INR changes and signs and symptoms of bleeding.

## ! PATIENTS' FAQs

### *What will this herb do for me?*

Cranberry products, in particular the juice, with high concentrations of proanthocyanidin, may reduce the risk of developing UTI in some populations.

### *When will it start to work?*

Studies using 1–2 glasses of cranberry juice suggest that 4–8 weeks' continual use is required.

### *Are there any safety issues?*

If fever or pain exists or symptoms of UTI become more severe, seek medical advice. People taking warfarin together with cranberry should monitor their INR for changes. People taking concentrated cranberry juice should also check with their health-care provider if also taking medication to avoid drug interactions.

# Creatine

**HISTORICAL NOTE** Creatine was first discovered in 1832 when it was identified in meat. The word creatine is derived from the Greek *kreas* for flesh, similar to the word 'creature'. About 15 years after its discovery, the meat from foxes killed in the wild was found to have 10-fold more creatine than meat from domesticated ones, suggesting that physical exercise must influence the amount of creatine that accumulates in muscles. Early last century, orally consumed creatine was shown to be partly retained in the body and able to increase creatine content in muscles, leading some to suspect this could influence the performance of muscles. Nowadays, creatine supplementation enjoys enormous popularity as a sports supplement and is being recommended to elite athletes by respected sporting bodies such as the Australian Institute of Sport (AIS) (AIS 2009). There is also new research investigating its potential role in other areas such as central nervous system and metabolic disturbances, cancer, muscle wasting and low bone density.

## BACKGROUND AND RELEVANT PHARMACOKINETICS

Creatine is a naturally occurring nitrogenous compound produced in the human liver, pancreas and kidneys at a rate of 1–2 g daily. The amino acids glycine, arginine and methionine and the three enzymes L-arginine-glycine amidinotransferase, guanidinoacetate methyltransferase and methionine adenosyltransferase are required for its synthesis. Any drain on glycine metabolism from creatine synthesis is minimal; however the demand is more appreciable for methionine (via S-adenosylmethionine) and arginine (Brosnan et al 2011). Cellular creatine uptake is controlled by the specific transporter protein Creat-T, which moves creatine into the cell against a concentration gradient which is sodium- and chloride-dependent (Gualano et al 2012). It is stored primarily in skeletal muscle, where it is in dynamic equilibrium with phosphocreatine and is a precursor to adenosine triphosphate (ATP), the main source of energy for muscle activity and many other biological functions. Orally ingested creatine is absorbed from the small intestine, then distributed via creatine transporters around the body to muscles and nerves (Persky et al 2003). These transporters also serve as a clearance mechanism because of creatine 'trapping' by skeletal muscle. Creatine monohydrate is not degraded during normal digestion and nearly 99% of orally ingested creatine monohydrate is either taken up by muscle or excreted in urine after being converted to creatinine.

## CHEMICAL COMPONENTS

Creatine is chemically known as *N*-(aminoiminomethyl)-*N*-methyl glycine.

## FOOD SOURCES

Animal protein and fish. It has been estimated that approximately 1–5 g is ingested daily from the diet by omnivores (Gualano et al 2012).

## DEFICIENCY SIGNS AND SYMPTOMS

Several rare inborn errors of synthesis (L-arginine-glycine amidinotransferase deficiency and

guanidinoacetate methyltransferase deficiency) or in the creatine transporter result in a lack of creatine and phosphocreatine in the brain and severe mental retardation. Other symptoms and signs of milder deficiencies include involuntary extrapyramidal movements, speech disability, epilepsy, muscular hypotonia and weakness; in older patients, autism with self-injurious behaviour has also been reported (Beard & Braissant 2010, Wyss & Schulze 2002). While supplementation has been found to be beneficial in those with impaired creatine synthesis (Longo et al 2011, Ndika et al 2012), it does not improve cerebral symptoms in those with defective transport (Valayannopoulos et al 2012, van de Kamp et al 2012).

People involved in intense physical activity, vegetarians and those with muscle diseases may have lower residual muscle creatine levels than others.

## MAIN ACTIONS

### Energy production

Although the exact mechanism is unclear, much is known about the biochemistry of endogenous creatine. In skeletal muscle tissue, it is used for the production of phosphocreatine, an important form of high-energy phosphate. Phosphocreatine is broken down into phosphate and creatine during high-intensity exercise lasting 15–30 s, in a reaction catalysed by creatine kinase. During the process, energy is released and is used to regenerate ATP, the primary source of energy. Creatine is involved in an energy transport system (the creatine-phosphocreatine shuttle), transferring energy from the mitochondria to the cytosol, linking sites of ATP generation to those of consumption (Sahlin & Harris 2011).

### Supplemental creatine

Oral supplementation with creatine has been shown to increase phosphocreatine levels in muscles and, as such, has been described as 'fuelling up' natural energy stores. Increased phosphocreatine creatine stores lead to faster regeneration of ATP, thereby

making more energy immediately available to muscles. This is particularly important during high-intensity physical activity where rapid energy production is required. Theoretically, increased free creatine allows depleted stores to replenish more quickly, thus shortening recovery times during repeated bouts of intense exercise. Increased muscle creatine may also buffer the lactic acid produced during exercise, delaying muscle fatigue and soreness. Another possible benefit of creatine supplementation is muscle glycogen-sparing during high-intensity intermittent exercise (Roschel et al 2010) and increased muscle glycogen accumulation (Hickner et al 2010), although not all evidence supports this theory (Rico-Sanz et al 2008). It has been estimated that short-term supplementation over 5–7 days with a daily dose of 20 g creatine increases total creatine content by 10–30% and phosphocreatine stores by 10–40% (Kreider 2003).

Overall, the response to creatine supplementation is highly variable and may be influenced by an individual's pretreatment levels, so that people with low levels, such as vegetarians, may respond to a greater extent than those with higher starting levels (AIS 2009).

### Neuroprotective

Creatine supplementation has displayed neuroprotective effects in several animal models of neurological diseases, such as Huntington's disease, Parkinson's disease (PD) or motor neuron disease (also known as amyotrophic lateral sclerosis or ALS) (Andreassen et al 2001, Dedeoglu et al 2003, Ferrante et al 2000, Wyss & Schulze 2002). The National Institute of Neurological Disorders and Stroke (NINDS) is currently conducting a large double-blind, placebo-controlled, phase III study involving 1720 people with early-stage PD to evaluate the effects of long-term creatine supplementation.

Creatine may exhibit antiaging benefits according to an in vivo study, where creatine-fed mice lived longer and exhibited improvements in neurobehavioural tests. Further, creatine significantly lowered the amounts of ageing pigment, lipofuscin, and upregulated various genes involved in neuroprotection and learning (Bender et al 2008). Preliminary data from a randomised, comparative, open study have shown a neuroprotective effect in cases of children with traumatic brain injury. Treatment with creatine improved a number of parameters, including duration of posttraumatic amnesia, length of recovery time, social/behaviour and cognitive function (Sakellaris et al 2006).

A number of theories of a possible mechanism for neuroprotection have been put forward. One theory proposes that creatine exerts antioxidant activity and mitochondrial stabilising effects, two mechanisms of benefit in neurodegenerative diseases, which are characterised by mitochondrial dysfunction and oxidative damage (Shefner et al 2004). Other protective actions suggested by in vitro and in vivo studies include attenuation of energy

depletion (Shen & Goldberg 2012), reducing damage to the brain induced by ischaemia, apoptosis, excitotoxicity (Genius et al 2012, Klopstock et al 2011, Perasso et al 2013) and ammonia toxicity (Braissant 2010). Oral doses of creatine have been shown to pass the blood–brain barrier (Andres et al 2008); however this occurs in relatively small amounts, with most creatine supplied by endogenous synthesis within the central nervous system (Braissant 2012). Interestingly, results from a recent in vivo study suggest that creatine supplementation may also play a protective role in neurodevelopment (Sartini et al 2012).

### Glycaemic control

The exact mechanisms of action for creatine on blood glucose regulation have not been well elucidated (Rocij et al 2011); however, it appears to modulate the expression of proteins and genes involved in insulin sensitivity and glycaemic control. These include protein kinase B, myocyte enhancer factor-2, insulin-like growth factor-1 (Safdar et al 2008) and AMPK- $\alpha$  protein (Alves et al 2012), which increases GLUT-4 translocation. In vitro and in vivo results also suggest the possibility that creatine increases insulin release (Rocij et al 2007, 2011).

### Mood

Antidepressant activity has been demonstrated in vivo using several different animal models (Allen et al 2010, 2012, Cunha et al 2012). Creatine appears to interact with several neurotransmitter receptors, including dopamine (D<sub>1</sub> and D<sub>2</sub>) (Cunha et al 2012), serotonin (Cunha et al 2013) and N-methyl-D-aspartate (Royes et al 2008). Interestingly, this action was observed only in females (Allen et al 2012).

### Anticancer

The anticancer effect of creatine had been demonstrated in experimental models and recent literature has reported low creatine content in several types of malignant cells. There are several reports of the anticancer effect of creatine and cyclocreatine and different theories, such as inhibition of glycolysis, generation of acidosis, had been put forward, together with an apoptosis-independent pathway. More recently, research with animal models suggests that tumour tissue supplemented with creatine might sequester significant amounts of ATP necessary for any growth-oriented cells such as malignant cells, thereby essentially starving the cells of fuel (Patra et al 2012).

### OTHER ACTIONS

Creatine has a direct and indirect antioxidant effect in the cell (Gualano et al 2012). It has been shown to reduce infarct volume after stroke by 40% in vivo. By using magnetic resonance imaging, the study found augmented cerebral blood flow after stroke in mice treated with creatine (Prass et al

2006). Creatine monohydrate exhibited a positive influence on bone mineral density in vivo (Antolic et al 2007) and affected bone mineral resorption clinically.

### CLINICAL USE

Creatine supplementation has been primarily used in sports where it is an extremely popular supplement. In the United States alone, creatine-containing dietary supplements make up a large portion of the estimated \$2.7 billion in annual sales of sports nutrition supplements (Jager et al 2011). Beyond its use in sports, there is growing investigation of its potential use in a variety of conditions such as myopathies, neurodegenerative, neuromuscular, neurometabolic and inflammatory diseases, diabetes and cancer.

Creatine monohydrate is the form generally used and tested in clinical trials; however it has very poor solubility. In practice, this is available in different forms, which differ according to particle size (granular, powder and micronised), with the belief that smaller particles are more fully absorbed and cause less gastric distress. Other forms of creatine are appearing and include creatine anhydrous, buffered creatine monohydrate, various creatine salts — pyruvate, citrate, malate, phosphate and orotate — as well as creatine ethyl esters and creatine gluconate. An effervescent form has also been produced (Jager et al 2011). The newer forms claim to have increased solubility and bioavailability, which may reduce some adverse effects (Gufford et al 2010); however, not all studies have shown this to be the case (Jagim et al 2012). Some manufacturers have started putting several different creatine forms together in the one supplement in an attempt to ensure sufficient creatine enters the target tissues and, possibly, as a means of extending the release of creatine into the system over a longer period of time.

According to in vivo research, creatine monohydrate bioavailability can be improved when taken together with insulin-stimulating ingredients such as high amounts of glucose or protein (Jager et al 2011). It is suspected that creatine uptake could be mediated in part by glucose and insulin.

### Ergogenic aid

Creatine supplementation has become one of the most widely used supplements taken by athletes and is touted by some as the only truly effective ergogenic aid, besides carbohydrate loading. It is used by athletes engaged in sprint disciplines (e.g. 100-m run or 50-m swim), strength disciplines (e.g. weight lifting) or high-intensity, repetitive-burst exercise (e.g. tennis, hockey, football, soccer) separated by short bouts of recovery.

Several hundred published studies have been conducted over the last few decades involving a variety of different athletes doing different physical tasks to clarify what types of physical activity may be improved, how and to what extent with oral creatine supplementation. In general, the majority

of studies with exercise performance outcomes support an ergogenic effect of creatine (Gualano et al 2012). Overall, studies indicate that creatine supplementation (about 20 g/day for 5 days or about 2 g/day for 30 days) results in increased skeletal muscle creatine and phosphocreatine concentrations by approximately 15–40%, enhances anaerobic exercise capacity and increases training volume, leading to potentially greater gains in strength, power and muscle mass (Jager et al 2011, Rawson & Venezia 2011). Studies have also been conducted with older adults in an attempt to determine whether creatine has benefits in this population and the available evidence appears to support a potential additive or synergistic effect of combining creatine supplementation with resistance training for improving lean mass and muscle strength (Buford et al 2013).

Creatine supplementation increases muscle fibre hypertrophy, myosin heavy-chain expression and swelling of myocytes, which may in turn affect carbohydrate and protein metabolism. Supplementation also increases acute weight-lifting performance and training volume, which may allow for greater overload and adaptation to training. Creatine significantly increases phosphocreatine resynthesis after intense muscle contractions and it is this improvement in resynthesis rates which is thought to contribute to positive improvements in body composition, muscle strength and exercise performance reported when combining creatine supplementation with exercise training (Buford et al 2013).

According to a double-blind, placebo study, creatine in combination with physical training increases fibre growth by increasing satellite cell number and myonuclei concentration. Researchers took muscle biopsies at various intervals during 16 weeks of heavy resistance training, where participants were given 6 g of creatine monohydrate four times a day for the loading phase of 7 days and then once a day (Olsen et al 2006). More recently identified effects of creatine on skeletal muscle hypertrophy include increased myogenic transcription factors (Saremi et al 2010), increased insulin-like growth factor-1 (Burke et al 2008), increased gene expression for collagen and glucose 4 transporter (Deldicque et al 2008) and increased neuromuscular function. In a double-blind randomised controlled trial (RCT), 16 men receiving 20 g of creatine for 5 days demonstrated enhanced neuromuscular function of the elbow flexors in both electrically induced and voluntary contractions during short-duration intermittent exercises, but not in endurance performance (Bazzucchi et al 2009).

### Cycling creatine loading

Due to the fact that human muscle appears to have an upper limit of creatine storage of 150–160 mmol/kg of dry muscle, which, once achieved with diet or supplementation, cannot be exceeded, creatine supplementation is likely to produce larger effects in subjects who ingest lower creatine in diet (e.g.

vegetarians) and consequently display lower tissue creatine than people on long-term high dietary creatine intakes (Gualano et al 2012). The fact that muscle storage is finite provides some rationale for undertaking creatine loading in cycles, thereby enabling muscle levels to reach maximal storage after a number of weeks, followed by a period of withdrawal when creatine supplementation stops, followed by another reloading phase after several weeks. When combined with a continuous training program, this could theoretically lead to even greater performance gains.

### Who will respond?

The observation that not every athlete responds to creatine supplementation with improved strength, performance and recovery has prompted investigation to identify the key features of responders. One study identified that responders had the lowest initial levels of muscle creatine, greatest percentage of type 2 fibres and greatest preload muscle fibre cross-sectional area and fat-free mass in comparison to non-responders (Syrotuik & Bell 2004). Other factors that are likely to influence an individual's response to creatine include training status, diet, age and the bioavailability of the creatine supplement being used. One review on the use of creatine in the elderly suggested that timing of creatine intake may be important, and if creatine is taken closely before or after the resistance training session it is likely to be more effective (Candow & Chilibeck 2008). Benefits would therefore be expected to be greater in those with the lower creatine levels at baseline, such as vegetarians. Not taking these factors into account may partly explain the inconsistent results obtained in RCTs.

### Short-duration, high-intensity exercise

Studies have been conducted in a variety of athletes, such as sprint cyclists, soccer players and sprint swimmers, and generally have used a dose of 20 g daily taken for at least 5 days. Most, but not all, controlled studies have shown that supplementation improves performance and delays muscle fatigue (Balsom et al 1995, Becque et al 2000, Burke et al 1996, Cox et al 2002, Finn et al 2001, Gilliam et al 2000, Kreider et al 1998, Maganaris & Maughan 1998, Mujika & Padilla 1997, Mujika et al 2000, Rawson et al 2011, Tamopolsky & MacLennan 2000, Williams & Branch 1998).

A meta-analysis of placebo-controlled RCTs investigating the effects of creatine on swim performance concluded that the majority of studies report an ergogenic effect, particularly in those activities lasting less than 30 s (Branch 2003). A later 2006 review reported that evidence did not suggest benefits for single bouts of swimming (distance 25–400 m) but did show improved performance for repeated bouts (2–15 bouts) and distances 25–100 m (Hopwood et al 2006). In regard to cycling, creatine supplementation appears most effective at improving exercise performance during repeated

bouts of brief (30 s) high-intensity exercise (Branch 2003). The few studies conducted in athletic sprint running suggest positive ergogenic effects (Gualano et al 2012).

Since the Hopwood et al (2006) and Branch reviews (2003), many other RCTs have been published, generally supporting the use of creatine supplementation in physical activity requiring sprint-like exertion.

For example, Juhasz et al (2009) reported creatine supplementation (20 g/day for 5 days) in elite young swimmers ( $n = 16$  males) reduced their swim time by approximately 1.8 s in two successive 100-m swims. This small change could make the difference between winning a medal at a major competition or not. In a study examining gender differences in response to creatine citrate (20 g/day), males (but not females) receiving 20 g creatine citrate for 4 days had a 23% greater anaerobic energy reserve during running sprints (Fukuda et al 2010). One small study with 10 cyclists found improved sprint cycling in the heat with a dose of 5 g given four times a day for 6 days (Wright et al 2007). In another study, 42 college-aged men undergoing high-intensity interval training (five 2-minute exercise bouts on a cycle ergometer) and receiving creatine (10 g/day) had greater endurance performance compared to those receiving the placebo (Kendall et al 2009). Similarly, Oliver et al (2013) found 5 g creatine (plus 15 g glucose) daily improved time to fatigue and reduced lactate during incremental cycling exercise following 6 days of supplementation.

The effects of creatine on jump height performance have recently been examined in two studies. In a study on 12 elite volleyball players receiving 4 weeks of creatine or placebo supplementation (loading dose of 20 g/day for 4 days, then 10 g/day on days 5–6, followed by 5 g/day for the remainder of the trial) in a double-blind RCT, the treatment group demonstrated improved repeated jump height capability but did not influence muscular fatigue and the decline in repeated performance (Lamontagne-Lacasse et al 2011). The effect of creatine compared to carbohydrate in maintaining performance during repeated bouts of high-intensity jumping exercises was investigated in another RCT. Active males ( $n = 60$ ) performed two sets of jump height tests (10 jumps over 60 s) separated by 5 days. The high-dose carbohydrate (containing 250 kcal carbohydrate drink) and the creatine group (creatine monohydrate 25 g supplement) had similar effects on increasing jump height compared to the placebo and low-carbohydrate groups (250 kcal carbohydrate drink). As the creatine group increased weight ( $1.52 \pm 0.89$  kg), the authors suggested that high-dose carbohydrates may be preferred by weight-conscious athletes (Koenig et al 2008).

While low-dose creatine supplementation does not usually have an ergogenic activity, a recent double-blind RCT in healthy young adult subjects found low-dose creatine (0.03 g/kg — approximately

2.3 g) for 6 weeks was beneficial in reducing resistance to fatigue during repeated bouts of high-intensity contractions compared to placebo (Rawson et al 2011). Similarly, a trial involving 18 rugby players during an 8-week rugby season of Rugby Union football found that creatine, at a relatively low dose (0.1 g/kg/day), increased muscular endurance without detrimentally affecting body composition or aerobic endurance (Chilibeck et al 2007).

While many studies show benefits with creatine supplementation, there are several that have not, such as a placebo-controlled RCT with 17 ice hockey players given 0.3 g/kg/day of creatine for 5 days (Cornish et al 2006). Also a double-blind study found no significant improvement on multiple sprint performance, fatigue or blood lactate concentration when testing creatine use with 42 physically active men who were given 5 g four times a day for 5 days (Glaister et al 2006). An RCT found lower-dose creatine monohydrate supplementation (3 g/day for 28 days) failed to improve sprint cycling performance in 12 subjects at the end of a 2-hour endurance cycle; however submaximal oxygen consumption near the end of the 2-hour ride was decreased by approximately 10% by creatine supplementation ( $P < 0.05$ ) (Hickner et al 2010). Another study examining the effects in sprint cycling performance failed to demonstrate a significant improvement on fatigue threshold in college men after receiving creatine loading for 5 days (four doses of 5 g dicreatine citrate plus 10 g fructose powder) (Walter et al 2008). A study with 36 tennis players found no significant benefits of creatine supplementation for 6 days on repetitive sprint power or strength of the upper and lower extremities (Pluim et al 2006). Similarly, a small recent study in males competing in judo failed to find significant benefit in anaerobic capacity or aerobic power (Sterkowicz et al 2012).

A review by Gualano et al (2012) provides further reading for those wanting greater details about creatine supplementation in specific sports.

### Lean body mass

Creatine increases exercise-related gains in lean body mass (Aguilar 2013, Chrusch et al 2001, Jowko et al 2001, Stone et al 1999). In 2009, a double-blind RCT examining the effects of creatine in men with HIV undergoing three weekly training sessions demonstrated a greater increase in lean muscle mass, but no difference in muscle strength compared to the placebo group. The dose used in this study was 20 g creatine monohydrate capsules daily for 5 days followed by 4.8 g daily for the remainder of the 14-week trial (Sakkas et al 2009).

### Enhanced power and/or strength

Many studies show that creatine supplementation in conjunction with resistance training augments muscle strength and size, although the effect is not consistent for everybody (Gualano et al 2012, Spriet

& Gibala 2004, Volek & Rawson 2004, Zungia et al 2012). A 2003 review of 22 studies estimated that the average increase in muscle strength following creatine supplementation as an adjunct to resistance training was 8% greater than the placebo (20% vs 12%) (Rawson & Volek 2003). Similarly, the average increase in weight-lifting performance (maximal repetitions at a given percentage of maximal strength) following creatine supplementation plus resistance training was 14% greater than the placebo (26% vs 12%).

Numerous recent studies have further investigated the effects of different types of creatine on various aspects of muscle performance, which have added to the understanding of its potential benefits. It appears that effects take at least 5 days to develop, often in combination with resistance training, different forms of creatine may have different effects and combining creatine with other substances may also change an individual's response.

Law et al (2009) examined the effect of 20 g creatine supplementation versus placebo in 17 trained men undergoing resistance training. Muscle performance was tested prior to supplementation and again after 2 and 5 days of supplementation. While creatine increased muscle strength and power compared to training alone, benefits were only seen after the 5 days of supplementation. Candow et al studied the effects of the timing and frequency of creatine supplement on muscle mass and muscle strength in a 6-week RCT of university students (21–28 years). The treatment groups received either creatine 0.15 g/kg creatine twice a week or 0.10 g/kg creatine three times a week on days they underwent resistance training. Compared to the control groups receiving the same dose and frequency of placebo, muscle thickness of the elbow flexors increased, and muscle strength increased in the men but not the women. There was no difference in effects between the frequency of supplementation (Candow et al 2011).

In a double-blind RCT, the effects of two different types of creatine were compared on performance of high-intensity intermittent hand grip exercises. Compared to placebo, both creatine citrate and creatine pyruvate (5 g/day for 28 days) increased mean power initially; however after numerous repetitions only creatine pyruvate was effective (Jager et al 2008), suggesting a superior effect on endurance.

Creatine monohydrate was compared with creatine ethyl ester in an RCT of 30 young men undergoing resistance training. A loading dose of approximately 20 g/day for 5 days followed by 5 g/day for 42 days of creatine ethyl ester, creatine monohydrate or placebo were compared. Neither creatine group was found to significantly improve muscle strength or performance compared to placebo, and furthermore the creatine ethyl ester supplementation significantly increased serum creatinine levels while not increasing serum or total muscle creatine content, suggesting it may be

degraded within the gastrointestinal tract after ingestion (Spillane et al 2009).

While many studies show some positive results, not all studies have shown benefits of adding creatine supplementation to a training protocol on either strength or lean body mass. It appears that some of these studies suffer from using insufficient doses or not using the correct dosage for an appropriate period of time (Carter et al 2005, Eckerson et al 2008, Ferguson & Syrotuik 2006).

#### IN COMBINATION

Combining creatine and sodium bicarbonate supplementation increased peak and mean power and had the greatest attenuation of decline in relative peak power over six repeated sprints. These data suggest that combining these two supplements may be advantageous for athletes participating in high-intensity, intermittent exercise. This crossover study utilised supplementation for 2 days followed by a 3-week washout and involved 13 trained men assessed during six 10-s repeated Wingate sprint tests on a cycle ergometer with a 60-s rest period between each sprint (Barber 2013).

One study examined the effect of creatine combined with glycerol on running economy in endurance. The supplement, taken for 7 days, was beneficial in attenuating the cardiovascular strain and thermal effects of a 30-min run in hot conditions (35°C), and, while it did increase body mass, it did not negatively affect running economy (Beis 2011).

The combined effects of supplementation with creatine, conjugated linoleic acid and whey protein for 5 weeks in addition to strength training resulted in a greater increase in muscle strength and lean mass compared to either creatine plus placebo or placebo alone (Cornish et al 2009). Another study examined the additive effects of creatine combined with other nutrients on muscle strength and body composition. This randomised double-blind study in 24 resistance-trained men aged 18–35 years compared the effects of creatine monohydrate (loading dose of 18 g/day for 5 days followed by 4.5 g/day for 23 days) combined with either 2 g/day of corn starch or D-pinitol for 5 days followed by 0.5 g/day for the remaining 23 days. While both groups increased upper- and lower-body strength and body composition, the creatine-only group had greater improvement in increases in lean mass and fat-free mass, suggesting that the addition of pinitol may negate some of the benefits of creatine on body composition (Kirkcaldy et al 2009).

#### Creatine without resistance training

The effects of creatine on muscle strength in untrained young adults without resistance training have recently been studied in a double-blind RCT. The treatment group received 5 g polyethylene glycosylated creatine daily for 28 days. There was a significant increase in upper-body strength (measured by one-repetition maximum bench press) but not lower-body strength or muscular power in the treatment group ( $n = 10$ ) compared to the placebo group ( $n = 12$ ) (Camic et al 2010), suggesting some

benefit to muscle strength may occur even without exercise. Furthermore, the effect of creatine on muscle mass and strength on immobilised limbs has been investigated. In a single-blind crossover study, 7 men aged 18–25 years received placebo on days 1–7 and creatine 20 g/day on days 15–21. An upper limb was immobilised in a cast during the placebo supplementation period, removed between days 8–14 and then the opposite limb was immobilised during creatine treatment. Compared to the placebo, the creatine supplementation better maintained lean muscle mass and muscle strength during immobilisation (Johnston et al 2009).

#### Physical performance benefits in the elderly

Ageing accompanied by reduced physical activity results in decreased muscle creatine, muscle mass, bone density and strength, which may be addressed by increasing creatine intake (Rawson & Venezia 2011). Short-term creatine supplementation in older adults, independently of physical exercise training, has shown increased muscle strength and performance of activities of daily living, and enhanced fatigue resistance and body mass in the majority of studies. When supplementation is combined with resistance training these benefits are amplified.

Several RCTs show benefits in both male and female older adults (Aguar 2013, Brose et al 2003, Candow & Chilibeck 2008, Chrusch et al 2001, Gotshalk et al 2008, Kreider et al 1998, Stout et al 2007). Study volunteers have included people aged over 70 years, and demonstrated benefits in lean tissue mass, leg strength, endurance and average power greater than placebo (Chrusch et al 2001), increase in total and fat-free mass, and gains in several indices of isometric muscle strength (Brose et al 2003), increases in grip strength, muscle endurance and physical working capacity at fatigue threshold (Stout et al 2007), muscle strength and function compared to placebo (Aguar 2013, Gotshalk et al 2008). Doses used have ranged from 5 g to 20 g daily for at least 5 days.

In contrast, a 7-day study of elderly women produced mixed results, as creatine supplementation (dosage 0.3 g/kg/day) did not show any benefits for endurance but did help volunteers to perform lower-body function exercises that involved quick movements (Canete et al 2006). No additional benefits were found in two studies in which creatine was given either alone or combined with protein powder (given on training days three times a week) on muscle strength or muscle mass in men aged 48–72 undergoing resistance training (Bemden et al 2010, Eliot et al 2008).

#### Improve recovery from exercise damage

Several studies have recently found positive effects in creatine in attenuating exercise-induced muscle injury, suggesting a therapeutic role in injured athletes. A small study of triathletes ( $n = 8$ ) receiving creatine (20 g/day plus 50 g maltodextrin in two doses) for 5 days prior to competition had decreased

markers of muscle damage (creatine kinase, lactate dehydrogenase and aldolase, glutamic oxaloacetic acid transaminase and glutamic pyruvic acid transaminase) following the IronMan competition, compared to the placebo group (Bassit 2010). In the second study, creatine loading in young males for 5 days prior to an eccentric resistance training session (0.3 g/day kg body weight) and postmaintenance for 14 days (0.1 g/day kg body weight) attenuated the loss of strength and muscle damage (measured by creatine kinase activity) compared to the placebo group (Cooke et al 2009). Positive results were also observed in a study in which 20 g/day creatine monohydrate for 6 days given to young men reduced markers of muscle damage, muscle soreness and a smaller reduction in range of movement after repeated bouts of resistance exercise compared to placebo (Veggi et al 2013). Possible reasons for these effects are the pre-exercise creatine enhancing the calcium-buffering capacity of the muscle, and postexercise creatine enhancing the regenerative response of the muscle (Cooke et al 2009).

Another mechanism of creatine which may protect muscles is its role as an antioxidant (Barros et al 2012, Coco & Perciavalle 2012, Deminice & Jordao 2012, Sestili et al 2011). In a study by Rahimi (2011) in resistance-trained males ( $n = 27$ ), 7 days of creatine supplementation (5 g four times daily) reduced the oxidation of DNA and lipid peroxidation following a single bout of strenuous resistance training. Creatine has direct and indirect antioxidant activity in the cell; however this has not always been observed clinically (Percario et al 2012, Silva et al 2013).

#### **Clinical note — The Australian Institute of Sport Supplement Program**

The AIS is world-renowned for its professionalism and high-quality training programs. In 2000, a project called the AIS Sports Supplement Program (AIS 2009) was developed to ensure that athletes use supplements correctly and confidently, and receive ‘cutting-edge’ advice on nutritional practices. In order to streamline the information available, a panel of experts categorised some of the most popular sports supplements into various classes to clarify which are approved or recommended and which are directly banned by international doping rules. Some of the approved supplements recommended for use include creatine, antioxidants (vitamins C and E), multivitamins, iron, calcium supplements and sports drinks.

### **Heart failure**

Muscle fatigue due to loss of skeletal muscle mass and strength, decreased oxidative capacity and other abnormalities of muscle metabolism have been associated with heart failure.

As a result, creatine supplementation has been suggested as a possible therapeutic agent in this condition and current RCT evidence suggests possible improvements in dyspnoea and reducing dysrhythmia but no change in ejection fraction.

This was most recently reported in a 2012 Cochrane systematic review which analysed the results of RCTs ( $n = 1474$ ) which examined the effectiveness of creatine supplementation and its analogues (creatine phosphate — orally, intravenously or intramuscularly; and phosphocreatinine) in adults with heart failure (six RCTs,  $n = 1226$ ), acute myocardial infarction (four RCTs,  $n = 220$ ) and one RCT in ischaemic heart disease ( $n = 28$ ). The duration of treatment ranged from acute 2-hour intravenous to 6 months. In regard to heart failure, no improvement was reported for ejection fraction; however there was improvement in reducing dysrhythmia and dyspnoea. There was insufficient evidence to determine which form of creatine, dose, route of administration and duration of therapy is most effective (Horjus et al 2011).

Other studies have sought to identify whether creatine has any other benefits in people with congestive heart failure (CHF). Three double-blind RCTs involving people with CHF have found improvements in muscle strength compared to placebo when creatine was taken for at least 5 days (Andrews et al 1998, Gordon et al 1995, Kuethe et al 2006). More recently, low-dose creatine (5 g/day) taken for 6 months by volunteers ( $n = 33$ ) with CHF showed no significant improvement in functional capacity over placebo, as assessed by cardiopulmonary exercise test and the six-minute walk test in a double-blind study (Carvalho et al 2012).

### **Fibromyalgia**

Theoretically, creatine supplementation may have value in fibromyalgia as a means of reducing muscle fatigue and/or improving strength. Two studies suggest it may be worth considering in this population.

An 8-week open-label study testing creatine monohydrate (3 g/day for 3 weeks then 5 g/day until 8 weeks) showed improvements in the symptoms of fibromyalgia measured by the Fibromyalgia Impact Questionnaire, sleep quality and pain levels. In addition, patients’ impression of disease burden had reduced at 8 weeks and again at the 4-week posttreatment mark (Leader et al 2009).

More recently, a 16-week, double-blind RCT involving 28 women showed that creatine monohydrate (20 g for 5 days in four equal doses, followed by 5 g/day for the remainder of the study) increased phosphoryl creatine muscle content and improved lower- and upper-body muscle function and strength (measured by leg-press and chest-press exercises) compared to placebo. However, no differences were seen in other outcomes measured, including aerobic conditioning, cognitive function, quality of sleep and quality of life (Alves et al 2012).

## Neurological degenerative diseases

Over the past few years, a considerable body of scientific evidence has given support to the idea that creatine supplementation may alleviate some of the clinical symptoms of neurological disease and delay disease progression (Wyss & Schulze 2002). Unfortunately, neuroprotective effects demonstrated in animal models have not been consistently demonstrated in clinical trials. This may be not only because the pathophysiological processes of neurodegenerative disease are different in humans, but also due to differences in dosage and timing of creatine supplementation relative to disease onset (Klopstock et al 2011). Traditionally, the existing studies may also have been underpowered and limited the detection of statistically significant effects (Klopstock et al 2011) and used insufficient doses, as some animal studies have used doses 10 times higher than in clinical trials (Andres et al 2008).

Theoretically, a combination of creatine and CoQ10 may have added benefits in neurological diseases as they both work in the mitochondria and are involved in ATP production, together with exerting antioxidant effects. Although thus far only studied in animal models of PD and Huntington's disease, several measurements of neuroprotection were enhanced, and motor performance and survival were improved (Yang et al 2009).

### Huntington's disease

A number of studies conducted with experimental animal models of Huntington's disease have identified a possible role for creatine supplementation (Andreassen et al 2001, Dedeoglu et al 2003, Ferrante et al 2000). Creatine was shown to increase survival, delay onset of symptoms and exert neuroprotective effects *in vivo*. A double-blind, placebo RCT with 64 Huntington's disease patients given creatine at a dose of 8 g/day for 16 weeks found that creatine concentrations in the brain and serum increased with supplementation and reduced oxidative injury to DNA (Hersch et al 2006).

### Parkinson's disease

Decreased muscle mass and strength are features of PD. Creatine monohydrate combined with resistance training showed improved muscular endurance and improvements in upper-body strength. This double-blind, placebo RCT had 20 patients given 20 g/day of creatine for 5 days and then 5 g/day for 12 weeks (Hass et al 2007). Another placebo RCT followed 60 patients for a 2-year period and found that creatine had no overall effect on Unified Parkinson's Disease Rating Scale scores (covering behaviour and mood, daily living activities, motor skills and complications of therapy; patients taking creatine did experience elevated mood and required smaller increases in dopamine medication) (Bender et al 2006). In a randomised, blinded phase II clinical trial, creatine showed a delay in the progression of PD by 50% compared to the placebo group (NINDS NET-PD Investigators 2006). In a

follow-up study 18 months later, the safety of creatine supplementation (10 g/day) was confirmed, as it did not cause any safety concerns or interactions with the PD therapy (minocycline 200 mg/day) in subjects with early PD (NINDS NET-PD Investigators 2008). It is currently in phase III trials (Elm et al 2012).

Interestingly, the effects of creatine on L-dopa-induced dyskinesia, which occurs with long-term treatment in PD patients, were investigated in an animal model. Rats which had a 6-hydroxydopamine lesion were fed creatine for 1 month prior to receiving 21 days of L-dopa medication. Treated rats had significantly fewer abnormal involuntary movements without any worsening of the disease, suggesting that creatine may attenuate the motor complications associated with L-dopa treatment (Valastro et al 2009).

### Amyotrophic lateral sclerosis/motor neuron disease (MND)

Despite the positive results from animal model MND, human trials have produced mixed results (Groeneveld et al 2003, Mazzini et al 2001, Rosenfeld et al 2008, Shefner et al 2004). A systematic review of three RCTs conducted in MND patients ( $n = 386$ ) found that low-dose creatine supplementation of 5–10 g/day did not improve disease survival or MND progression. There was a slight trend towards creatine worsening breathing ability (measured by forced vital capacity); however the authors suggested this may have been a misleading statistical variability (Pastula & Bedlack 2010). One possible explanation for this finding is the dose used. In a phase I open-label study on the pharmacokinetics of creatine in 6 patients with MND, the effects of escalating doses of 5 g, 10 g and 15 g twice daily (taken for 1 week at each dose) were evaluated via changes in blood levels of creatine and brain metabolites measured by proton magnetic resonance spectroscopy. Plasma levels of creatine increased in a dose-dependent manner, with the magnetic resonance spectroscopy results suggesting it crosses the blood-brain barrier at the highest dose, increasing brain creatine levels. The highest dose was also found to reduce brain glutamate concentrations by 17%, which may be of significance as glutamate-mediated injury to motor neurons is thought to occur in MND (Atassi et al 2010).

### Charcot-Marie-Tooth disease (CMT)

Muscle function improved when creatine and resistance training were undertaken by people with CMT, according to a randomised, placebo-controlled trial of 18 people. Over the 12-week period, combined treatment also resulted in improved muscle myosin heavy-chain composition (Smith et al 2006).

### Multiple sclerosis (MS)

In a small double-blind, crossover trial, with a 3-week wash-out period, in multiple sclerosis

subjects ( $n = 11$ ) given either creatine (5 g four times a day for a week; 2.5 g twice a day for the second week) or placebo for two 14-day periods, creatine did not improve muscle capacity or habitual fatigue (Malin et al 2008).

### Cervical-level spinal cord injury

According to a randomised, double-blind, placebo-controlled crossover trial, creatine supplementation enhances upper-extremity work capacity in subjects with complete cervical-level spinal cord injury (Jacobs et al 2002).

### Bone mineral density

The combination of high energy requirement for bone and cartilage repair and development and the positive role muscle plays on bone mass makes creatine a possible therapy for bone disorders such as osteoporosis and osteoarthritis.

According to a double-blind, placebo-controlled study with 29 older men, creatine (0.3 g/kg for 5 days and 0.07 g/kg thereafter) administered for 12 weeks while undergoing resistance training significantly increased bone density. Creatine supplementation had an additional benefit for regionalised bone mineral content where there was a change in lean tissue mass. It was suggested that the effect may be due to greater tension on the bone due to an increase in muscle mass in the creatine participants (Chilibeck et al 2005). Additionally, creatine supplementation 0.1 g/kg for 3 days/week (for 10 weeks) in healthy older males undergoing supervised resistance training was found to reduce bone resorption (measured by cross-linked *N*-telopeptides of type I collagen) by 27% (Candow & Chilibeck 2008).

### Osteoarthritis

Creatine supplementation (20 g/day for 1 week and then 5 g daily thereafter) in addition to strengthening exercises for 3 months improved quality of life, physical function, stiffness and lower-limb lean mass compared to placebo in a double-blind RCT of 24 postmenopausal women with knee osteoarthritis. The authors attributed the positive outcomes to creatine's effect on strength training and possibly increased cartilage metabolism, as a direct role in cartilage repair is unlikely to occur within 3 months (Neves et al 2011a).

### Muscular dystrophy

A number of muscle diseases are associated with a decrease in intracellular creatine concentration, which could theoretically contribute to muscle weakness and degeneration of muscle tissue (Wyss et al 1998).

An updated 2011 systematic review of literature looking at creatine supplementation in muscle diseases evaluated 14 RCTs ( $n = 364$ ) and found that both short- and medium-term creatine supplementation improved muscular strength activities of daily living in those with muscular dystrophies and

idiopathic inflammatory myopathy but there was no significant improvement in metabolic myopathies. However, people with glycogen storage disease type V should avoid high-dose creatine supplementation, as it caused a significant increase in pain in one study (Kley et al 2011).

It appears the potential positive or negative effects of creatine supplementation depend on the type of myopathy and creatine transport system disorder (Tarnopolsky 2011).

### Reduces mental fatigue and improves cognitive function

Creatine supplementation improves cognitive performance, with generally positive effects being reported in both young (Benton & Donohoe 2011, Ling et al 2009, Watanabe et al 2002) and older individuals (McMorris et al 2007). Supplementation has been found to increase brain creatine and phosphocreatine levels and is associated with improved cognitive performance (Rawson & Venezia 2011).

Hammett et al (2010) showed that creatine (20 g/day for 5 days then 5 g for 2 days) given to healthy adults ( $n = 22$ ) improved short-term memory and abstract reasoning compared to placebo. Treatment with 5 g/day creatine ethyl ester improved tasks associated with memory and attention span (assessed by memory scanning, arrow flankers and Raven's matrices) compared to placebo in another study of 14 young adults (Ling et al 2009). Similarly, creatine (8 g/day for 5 days) reduced mental fatigue when examined under double-blind, placebo-controlled conditions in 24 healthy volunteers (Watanabe et al 2002). A study of 45 healthy vegetarians showed that creatine significantly improved tasks requiring speed of processing, both working memory and intelligence (Raven's advanced progressive matrices) (Rae et al 2003). This is further supported by a recent double-blind RCT ( $n = 128$ ) in which creatine supplementation (20 g/day for 5 days) was found to have a greater effect on memory in young healthy vegetarians compared to omnivores (Benton & Donohoe 2011).

A placebo RCT demonstrated that creatine improved cognitive function in elderly patients, with various cognitive performance tasks showing significant improvement on baseline, apart from backward number recall, where no improvement was found (McMorris et al 2007). Alternatively, a negative double-blind, placebo-controlled study of 22 individuals given low-dose creatine (0.03 g/kg of body weight) daily for 6 weeks found no significant difference in cognitive function (Rawson et al 2008).

### Depression

A potential role for the use of creatine in psychiatric disorders is beginning to be explored, with magnetic resonance spectroscopy finding changes to brain creatine metabolism in a number of psychiatric illnesses, including depression; reduced creatine

metabolism has been associated with a worse disease course and outcome (Allen et al 2012).

Three clinical trials of different designs have also found a beneficial effect of augmenting antidepressant medication with creatine (4–5 g/day) in those with major depression disorder (Kondo et al 2011, Lyoo et al 2012, Roitman et al 2007). Current evidence suggests it may be best suited to unipolar depression; however, further research is required to confirm the role of creatine in depression.

In a recent double-blind placebo-controlled trial, 52 women with major depression were given either 5 g creatine monohydrate or placebo in addition to the selective serotonin reuptake inhibitor (SSRI) escitalopram for 8 weeks. Significant improvements in symptoms, as measured by the Hamilton Depression Rating Scale score, were seen in the treatment group commencing after 2 weeks of treatment. There was no difference in adverse effects reported (Lyoo et al 2012). This supports the findings of two earlier preliminary studies. An open-label, add-on study involving 5 treatment-resistant female adolescents receiving fluoxetine reported that 4 g of creatine daily for 8 weeks had increased brain phosphocreatine concentrations compared to healthy controls and there was a 56% reduction in the depressive symptom score (measured by Children's Depression Rating Scale-Revised) (Kondo et al 2011). In contrast, a shorter pilot study involving 18 treatment-resistant patients (4 men and 14 women) with major depression treated with SSRI/serotonin-noradrenaline reuptake inhibitor or noradrenergic specific serotonin antidepressant for 3 weeks, who received either 5 or 10 g/day creatine or placebo for 4 weeks in addition to their antidepressant, reported no difference in symptoms measured by the Hamilton Depression Rating Scale and the Clinical Global Impression Severity Scale compared to placebo (Nemets & Levine 2013). The lack of effect reported in this trial may be due to the shorter timeframe — only 4 weeks compared to 8 weeks in previous positive studies. However this should be explored further for confirmation.

An open-label study suggests that creatine supplementation may be better suited to unipolar depression. In this trial, people with treatment-resistant depression were given creatine 3–5 g/day for 4 weeks. This treatment resulted in symptom improvement in patients with unipolar depression. However, in two patients with bipolar, hypomania/mania was experienced, suggesting the need for caution (Roitman et al 2007).

## Diabetes

Creatine supplementation (10 g/day) for 3 months improved glucose tolerance but not insulin sensitivity when combined with aerobic training in a double-blind, randomised, placebo-controlled trial with 22 healthy sedentary males (Gualano et al 2008). A 12-week randomised, double-blind, placebo-controlled trial of 25 subjects with type 2 diabetes undergoing exercise training found creatine

5 g/day resulted in improved glycaemic control (HbA<sub>1c</sub>), postprandial glycaemia and GLUT-4 translocation compared to placebo. No changes were seen in the surrogate measures of insulin sensitivity such as insulin and C-peptide concentrations, physical capacity or lipid profile. The underlying mechanism in increased glucose disposal is thought to be further enhancement of GLUT-4 recruitment to the sarcolemma compared to exercise alone (Gualano et al 2011).

The effectiveness of short-term creatine on glycaemic control in type 2 diabetics has been examined in two crossover RCTs.

The first randomised crossover study ( $n = 30$  unmedicated subjects) found that creatine ( $2 \times 3$  g/day) was as effective as metformin ( $2 \times 500$  mg/day) in reducing fasting and postprandial blood glucose levels measured at 60, 90, 120, 180 and 240 minutes post-meal consumption; however creatine had a greater effect at 120 minutes. Neither treatment resulted in changes in blood insulin, C-peptide or HbA<sub>1c</sub> (Rocic et al 2009). Soon after, Rocic et al (2011) reported that creatine (3 g/day) was as effective as glibenclamide (3.5 g/day) in lowering blood glucose levels from baseline, measured before and postprandially. The study of 31 people with type 2 diabetes also showed both treatments increased plasma insulin and C-peptide (Rocic et al 2011).

## OTHER USES

### Gyrate atrophy

Doses of 1.5 g/day for 1 year resulted in improvement of the skeletal muscle abnormality that accompanies gyrate atrophy, a genetically acquired form of blindness (Feldman 1999).

## DOSAGE RANGE

There are two common dosing regimens.

### Loading

Creatine loading protocols have been well studied.

- **Rapid loading:** a dose of 5 g is taken four times daily for 5–7 days as a loading phase, followed by 2–10 g daily as maintenance for 1 week to 6 months (Bemben & Lamont 2005). This is followed by a 4-week break and then restarted, in a process known as 'cycling'.

- **Slower loading:** a similar effect can be achieved by taking 3 g daily over 28 days.

Concurrent ingestion of carbohydrate (50–100 g) may improve creatine uptake.

Once muscles have become saturated, it takes approximately 4 weeks to return to baseline levels.

### Non-loading

- Daily dose of 3 g.

In practice, creatine is often taken with simple carbohydrates, such as glucose or fruit juice, in order to increase creatine accumulation within muscle.

**Clinical note — Interview with Steve Brown, former Mr Australia National Powerlifting Champion, world record holder and personal trainer**

In practice, micronised creatine supplements have changed enormously since their introduction to the mainstream market 10 years ago. The greater majority of creatine supplements have no negative impact or side effects on the gastrointestinal tract and, typically, most creatine supplements are now available as hybrids. This means they are presented as a combination of different forms all blended together and are very easily assimilated into the body with water. Good hydration is very important when using a creatine supplement in order to ensure minimal fluid retention within the layers of skin, according to Steve Brown (personal communication, 2014). The loading regimen typically increases the ability to lift heavier weights for greater repetitions within a week and occurs quite suddenly. Also, creatine increases alertness and mental sharpness, effects that are obvious after the first week. Although there can be a very slight weight gain due to water retention, lean body mass also increases, because the body is able to work harder and for longer with creatine. Once supplementation stops, the physical effects on performance quickly reduce and are noticeable after the first week.

- Depression: 4–5 g/day for 4–8 weeks as an add-on therapy to antidepressant medication.
- Diabetes / glucose intolerance: 5–10 g/day.
- Gyrate atrophy: 1.5 g/day.
- Reducing effects of sleep deficit: 50–100 mg/kg body weight.
- Rett's syndrome: 200 mg/kg body weight.

### ADVERSE REACTIONS

Side effects can include gastrointestinal distress with nausea and vomiting, diarrhoea, muscle fatigue, pain and cramping, dehydration and heat intolerance. The effects may be reduced when micronised forms of creatine are taken together with glucose or simple carbohydrates. A systematic review and meta-analysis however found creatine supplementation did not increase symptoms, adversely affect hydration or thermoregulation in athletes exercising in the heat (Lopez et al 2009) and, interestingly, may even reduce perceived exertion when exercising in the heat (Hadjicharalambous et al 2008). Recent reviews of creatine safety found no negative effects on kidney function in healthy individuals (Gualano et al 2012, Kim et al 2011); however in those with a pre-existing kidney disease or dysfunction, supplementation greater than 3–5 g/day should be avoided (Kim et al 2011). Splitting the daily dose or using a slow-release formulation may assist in reducing the accumulation of potential toxic metabolites (Gualano et al 2012).

### Dosing range according to clinical studies

- Short-duration, high-intensity exercise: 20 g/day for 5 days.
- Lean muscle mass: 20 g/day for 5 days followed by 4.8 g daily.
- Muscle strength with training: 0.15 g/kg body weight twice a week; 0.10 g/kg three times a week; 5 g/day creatine pyruvate.
- Muscle strength without training: 5 g polyethylene glycosylated creatine daily for 28 days.
- Maintaining muscle mass with limb immobilisation: 20 g/day for 1 week.
- Muscle strength and function in the elderly: 5–20 g/day for at least 5 days.
- Muscle recovery from exercise: 20 g/day plus 50 g maltodextrin for 5 days prior to competition/training; 0.3 g/kg body weight for 5 days prior to training and 0.1 g/kg body weight posttraining.
- Fibromyalgia: 3 g/day for 3 weeks followed by 5 g/day; 20 g/day for 5 days followed by 5 g/day.
- Bone mineral density: 0.3 g/kg body weight for 5 days followed by 0.07 g/kg combined with resistance training.
- Osteoarthritis: 20 g/day for 1 week followed by 5 g daily combined with resistance training.
- Huntington's disease: 8 g/day.
- PD: 20 g/day for 5 days followed by 5 g/day.
- Mental fatigue and brain function: 5–20 g for 5 days.

### CONTRAINDICATIONS AND PRECAUTIONS

Use of high-dose creatine is contraindicated in individuals with renal failure, although it appears to be relatively safe in people at risk of kidney dysfunction. This was seen in several studies examining the effect of creatine in those at risk of kidney dysfunction, including type 2 (Gualano et al 2011b), older individuals (postmenopausal women) (Neves et al 2011), elderly Parkinson's patients (Bender et al 2008) or those with a single kidney (Gualano et al 2010b): no negative effects on renal function were found.

Caution in people with bipolar depression based on a report of increased mania in an open study (Roitman et al 2007).

A risk assessment report using data from clinical trials concluded that, overall, creatine has a good safety profile in healthy individuals, with the main side effect being gastrointestinal upset when taken in large doses. Doses up to 5 g/day are generally considered safe but the long-term safety of larger doses is yet to be established (Shao & Hathcock 2006). Creatine supplementation for up to 8 weeks has not been associated with major health risks, but the safety of long-term creatine supplementation has not been established (Gualano et al 2012, Williams & Branch 1998).

Gastrointestinal disturbance may further be reduced if doses are divided (e.g. two doses of 5 g/day may be better tolerated than a single 10-g dose) (Ostojic & Ahmetovic 2008).

Fluid retention is commonly observed during the loading phase of supplementation and it can result in early weight gain of 1.6–2.4 kg.

### SIGNIFICANT INTERACTIONS

Controlled studies are not available and there is insufficient reliable evidence to determine interaction potential.

#### PREGNANCY USE

Insufficient reliable data are available, but it is generally not recommended in pregnancy.

#### Practice points/Patient counselling

- Creatine is a very popular sports supplement and is not a substance banned by the International Olympic Committee. Although scientific evidence supports its use in high-intensity, repetitive-burst exercise, not every individual will respond. It appears that vegetarians and those with low starting creatine levels in muscle are most likely to respond.
- Creatine is also used in the treatment of numerous conditions involving fatigue or muscle weakness.
- Creatine is used in the production of ATP, the main source of energy for muscle activity and many other biological functions.
- Clinical studies suggest that creatine supplementation may improve cognitive function and mood, glycaemic control in type 2 diabetes and possibly also have benefits in fibromyalgia, PD and osteoarthritis when combined with exercise and improving bone mineral density.
- Neuroprotective effects observed in animal studies and some clinical studies suggest a possible role in neurodegenerative diseases; however, further research is still required to clarify its role.
- In practice, creatine is often taken in high doses for 5–7 days, followed by lower maintenance doses for up to 8 weeks. This is called 'loading'. Stopping creatine after this time and then starting the treatment regimen again is common among athletes and is supported by the fact that muscles have a finite storage capacity for creatine.
- High-dose creatine is contraindicated in renal failure.

#### PATIENTS' FAQs

##### What will this supplement do for me?

Creatine enhances physical power and recovery in most cases and appears most effective when

combined with resistance training. It may also reduce mental fatigue, enhance mood and memory and have a protective effect on nerves. Research shows a possible role in neurodegenerative diseases, glycaemic control in type 2 diabetes, fibromyalgia, PD and osteoarthritis when combined with exercise and improving bone mineral density.

##### When will it start to work?

The physical effects generally develop within 1–4 weeks of use. The effects on mood and concentration take longer — 4–8 weeks.

##### Are there any safety issues?

Creatine should not be taken in high doses by people with kidney disease and its long-term safety has not been established.

# Damiana

**HISTORICAL NOTE** Damiana is a wild deciduous shrub found in the arid and semiarid regions of South America, Mexico, the United States and West Indies. It is believed that Mayan Indians used damiana to prevent giddiness, falling and loss of balance, and as an aphrodisiac. It has also been used during childbirth, and to treat colic, stop bedwetting and bring on suppressed menses. Today its leaves are used for flavouring in food and beverages, and infusions and other preparations are used for a variety of medicinal purposes.

## COMMON NAME

Damiana

## OTHER NAMES

Herba de la pastora, Mexican damiana, miziboc, old woman's broom, shepherd's herb, stag's herb

## BOTANICAL NAME/FAMILY

*Turnera diffusa*, *Damiana aphrodisiaca*, *Turnera aphrodisiaca* (family Turneraceae)

## PLANT PARTS USED

Dried leaves and stems

## CHEMICAL COMPONENTS

Alkaloids, flavonoids, arbutin (a glycosylated hydroquinone), essential oils containing caryophyllene, delta-cadinene, beta-elemene and 1,8-cineole and other lesser constituents, tetraphylin B (a cyanogenic glycoside, 0.26%), resin, tannins, gum, mucilage, starch, a bitter element and possibly caffeine (Piacente et al 2002, Zhao et al 2007).

## MAIN ACTIONS

### Hormonal effects

One study that investigated the effects of over 150 herbs for their relative capacity to compete with oestradiol and progesterone binding to intracellular receptors identified damiana as a herb that binds to intracellular progesterone receptors, exerting a neutral effect and also exerting weak oestrogen agonist activity (Zava et al 1998). It has been reported that delta-cadinene is a testosterone inducer and 1,8-cineole is a testosterone hydroxylase inducer (Duke 2006).

A study analysing the constituents of the essential oils found in various damiana samples identified that fresh and dry samples contained both compounds, but wild plants contained more delta-cadinene than cultivated plants (Alcaraz-Melendez et al 2004). The action of these constituents may support the common belief that damiana is useful as an aphrodisiac. An in vitro study assaying the antiaromatase activity of a methanolic extract of damiana found a dose-dependent inhibitory effect on aromatase enzyme. The isolates pinocembrin and acacetin (flavonoids) were the most potent inhibitors of 24 compounds isolated from the methanolic extract. Further studies

are required to verify if these findings can be replicated in vivo (Zhao et al 2008).

### Hypoglycaemic agent

A decoction of dried damiana leaves caused a significant reduction of the hyperglycaemic peak, exerting a hypoglycaemic effect comparable to that of tolbutamide in an experimental model (Alarcon-Aguilara et al 1998).

## OTHER ACTIONS

### Anxiolytic activity

An animal model investigated the antianxiety effects of damiana in mice exposed to the elevated pulse maze. A methanolic extract was found to exhibit anxiolytic activity at a dose of 25 mg/kg (Kumar & Shumar 2005). A further preclinical study using an apigenin (flavone) fraction derived from damiana demonstrated anxiolytic effects in mice exposed to various animal models of anxiety (Kumar et al 2008).

## CLINICAL USE

Damiana has not been significantly investigated under clinical trial conditions; therefore, evidence is derived from traditional use, in vitro and animal studies, and its clinical significance is unknown.

### Sexual dysfunction or decreased libido

Damiana has been used traditionally for sexual dysfunction or as an aphrodisiac to enhance sexual activity. Scientific studies in experimental models provide preliminary support for its use in these conditions, but controlled trials testing damiana as a stand-alone treatment are lacking. One in vivo study established that damiana fluid extract significantly improves the copulatory performance of sexually sluggish animals, but has no effect on normally functioning ones (Arletti et al 1999). The effect appears to be dose-dependent, as positive results were obtained only when the highest dose was administered.

A study investigating the effects of damiana on sexually exhausted male rats showed a significant increase in proportion of copulating animals following a single oral dose of damiana aqueous extract (80 mg/kg), with a significantly reduced postejaculatory interval (Estrada-Reyes et al 2009). It is thought

the prosexual effects are exerted via the nitric oxide pathway and anxiolytic-like effects (Estrada-Reyes et al 2013).

#### IN COMBINATION

In a randomised controlled trial involving 78 men suffering from mild to moderate erectile dysfunction, oral treatment with a multi-herb preparation containing *Turnera diffusa*, *Panax ginseng*, *Serenoa repens*, *Crataegus rivularis*, *Ginkgo biloba*, *Tribulus terrestris*, *Erythroxylum catuaba*, *Cuscuta chinensis*, *Epimedium sagittatum* and bioperine resulted in significantly improved erectile function scores after 12 weeks of treatment (Shah et al 2012).

Another clinical study of unknown design compared a herbal combination product consisting of ginseng, ginkgo, damiana, l-arginine and a variety of vitamins and minerals with placebo in 77 female volunteers. After 4 weeks, 73.5% of the women in the treatment group reported an increase in sexual satisfaction compared with 37.2% receiving placebo (Ito et al 2001). Although promising, the role of damiana in achieving this result is unknown.

#### Diabetes

Although in vivo studies suggest significant hypoglycaemic activity, no clinical studies are available to determine whether the effects are clinically significant.

#### Weight loss

No controlled studies are available to determine the effectiveness of damiana as a stand-alone treatment in weight loss; however, one study that used a combination of herbs that included damiana has produced positive results. The randomised, double-blind study involving 47 overweight subjects tested a herbal combination product known as YGD (*Yerba mate*, *Paullinia cupana* and damiana) for weight loss activity. Treatment resulted in a prolonged gastric emptying time and a body weight reduction of  $5.1 \pm 0.5$  kg compared with  $0.3 \pm 0.08$  kg after placebo over 45 days. A 12-month follow-up revealed that weight loss was maintained in the active treatment group (Andersen & Fogh 2001). A further double-blind, placebo-controlled crossover study on the YGD formulation revealed a decrease in food intake and energy intake in female subjects, suggesting an effect on in-meal satiation. The same study showed an increased amount of satiation following administration of YGD and a soluble fermentable fibre together (Harrold et al 2013). Until studies using damiana as sole therapy are conducted, the effectiveness of this herb in weight loss is still unknown.

#### OTHER USES

In practice, damiana is sometimes used to treat anxiety and depression associated with hormonal changes (e.g. menopause) or where there is a sexual factor involved. It is also used as a mild stimulant and aphrodisiac, to enhance stamina generally and for nervous dyspepsia and constipation.

#### DOSAGE RANGE

- Dried leaf: 2–4 g taken three times daily.
- Infusion: pour a cup of boiling water on to one teaspoonful of the dried leaves and let infuse for 10–15 min. Drink three cups daily.
- Liquid extract (1:2) or solid-dose equivalent: 20–40 mL/week or 3–6 mL/day.

#### ADVERSE REACTIONS

There is insufficient reliable information available.

#### SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

#### Hypoglycaemic agents

Additive effects are theoretically possible, with unknown clinical significance — observe patients.

#### CONTRAINDICATIONS AND PRECAUTIONS

Traditionally, the herb is not recommended for people with overactive sympathetic nervous system activity.

#### PREGNANCY USE

Safety in pregnancy has not been scientifically evaluated; however, no increase in fetal abnormalities has been observed from limited use in women (Mills & Bone 2005).

#### Practice points/Patient counselling

- Damiana is a herb with a traditional reputation as being an aphrodisiac, stimulant, mood enhancer and general tonic.
- Currently, evidence to support its use as an aphrodisiac is limited to research in animals, which has produced some positive results.
- In vivo studies have identified significant anti-inflammatory and hypoglycaemic activity, although human studies are still required to determine clinical significance.
- It is also suspected that the herb exerts some degree of hormonal activity.

#### PATIENTS' FAQs

##### *What will this herb do for me?*

Damiana has not been significantly tested in human studies, so much information is taken from traditional sources or preliminary research in animals. According to these sources, it may increase sexual function and libido in some cases of dysfunction,

lower blood glucose levels and exert anti-inflammatory actions.

#### **When will it start to work?**

There is insufficient evidence to predict when effects may develop.

#### **Are there any safety issues?**

A long history of use suggests it is generally safe. However, scientific testing has not been conducted.

# Dandelion

**HISTORICAL NOTE** Dandelion grows as a perennial native herb throughout the Northern Hemisphere and as a weed in other temperate zones. It has a long history of medicinal and culinary use. Dandelion is an entirely edible plant (Gonzales-Castejon et al 2012). Its leaves are added to salads, providing a good source of minerals, and the roasted root is used as a coffee substitute. In Europe, dandelion flowers were used for the preparation of drinks and salads (Mlcek & Rop 2011), and particular extracts used as flavourings in various dairy desserts, baked goods, candy gelatins, puddings and cheese (Gonzales-Castejon et al 2012). Traditionally, dandelion leaves are used as a diuretic, and the root as a liver tonic. This use has no doubt led to its trivial names *pissenlit* (French) and *piscialetto* (Italian) both hinting at its property of enuresis provocation (Gonzales-Castejon et al 2012).

## OTHER NAMES

Blowball, cankerwort, common dandelion, lion's tooth, priest's crown, puffball, swine snout, taraxacum, wild endive, white endive

## BOTANICAL NAME/FAMILY

*Taraxacum officinale* Weber; synonyms: *Leontodon taraxacum*, *Taraxacum vulgare* (family Compositae [Asteraceae])

## PLANT PARTS USED

Leaf, root and flowers (used less commonly)

## CHEMICAL COMPONENTS

Nutritionally, dandelion is a particularly rich source of potassium (Hook et al 1993, Gonzales-Castejon et al 2012), as well as iron, magnesium, zinc, manganese, copper, choline, selenium, calcium, boron and silicon (Queralt et al 2005), and a rich source

of vitamins A, C, D and B complex (US Department of Agriculture 2003). It is one of the richest green-vegetable sources of  $\beta$ -carotene (Gonzales-Castejon et al 2012). The relatively high protein, fibre and linoleic acid content of dandelion leaves has led to suggestions that dandelion is a nutritious and underutilised food source (Escudero et al 2003). Dandelion's constituents also include sugars and mucilage (Blumenthal et al 2000).

Seasonal variations, soil composition, growing location, companion plants, fungi and insects may result in phytochemical variations in dandelion (Romm et al 2010b).

The major phytochemical groups identified in dandelion are terpenes, phenolic compounds and storage carbohydrates. Some phytochemicals are found in all parts of the plant (i.e. the phenolic caffeic acid); however, some are unique to a single plant part. The root contains at least nine different

sesquiterpene lactones (anti-inflammatory and antimicrobial properties), nine different triterpenes and phytosterols (promote reduced cholesterol absorption), at least twelve different phenolic acids (immunostimulatory properties), three different coumarins (cardiovascular system actions) and the prebiotic-acting, oligosaccharide soluble fibre inulin (Gonzales-Castejon et al 2012). The levels of inulin in dandelion root range from 2% to 40% from spring to autumn (Romm et al 2010b). Dandelion leaves and stems contain two sesquiterpene lactones, three triterpenes, five phenolic acids, five different flavonoids with antioxidant properties and two coumarins. There are numerous xanthophylls within dandelion leaf, with particularly high levels of lutein (Znidarcic 2011). Dandelion flowers contain three different phenolic acids and four flavonoids (Gonzales-Castejon et al 2012).

## MAIN ACTIONS

### Diuretic

Dandelion leaf has been found to have a greater diuretic effect than the roots, with activity comparable to that of frusemide, without causing potassium loss because of the leaves' high potassium content (Newell et al 1996). A small clinical trial confirmed oral intake of dandelion leaf extract significantly increases urinary output (Clare et al 2009). Dandelion root does not appear to have the same diuretic effect according to research with animal models using an infusion of the root (Grases et al 1994), and no secondary metabolites showing major diuretic activity were found (Hook et al 1993).

### Choleretic

The bitter constituents in dandelion root are believed to be responsible for increasing bile production and flow, as well as contributing to the root's mild laxative effects.

### Hepatic enzyme induction

In vivo studies have demonstrated decreased activity of CYP1A2 and CYP2E enzymes and dramatic increases in levels of the phase II detoxifying enzyme UDP-glucuronosyltransferase in liver microsomes of rats receiving dandelion tea (Maliakal & Wanwimolruk 2001). The same study found that dandelion tea had no effect on the activities of CYP2D and CYP3A.

### Anti-inflammatory

Dandelion extract exhibited a mild analgesic and anti-inflammatory effect in vivo (Tito et al 1993). Dandelion influences inflammatory mediators (TNF-alpha, COX-2, IL-1, iNOS) in leucocytes (root methanol extract), astrocytes (leaf extract) and macrophages (isolated polyphenols) in vitro. Dandelion ethanolic, aqueous and methanolic extracts have been found to inhibit inflammatory cytokines in vivo. (Gonzales-Castejon et al 2012).

### Antioxidant activity

Dandelion flower, root, stems and leaf extracts demonstrate antioxidant activity in a number of preclinical models (Cho et al 2002, Colle 2012, Kaurinovic et al 2003, Liu et al 2010, Yanghee 2010).

Dandelion flower extract demonstrated marked antioxidant activity that has been attributed to its phenolic content, with suppression of reactive oxygen species and nitric oxide (Hu & Kitts 2003, 2005, Kery et al 2004). Dandelion aqueous extract demonstrated antioxidant activity in a diabetic rat model, preventing diabetic complications due to lipid peroxidation and excessive free radicals (Cho et al 2002), and in a model of acute lung injury (Liu et al 2010). Aqueous extract of dandelion root provided protection against the development of alcoholic liver disease by increasing antioxidant capacity (Yanghee 2010). The leaf extract also protected against paracetamol-induced hepatotoxicity via an antioxidant mechanism (Colle 2012).

### Anti-Cancer Activity

Traditional medicines of China, Arabia and Native America all use the plants of the genus *Taraxacum* (dandelions) to treat a variety of diseases, including cancer. An extract of dandelion leaf (but not root or flowers) has been demonstrated to decrease the growth of MCF-7/AZ breast cancer cells in vitro, suggesting that it may be of value as an anticancer agent. There is preliminary scientific evidence from animal and in vitro studies that suggest the roots of *Taraxacum japonicum* (Japanese dandelion) may have a cancer-preventive effect. The extract has been shown to induce cytotoxicity through TNF-alpha and IL-1-alpha secretion in vitro. The ethanol extract of dried, arial *Taraxacum officinalis* (n-butanol fraction (BuOH)) exhibited potent anti-angiogenic activity. The flavonoid luteolin is one of the key constituents responsible for the activity (Jeon et al 2008), and is particularly potent in inhibiting hepato-cellular carcinoma cells (Stagos et al 2012). Furthermore, aqueous extract of dandelion root contains compounds which selectively induce apoptosis in human leukaemia cells in vitro (Ovadjie et al 2011).

### OTHER ACTIONS

Traditionally, dandelion root is understood to have laxative activity and to stimulate digestion, whereas dandelion leaf has antirheumatic effects. Dandelion root infusion, which contains oligofructans, has been found to stimulate the growth of multiple strains of bifidobacteria, suggesting its use as a prebiotic (Trojanova et al 2004). Possible hypolipidaemic effects were suggested in a cholesterol study of rabbits fed dandelion leaf and roots (Ung-Kyu 2010).

Dandelion may have antidiabetic actions because ethanolic extracts of whole dandelion exhibited insulin secretagogue activity (Hussain et al 2004).

Three peptides purified from *Taraxacum officinalis* flowers have been discovered which display strong

antifungal and antibacterial properties. The peptides are cationic and cysteine-rich, and represent two novel families of plant antimicrobial peptides, evidently evolved to protect the plant from fungal and microbial invasion (Astafieva 2012).

Dose-dependent activity was observed against the replication of a pseudotyped HIV-1 in test tube studies using an aqueous extract of the entire dandelion plant (Han et al 2011).

## CLINICAL USE

The therapeutic effectiveness of dandelion has not been significantly investigated under clinical trial conditions, so evidence is derived from traditional, in vitro and animal studies.

### Diuretic

Dandelion has a long history of use as a diuretic in well-established systems of traditional medicines; however, the scientific and clinical evidence to support this use is limited to animal studies (see above). The high potassium content of dandelion is considered to be partly responsible for any diuretic activity (Hook et al 1993). A significant increase in the frequency of urination ( $P < 0.05$ ) has been confirmed in a small study ( $n = 17$ ) which gave volunteers 8 mL TDS of 1:1 high quality hydroethanolic dandelion leaf extract in a single day and compared urinary output to the previous 2 days. The effect was apparent within the 5-hour period immediately after the first dose, indicating relatively quick-acting effects. There was also a significant ( $P < 0.001$ ) increase in the volume of urine within the 5-hour period after the second dose of extract.

### IN COMBINATION

A double-blind RCT of 57 women with recurrent cystitis found that a commercial preparation known as Uva-E (a combination of bearberry leaves and dandelion root) significantly reduced the frequency of recurrence of cystitis compared with placebo. At the end of 12 months, none of the patients taking Uva-E had a recurrence of cystitis, compared with 23% recurrence in the control group ( $P < 0.05$ ) (Larsson et al 1993). The role of dandelion in achieving this result is unknown; however, the researchers suggested that its diuretic effect was likely to have contributed to the positive results.

### Liver tonic

Dandelion root has a long history of use as a liver tonic (Macia et al 2005); however, the scientific and clinical evidence to support this use is limited. Preliminary studies suggest that dandelion root stimulates the flow of bile.

Commission E approves the use of dandelion root and herb for disturbances in bile flow, loss of appetite and dyspepsia (Blumenthal et al 2000).

European Scientific Co-Operative on Phytotherapy (ESCOP 2003) recommends dandelion root for 'restoration of hepatic and biliary function, dyspepsia, and loss of appetite'.

## OTHER USES

Dandelion has been used traditionally as a source of minerals and for treating diabetes, rheumatic conditions, heartburn, bruises and for recurrent hives, urticaria and eczema. It has also been used to treat various digestive complaints, such as dyspepsia, lack of appetite and constipation (Newell et al 1996), as well as for breast and uterine cancers (Koo et al 2004). The sap has been used topically on warts (Guarrera 2005).

## DOSAGE RANGE

### Leaf

- Infusion of dried herb: 4–10 g three times daily.
- Fluid extract (25%): 4–10 mL three times daily.
- Fresh juice: 10–20 mL three times daily.

### Root

- Decoction of dried root: 2–8 g three times daily.
- Tincture (1:5): 5–10 mL three times daily.
- Fluid extract (30%): 2–8 mL three times daily.
- Juice of fresh root: 4–8 mL three times daily.

### According to clinical studies

Diuresis: 8 mL three times daily for a 1:1 hydroethanolic extract of dandelion leaf.

## ADVERSE REACTIONS

Dandelion is generally considered safe when consumed in amounts commonly found in foods. Side effects are rare, and the likelihood of dandelion leaf preparations causing a contact allergy is low. However, cross-reactivity may exist between dandelion and other members of the Compositae (Asteraceae) family, such as ragweed, mugwort, sunflower, daisy and chamomile (Cohen et al 1979, Fernandez et al 1993, Jovanovic et al 2004). The most common type of allergy to dandelion is dermatitis following direct skin contact. Contact allergy to herbal teas derived from the plant family was investigated in patients allergic to sesquiterpene lactones (SLs). Ninety per cent had positive test reactions to the Compositae teas, mainly to those based on dandelion, German chamomile and wormwood. Children with a family or personal history of atopy, summer-related or -exacerbated dermatitis of any kind may be more sensitive to exposure to Compositae weeds, especially dandelions.

Avoid in patients with hypersensitivity/allergy to dandelion or other member of the Asteraceae family.

## SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

### Diuretic agents

Dandelion leaf may theoretically potentiate the diuretic effect of pharmaceutical diuretics—observe.

## Quinolone antibiotics

The high mineral content of dandelion may result in the formation of chelate complexes with quinolone antibiotics and reduce their absorption and bioavailability. This has been demonstrated in rats with *Taraxacum mongolicum* (Chinese dandelion) (Zhu et al 1999). While the clinical significance of this is unknown, it is recommended to avoid concomitant use of these substances or to separate their dosing.

### Practice points/Patient counselling

- Dandelion leaf and root have a long tradition of culinary and medicinal use.
- Dandelion has been traditionally used as a diuretic and liver tonic. It has also been used to treat various digestive complaints such as dyspepsia, lack of appetite and constipation.
- The therapeutic effectiveness of dandelion has not been significantly investigated under clinical trial conditions, so evidence is derived from traditional, in vitro and animal studies.
- Dandelion is generally considered to be safe and non-toxic, but may cause allergy in people allergic to ragweed and daisies.

### CONTRAINDICATIONS AND PRECAUTIONS

It is recommended that dandelion not be used by people with obstruction of the bile ducts or other serious diseases of the gall bladder (Blumenthal et al 2000).

### PREGNANCY USE

Based on a long history of use in traditional medicine, dandelion is generally considered safe in pregnancy and lactation (Blumenthal et al 2000, McGuffin et al 1997). Dandelion root and leaf is used for various complaints, such as digestive issues, diuretics and iron support during pregnancy (Romm et al 2010a).

### PATIENTS' FAQs

#### What will this do for me?

In practice, dandelion is used to improve digestion and detoxification, as a diuretic and laxative and to treat diabetes, rheumatic conditions, heartburn, bruises and for recurrent hives, urticaria and eczema. Controlled studies are not available to determine its effectiveness in these conditions.

#### When will it work?

Stimulation of digestive processes is thought to occur rapidly after one dose.

#### Are there any safety issues?

Dandelion is generally considered to be safe and non-toxic but may cause allergy in people allergic to ragweed and daisies.

### Does the roasted dandelion root drink have the same properties?

Heating will affect some constituents in the root, however as no studies have been performed on the roasted dandelion root, it is not possible to comment on its therapeutic effect.

## Devil's claw

**HISTORICAL NOTE** The botanical name *Harpagophytum* means 'hook plant' in Greek, after the hook-covered fruits of the plant. Devil's claw is native to southern Africa and has been used traditionally as a bitter tonic for digestive disturbances, febrile illnesses and allergic reactions, and to relieve pain (Mills & Bone 2000). It has been used in Europe for the treatment of rheumatic conditions for over 50 years, and was first cited in the literature by Zorn at the University of Jena, Germany, who described his observations on the antiphlogistic and anti-arthritis effects after administration of oral aqueous extracts prepared from the secondary roots of *H. procumbens* in patients suffering from arthritides (Chrubasik et al 2006).

### COMMON NAMES

Devil's claw root, grapple plant, harpagophytum, wood spider

### BOTANICAL NAME/FAMILY

*Harpagophytum procumbens* (family Pedaliaceae)

The closely related *H. zeyheri* and *H. procumbens* are collectively known as devil's claw and have been used interchangeably. However, *H. zeyheri* has a lower concentration of the biologically active constituents. Sometimes it is included in raw materials and products as an adulterant of *H. procumbens*, the preferred species of commerce (Mncgwangi et al 2014).

### Plant Part Used

Dried tuber/roots. Forms used include dried raw materials, aqueous and ethanol extracts, aqueous-ethanol extracts standardised for harpagoside content, and powdered dry herb tablets (Mncgwangi et al 2012).

### Chemical Components

The major active constituent is considered to be the bitter iridoid glycoside, harpagoside (8-cinnamoyl harpagide), which should constitute not less than 1.2% of the dried herb (Georgiev et al 2013). Other iridoid glycosides include harpagide, procumbide, 8-O-(p-coumaroyl)-harpagide and verbascoside, and a newly discovered minor constituent, tentatively identified as methoxypagoside (Karioti et al 2011).

About 50% of the herb consists of sugars. There are also triterpenes, phytosterols, plant phenolic acids, flavonol glycosides and phenolic glycosides. *Harpagophytum zeyheri*, which has a lower level of active compounds, may be partially substituted for *H. procumbens* in some commercial preparations (Stewart & Cole 2005). The extraction solvent (e.g. water, ethanol) has a major impact on the active principle of the products (Chrubasik 2004a), and a concentrated aqueous maceration blended with methanol was found to be most efficient for optimal extraction of harpagoside (El Babili et al 2012). When administering *H. procumbens* extract topically it was found that higher penetration of all compounds occurred from an ethanol/water preparation (Abdelouhab & Heard 2008b), and the hydro-alcoholic tincture of devil's claw is very stable when tested over a 6 month period, with levels of marker iridoids not falling below 90% of their initial concentration (Karioti et al 2011).

### MAIN ACTIONS

#### Anti-inflammatory/analgesic

There is good in vitro and in vivo pharmacological evidence of the anti-inflammatory and analgesic properties of devil's claw, although some negative findings have also been reported (McGregor et al 2005). Overall, greatest activity appears to be in semi-chronic rather than acute conditions.

Devil's claw exerted significant analgesic effects against thermally and chemically-induced nociceptive pain stimuli in mice and significant dose-related reduction of experimentally-induced acute inflammation in rats (Mahomed & Ojewole 2004), as well as reducing pain and inflammation in Freund's adjuvant-induced arthritis in rats (Andersen et al 2004). Results from a study in mice suggest that the opioid system is involved in the antinociceptive effects of *H. procumbens* extract (Uchida et al 2008).

The iridoids, particularly harpagoside, are thought to be the main active constituents responsible for the anti-inflammatory activity; however, in vitro evidence suggests that the anti-inflammatory effect may in part be due to antioxidant activity (Denner 2007, Grant et al 2009, Langmead et al 2002), and it is particularly rich in water-soluble antioxidants (Betancor-Fernandez et al 2003). A study administering *H. procumbens* extract intraperitoneally to rats found that the anti-inflammatory response does not depend on the release of adrenal corticosteroids (Catelan et al 2006).

Contradictory evidence exists as to whether devil's claw affects prostaglandin (PG) synthesis. Early in vitro and in vivo and clinical studies suggest that it does not inhibit PG synthesis (Whitehouse et al 1983, Moussard et al 1992); however, more recent investigations have suggested that its anti-inflammatory and analgesic activities are due to suppression of PGE<sub>2</sub> synthesis and nitric oxide production and that the herb may suppress expressions of COX-2 and iNOS (Jang et al 2003). Harpagoside alone has been shown to suppress COX-2 and iNOS at both the mRNA and the protein level in vitro due to a suppression of NF-kappaB activation, although no influence on COX-1 was noted (Huang et al 2006). In vitro research shows that harpagoside and 8-O-(p-coumaroyl)-harpagide exhibit a greater reduction in COX-2 expression than verbasoside and that harpagide on the other hand causes a significant increase in COX-2 expression (Abdelouahab & Heard 2008a). Methanolic extracts of devil's claw have been shown to inhibit COX-2 in vivo (Kundu et al 2005, Na et al 2004), and more recently an ethanol extract of devil's claw was found to inhibit the expression of COX-2 and PGE-2 when applied to freshly excised porcine skin, although no significant effect on 5-LOX or iNOS was noted (Quitas & Heard 2009).

Inhibition of leukotriene synthesis has been observed in vitro, which appears to relate to the amount of harpagoside present (Loew et al 2001, Anauate et al 2010). A study using subcritical and supercritical CO<sub>2</sub> extracts (15 to 30% harpagoside) showed almost total inhibition of 5-lipoxygenase biosynthesis at 51.8 mg/mL of extract, whereas the conventional extract (2.3% harpagoside) did not inhibit the enzyme significantly (Gunther et al 2006).

In vivo experiments have determined that the method of administration of devil's claw affects its anti-inflammatory properties. Intraperitoneal and

intraduodenal administration was shown to reduce carrageenan-induced oedema, whereas oral administration had no effect, suggesting that exposure to stomach acid may reduce its anti-inflammatory activity (Soulimani et al 1994). This is supported by a study that found a loss of anti-inflammatory activity after acid treatment (Bone & Walker 1997). In addition, harpagoside inhibits release of the inflammatory mediator RANTES (Regulated on Activation, Normal T cell Expressed and Secreted) by stimulated human bronchial epithelial (BEAS-2B) cells, indicating that it has potential utility for treating respiratory disorders (Boeckenholt et al 2012). It also ameliorates dopaminergic neurodegeneration and movement disorder in a mouse model of Parkinson's disease by elevating the glial cell line-derived neurotrophic factor (Sun et al 2012).

In vitro studies on rat mesangial cells suggest that devil's claw may be used as an anti-inflammatory agent in the treatment of glomerular inflammatory diseases (Kaszkin et al 2004a). Devil's claw extract produced a concentration-dependent suppression of nitrite formation in rat mesangial cells in vitro due to an inhibition of iNOS expression through interference with the transcriptional activation of iNOS. It was found that this activity was due to harpagoside, together with other constituents that possibly have strong anti-oxidant activity (Kaszkin et al 2004b).

It has been suggested that the suppression of inflammatory cytokine synthesis, demonstrated in vitro and vivo (Fiebich et al 2001, Spelman et al 2006), could explain its therapeutic effect in arthritic inflammation (Kundu et al 2005). Fiebich and co-workers found that a 60% ethanolic extract decreases the expression of IL-1-beta, IL-6 and TNF-alpha (Fiebich et al 2001). A follow up study by the same authors found a dose-dependent inhibition of release of TNF- $\alpha$ , interleukin (IL)-6, IL-1-beta and prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) in addition to inhibiting the induction of pro-inflammatory gene expression in human monocytes (Fiebich et al 2012). Another study showed that devil's claw extract inhibits inflammation in the chronic stage of adjuvant-induced arthritis, and the same study showed that devil's claw extract displays potent inhibitory activity against IL-1 $\beta$ , IL-6, and TNF- $\alpha$  production in mouse macrophages. Harpagoside also inhibited production of these inflammatory cytokines without cytotoxicity (Inaba et al 2010).

### Chondroprotective

In vitro data suggest that the active principles of *H. procumbens* inhibit not only inflammatory mediators but also mediators of cartilage destruction, such as matrix metalloproteinases, NO and elastase (Boje et al 2003, Schulze-Tanzil et al 2004). A study using an animal model confirmed a chondroprotective effect in which the tissue inhibitor of metalloproteinase-2 is involved (Chrubasik et al 2006).

### Hypoglycaemic

Devil's claw extract produced a dose-dependent, significant reduction in the blood glucose concentrations of both fasted normal and fasted diabetic rats (Mahomed & Ojewole 2004).

### OTHER ACTIONS

Traditional uses include dyspepsia, fever, blood diseases, urinary tract infections, postpartum pain, sprains, sores, ulcers and boils (Mncwangi et al 2012). Recent research with animal models indicates an analgesic effect on acute postoperative and chronic neuropathic pain (Lim et al 2014). In vitro and in vivo evidence suggests that harpagoside may exhibit cardiac effects and lower blood pressure, heart rate and reduce arrhythmias (Fetrow & Avila 1999). As an extremely bitter herb, devil's claw is thought to increase appetite and bile production. Diterpenes extracted from the roots and seeds of devil's claw exhibited selective antiplasmodial (Clarkson et al 2003) and antibacterial activity (Weckesser et al 2007) in vitro, which may have future relevance in view of the increasing resistance to conventional antimalarials and antibiotics. One study showed that aqueous devil's claw extract can markedly delay the onset, as well as reduce the average duration, of convulsion in mice. Although not conclusive, it seems that the extract produces its anticonvulsant activity by enhancing GABAergic neurotransmission and/or facilitating GABAergic action in the brain (Mahomed & Ojewole 2006).

### CLINICAL USE

#### Arthritis

Devil's claw is mainly used to reduce pain and inflammation in practice, with a focus on musculoskeletal conditions. Overall, evidence from clinical trials suggests that devil's claw is effective in the treatment of arthritis; however, additional well-designed, long term studies are required in order to determine effects of its long-term administration in chronic models of joint inflammation and the minimum effective doses, safety and optimal administration routes must be thoroughly determined (Georgiev et al 2013, DiLorenzo et al 2013).

An observational study of 6 months' use of 3–9 g/day of an aqueous extract of devil's claw root reported significant benefit in 42–85% of the 630 people suffering from various arthritic complaints (Bone & Walker 1997). In a 12-week uncontrolled multicentre study of 75 patients with arthrosis of the hip or knee, a strong reduction in pain and the symptoms of osteoarthritis were observed in patients taking 2400 mg of devil's claw extract daily, corresponding to 50 mg harpagoside (Wegener & Lupke 2003). Similar results were reported in a 2-month observational study of 227 people with osteoarthritic knee and hip pain and non-specific low back pain, where both the generic and the disease-specific outcome measures improved by week 4 and further by week 8 (Chrubasik et al 2002). A double-blind study of 89 subjects with

rheumatic complaints used powdered devil's claw root (2 g/day) for 2 months, which also provided significant pain relief, whereas another double-blind study of 100 people reported benefit after 1 month (Bone & Walker 1997). A case report suggests that devil's claw relieved strong joint pain in a patient with Crohn's disease (Kaszkin et al 2004b). A single group open study of 8 weeks duration involving 259 patients showed statistically significant improvements in patient assessment of global pain, stiffness and function, and significant reductions in mean pain scores for hand, wrist, elbow, shoulder, hip, knee and back pain. Moreover, quality of life scores significantly increased and 60% of patients either reduced or stopped concomitant pain medication (Warnock et al 2007).

#### Comparison studies

Comparisons with standard treatment have also been investigated. In 2000, encouraging results of a randomised double-blind study comparing the effects of treatment with devil's claw 2610 mg/day with diacerein 100 mg/day were published (Leblan et al 2000). The study involved 122 people with osteoarthritis of the hip and/or knee and was conducted over 4 months. It found that both treatment groups showed similar considerable improvements in symptoms of osteoarthritis; however, those receiving devil's claw required fewer rescue analgesics.

One double-blind, randomised, multicentre clinical study of 122 patients with osteoarthritis of the knee and hip found that treatment with Harpadol (6 capsules/day, each containing 435 mg of cryo-ground powder of *H. procumbens*) given over 4 months was as effective as diacerein (an analgesic) 100 mg/day (Chantre et al 2000). However, at the end of the study, patients taking Harpadol were using significantly fewer NSAIDs and had a significantly lower frequency of adverse events. In a 6-week study of only 13 subjects, similar benefits for devil's claw and indomethacin were reported (Newall et al 1996). A preliminary study comparing the proprietary extract Doloteffin with the COX-2 inhibitor rofecoxib reported a benefit with the herbal treatment but suggested that larger studies are still required (Chrubasik et al 2003b).

Previously reviews have concluded that there is moderate evidence of the effectiveness of *H. procumbens* in the treatment of osteoarthritis of the spine, hip and knee; however it is suggested, as with many herbal medicines, that evidence of effectiveness is not transferable from product to product and that the evidence is more robust for products that contain at least 50 mg of harpagoside in the daily dosage (Chrubasik et al 2003a, Gagnier et al 2004, Long et al 2001, Lopez 2012). Two reviews have concluded that 'data from higher quality studies suggest that devil's claw appeared effective in the reduction of the main clinical symptom of pain' (Brien et al 2006) and that the evidence of effectiveness was 'strong' for at least 50 mg of harpagoside as the daily dose, with extracts of devil's claw resulting in pain relief for 60% of patients with an

osteoarthritic hip or knee, or nonspecific lower back pain (Chrubasik JE et al 2007). Nevertheless, two other reviews concluded that there was only 'limited evidence' (Ameje & Chee 2006) and 'insufficient reliable evidence' regarding the long term effectiveness of devil's claw (Gregory et al 2008), however this may be as the result of lack of continuity in clinical testing and the definition of 'physical impairment'. Different measures of physical impairment have been used in the clinical trials (including the Arhus low back pain index, the Schober test and the Waddell scale), and this may be a reason for varied results rather than a lack of effectiveness of the extracts (Chrubasik 2008).

The herb is Commission E approved as supportive therapy for degenerative musculoskeletal disorders (Blumenthal et al 2000) and approved for painful osteoarthritis by the European Scientific Cooperative on Phytotherapy (ESCOP 2003).

### Back pain

Three reviews looking at the treatment of low back pain concluded that there is strong evidence for short-term improvements in pain and reduction in rescue medication for devil's claw treatment, standardised to 50 and 100 mg harpagoside as daily doses (Chrubasik et al 2007, Gagnier 2008, Gagnier et al 2006, 2007). The reliability and quality of some of these clinical trials have been investigated in detail by different research groups (Brien et al 2006, Chrubasik et al 2003a, Gagnier et al 2004, 2007). All reviews of clinical studies conclude that Harpagophytum extracts show strong evidence of efficacy and reliability in the treatment of lower back pain.

Eight weeks treatment with devil's claw extract LI 174, known commercially as Rivoltan, significantly decreased back pain and improved mobility in a double-blind RCT of 117 people (Laudahn & Walper 2001) although another double blind RCT using the same product found that pain relief was established more quickly, after 4 weeks amongst subjects with muscle stiffness (Gobel et al 2001). Similar results were reported in two double-blind studies of 118 people (Chrubasik et al 1996) and 197 people (Chrubasik et al 1999) with chronic lower back pain.

Devil's claw appears to compare favourably to conventional treatments. A 6-week double-blind study of 88 subjects comparing devil's claw to rofecoxib found equal improvements in both groups (Chrubasik et al 2003b). A follow-up of the subjects from that study who were all given devil's claw for 1 year found that it was well tolerated and improvements were sustained (Chrubasik et al 2005). In an open, prospective study, an unspecific lower back pain treatment with *Harpagophytum* extract and conventional therapy were found to be equally effective (Schmidt et al 2005).

### Dyspepsia

Traditionally, devil's claw has also been used to treat dyspepsia and to stimulate appetite (Fisher & Painter

1996). The bitter principles in the herb provide a theoretical basis for its use in these conditions, although controlled studies are not available to determine effectiveness. The herb is Commission E (Blumenthal et al 2000) and ESCOP (2003) approved for dyspepsia and loss of appetite.

## OTHER USES

### Use in oncology

There is a case report that two Stage IIIA follicular lymphoma patients demonstrated objective tumour regression after taking 500 mg daily doses of devil's claw without cytotoxic therapy, which was confirmed by computed tomography (CT) scans. This result was presumably as a result of COX-2 inhibition, which has been implicated in lymphomagenesis. Although this case report introduces a possible use of the herb, it is unknown as to whether the regression was spontaneous (as has been observed in up to 16% of lymphoma patients) or due to devil's claw, and further studies are warranted (Wilson 2009).

### Traditional use

Traditionally, the herb is also used internally to treat febrile illnesses, allergic reactions and to induce sedation, and topically for wounds, ulcers, boils and pain relief (Fisher & Painter 1996, Mills & Bone 2000), as well as for diabetes, hypertension, indigestion and anorexia (Van Wyk 2000).

## DOSAGE RANGE

### Musculoskeletal conditions

- Dried root or equivalent aqueous or hydroalcoholic extracts: 2–6 g daily for painful arthritis; 4.5–9 g daily for lower back pain.
- Liquid extract (1:2): 6–12 mL/day.
- Tincture (1:5): 2–4 mL three times daily.

It is suggested that devil's claw extracts with at least 50 mg harpagoside in the daily dosage should be recommended for the treatment of pain, and dosages corresponding to 30–100 mg harpagosides have been used in clinical trials (Chrubasik 2004a, 2004b, Street & Prinsloo 2012).

### Digestive conditions (e.g. dyspepsia)

- Dosages equivalent to 1.5 g/day dried herb are used (Blumenthal et al 2000). It is suggested that devil's claw preparations be administered between meals, when gastric activity is reduced.

## TOXICITY

The acute LD<sub>50</sub> of devil's claw was more than 13.5 g/kg according to one study (Bone & Walker 1997). In a recent review of 28 clinical trials only a few reports on acute toxicity were found, whereas no reports on chronic toxicity had been reported. The review concluded that more studies for long-term treatment are needed (Vlachojannis et al 2008). An earlier review looking at 14 clinical trials had come to the same conclusion (Brien et al 2006).

## ADVERSE REACTIONS

Devil's claw is a well tolerated treatment. In a recent review of 28 clinical trials it was found that only minor adverse events, mainly mild gastrointestinal symptoms (e.g. diarrhoea), occur in 3% of the patients. The incidence of adverse effects in the treatment groups was never higher than in the placebo groups for all 28 trials (Vlachojannis et al 2008).

## SIGNIFICANT INTERACTIONS

Devil's claw was previously found to moderately inhibit cytochrome P450 enzymes (CYP2C9, 2C19, 3A4) in vitro (Unger & Frank 2004); however a subsequent study found no significant interactions when testing 10 different commercial devil's claw preparations (Modari et al 2011). An in vitro study found commercial preparations of devil's claw and pure harpagoside upregulated P-glycoprotein in a dose-dependent manner (Romiti et al 2009); however the effect has not been tested in vivo. In contrast to NSAIDs, devil's claw does not affect platelet function (Izzo et al 2005).

## Warfarin

Rare case reports suggest that devil's claw may potentiate the effects of warfarin, but the reports are mostly inconclusive (Argento et al 2000, Heck et al 2000, Izzo et al 2005). Clinical testing would be required to confirm a possible interaction.

## Anti-arrhythmic drugs

Theoretical interaction exists when the herb is used in high doses; however, clinical testing is required to determine significance — observe patients taking concurrent antiarrhythmics (Fetrow & Avila 1999).

### Practice points/Patient counselling

- Devil's claw reduces pain and inflammation and is a useful treatment in arthritis and back pain, according to controlled studies.
- The anti-inflammatory action appears to be different to that of NSAIDs and has not been fully elucidated. There is also preliminary evidence of a chondroprotective effect.
- Preliminary research suggests that it is best to take devil's claw between meals, on an empty stomach.
- Devil's claw appears to be relatively safe but should not be used in pregnancy and should be used with caution in people with ulcers or gallstones or in those taking warfarin.

## CONTRAINDICATIONS AND PRECAUTIONS

Use cautiously in patients with gastric and duodenal ulcers, gallstones or acute diarrhoea, as devil's claw may cause gastric irritation (Blumenthal et al 2000).

## PREGNANCY USE

Devil's claw is not recommended in pregnancy, as it has exhibited oxytocic activity in animals.

## ! PATIENTS' FAQs

### What will this herb do for me?

Devil's claw is a useful treatment for arthritis and back pain. It may also increase appetite and improve digestion and dyspepsia.

### When will it start to work?

Results from studies suggest that pain-relieving effects will start within 4–12 weeks reaching maximum pain relief after 3–4 months (Chrubasik S et al 2007, Thanner et al 2008).

### Are there any safety issues?

Devil's claw should be used cautiously by people with gallstones, diarrhoea, stomach ulcers and those taking the drug warfarin. It is also not recommended in pregnancy.

## Dunaliella salina

**HISTORICAL NOTE** Microalgae are nutrient-dense natural foods and medicines that have been used for thousands of years by the Aztecs, some African and Asian peoples and South Pacific islanders. It has been suggested that gram for gram, microalgae are the most nutrient-dense food on earth (Passwater & Solomon 1997) with minimal indigestible structures, in contrast to higher plants or animals, which typically have less than half their dry weight being nutritionally useful (Bruno 2001). Examples of edible algae include *Spirulina*, *Chlorella* and *Dunaliella salina*. The last may be the most nutrient dense of the three, primarily due to its extremely high concentration of carotenoid antioxidants. The high carotenoid content imparts a pink colouring to salt lakes where the microalgae flourish. This colour is amplified through the food chain to give the pink colour to brine shrimp and flamingos (Skinner & Tomkins 2008).

### COMMON NAME

*Dunaliella salina*

### BOTANICAL NAME/FAMILY

*Dunaliella salina* and *Dunaliella bardawil* are considered to be the same species (Borowitzka & Borowitzka 1988).

### OTHER NAMES

Red marine phytoplankton (microalgae)

### PLANT PARTS USED

*Dunaliella salina* is a marine phytoplankton that is a unicellular, biflagellate, soft-walled, green alga that lives in salt-water lakes and coastal waters. As a phytoplankton, *D. salina* can be considered a whole plant; yet, it has a soft cell membrane that makes it easily digestible, compared with other microalgae that have hard cell walls (Ben-Amotz & Avron 1983). *D. salina* is one of the most salt-tolerant life forms known and is found in hypersaline waters generally >20% (salt lakes and evaporation ponds of salt works). It has a wide tolerance to environmental extremes, especially salinity, pH (pH 1–11), temperature (>45°C) and high ultraviolet (UV) exposure (Borowitzka & Borowitzka 1988). To cope

with these extreme environments, *D. salina* produces very high levels of carotenoids in the chloroplast (organelles that conduct photosynthesis) as well as maintaining a high mineral content.

### CHEMICAL COMPONENTS

*D. salina* contains a range of macro- and micronutrients, including amino acids, lipids and fatty acids, carbohydrates, chlorophyll, vitamins and minerals, along with very high levels of carotenoids. As a phytoplankton that grows in seawater, *D. salina* is rich in many trace minerals. *D. salina* is also extremely high in carotenoids and, while it contains over 500 different carotenoids, including alpha-carotene, lutein, zeaxanthin and cryptoxanthum, it is the richest known natural source of beta-carotene (USDA 2005), which can make up to 8% of its dry weight (Ben-Amotz & Avron 1983). *D. salina* is therefore commonly used as a source of natural beta-carotene or mixed carotenoids in nutritional supplements (see *Beta-carotene* monograph).

Unlike synthetic (all-*trans*) beta-carotene, the beta-carotene from *D. salina* is composed of near-equal amounts of the all-*trans* and 9-*cis* stereoisomers, which differ in their physicochemical features and antioxidative activity. The 9-*cis* isomer is

considered to be one of nature's most powerful antioxidants and provides much greater bioavailability and antioxidant activity than synthetic beta-carotene supplements (Ben-Amotz & Levy 1996, Ben-Amotz et al 1989, Stahl et al 1993) (see *Beta-carotene* monograph).

*D. salina* is the richest natural source known of the 9-*cis* isomer (Ye et al 2008) and it is believed that exposure to reactive oxygen species triggers extensive carotenoid accumulation in *D. salina* (Ye et al 2008). There are a number of biotechnology processes aimed at extracting its natural beta-carotene content (Lamers et al 2008, Raja et al 2007a). As a supplement, *D. salina* can be produced in either the whole dried (unwashed) form that contains high levels of minerals or a washed (desalinated) form that has higher carotenoid levels and lower mineral levels. Recently, advances in production technology have allowed the whole dried *D. salina* biomass with its full range of nutrients and minerals to become commercially available in supplement form (Tracton & Bobrov 2005).

## MAIN ACTIONS

### Antioxidant and anti-inflammatory

Animal studies suggest that natural beta-carotene from *D. salina* can protect rats against central nervous system oxygen toxicity (Bitterman et al 1994), whole-body irradiation (Ben-Amotz et al 1996) and gastrointestinal inflammation (Lavy et al 2003, Takenaka et al 1993). It is suggested that the gastric cytoprotective effect may depend on the amount of beta-carotene accumulated. A study that fed rats with diets containing up to 0.1% beta-carotene for 2 weeks using dry *D. salina*, purified natural beta-carotene from *D. salina* or synthetic beta-carotene found that the rats showed higher accumulations of the algal beta-carotene than of the synthetic all-*trans* beta-carotene and that the *D. salina* and algal beta-carotene supplementation both significantly decreased the gastric mucosal lesions after water immersion stress, while synthetic beta-carotene did not (Takenaka et al 1993).

### Cytoprotection

Animal studies suggest that supplementation with *D. salina* has hepatoprotective effects and can protect rats against laboratory models of liver toxicity to a significantly greater degree than synthetic beta-carotene. This is most likely due to the presence of various isomeric forms of carotene and other oxygenated carotenoids (Chidambara Murthy et al 2005, Vanitha et al 2007). *D. salina* supplementation has also been found to protect rats against laboratory-induced fibrosarcoma (Raja et al 2007b). Further studies have shown that prefeeding rats with *D. salina* ameliorated acid-induced enteritis (Lavy et al 2003). A double-blind trial in humans found that a single dose of natural beta-carotene from *D. salina* reduced the severity, but not the incidence, of postprocedural

pancreatitis after endoscopic retrograde cholangiopancreatography (Lavy et al 2004).

### Anti-atherogenic

Supplementation with *D. salina* powder inhibited atherogenesis in animal models using high-fat diet-fed low-density lipoprotein (LDL) receptor knockout mice. Reductions of plasma cholesterol of 40–63% and atherosclerotic lesions of 60–83%, along with reduced liver fat accumulation, liver inflammation and mRNA levels of inflammatory genes, were also observed. By administering *D. salina* powder containing different levels of 9-*cis* and all-*trans* beta-carotene isomers, these effects were shown to be 9-*cis*-dependent (Harari et al 2008).

### Photoprotection

The red, orange and yellow colours of *D. salina* preferentially absorb UV light; therefore, ingestion of the microalgae adds pigmentation to the skin which helps to absorb UV light and reduce the effects of UV-induced erythema (sunburn) (Heinrich et al 2003). The beta-carotene in *D. salina* demonstrates photoprotective activity in plant cells and human skin (Heinrich et al 2003, Stahl et al 2000) and supplementation with *D. salina* was found to exhibit potent protective effects on UVB radiation-induced corneal oxidative damage in mice (Tsai et al 2012).

## OTHER ACTIONS

### Detoxification

*D. salina* contains chlorophyll, along with other vitamins and minerals such as selenium and magnesium that are believed to aid in detoxification (Murray 1997). A small cohort study found that 14 weeks of supplementation with 3 g/day of *D. salina* powder produced marked reduction in hair tissue levels of various heavy metals. These findings await further confirmation in controlled trials (Bobrov et al 2008).

### Antibacterial

A study on the antimicrobial activity of different pressurised liquid extracts obtained from *D. salina* found that 15 different volatile compounds as well as several fatty acids (mainly palmitic, alpha-linolenic and oleic acids) may be responsible for the observed antibacterial activity (Herrero et al 2006).

### Antiproliferative

An ethanol extract of *D. salina* has been found to have antiproliferative effects and induce cell cycle G0/G1 arrest and apoptosis of human lung cancer (Sheu et al 2008) and prostate cancer cells (Jayapriyan et al 2013). An ethanolic extract of *D. salina* has also been found to inhibit proliferation of rat and human smooth-muscle cells, suggesting a possible role in preventing restenosis following balloon angioplasty (Sheu et al 2010).

## Chemoprevention

There has been considerable research into carotenoids and chemoprevention. Many studies have shown the correlation between high intakes of natural beta-carotene from food and a decreased risk in the carcinogenesis of stomach, prostate and breast cancers (see *Beta-carotene* monograph). It is likely that natural beta-carotene from *D. salina* has different biological activity from synthetic beta-carotene — while synthetic beta-carotene has been shown to increase the risk of lung cancer in some populations, this has not been demonstrated with natural beta-carotene. As such, it is possible that long-term usage of *D. salina* may also decrease the risk of various cancers; however, this has yet to be investigated.

## CLINICAL USE

*D. salina* is nature's richest source of natural beta-carotene and as such has similar uses to beta-carotene. To date, most of the clinical research on *D. salina* has been conducted with beta-carotene-containing extracts rather than the whole organism. This research suggests that potential benefits of supplementation with *D. salina* include prevention of cancer and cardiovascular disease, protection against sun damage and photosensitivity, supporting healthy eye, skin and immune function, providing benefits in asthma, macular degeneration and promotion of overall health and wellbeing (see *Beta-carotene* monograph). Human studies on *D. salina* extracts suggest many positive clinical effects, mainly due to its antioxidant activity.

## Diabetes

A reduction in oxidative injury (Levy et al 1999) along with normalisation of LDL oxidation (Levy et al 2000) was reported in two studies involving supplementation with a *D. salina* extract containing 60 mg/day of beta-carotene given for 3 weeks in patients with non-insulin-dependent diabetes mellitus.

## Radiation exposure

A study of 709 children with long-term exposure to radiation during and after the Chernobyl accident found that 3-month supplementation with 40 mg of beta-carotene powder from *D. salina* reduced serum markers for oxidation and acted as a lipophilic antioxidant and radioprotector (Ben-Amotz et al 1998).

## Photoprotection

*D. salina* extracts protect the skin from sunburn and sun damage due to increased protective pigmentation of the skin along with reduced susceptibility to sunburn, according to a clinical study (Heinrich & Tronnier 1998, Stahl et al 1993). The placebo-controlled ( $n = 24$ ) trial found 12 weeks of supplementation with 24 mg/day of *Dunaliella*-derived carotenoids significantly increased protection from sunburn (Heinrich et al 2003).

## Exercise-induced asthma

A double-blind, placebo-controlled trial involving 38 subjects found that 1-week supplementation with *D. salina* provided a protective effect for patients with exercise-induced asthma (Neuman et al 1999).

### Practice points/Patient counselling

- *D. salina* is a marine phytoplankton that grows in extreme environments and is nature's richest source of natural beta-carotene.
- *Dunaliella* is a 'whole-food' supplement that provides a range of trace minerals and other nutrients that provide antioxidant, anti-inflammatory and photoprotection activity.
- Supplementation with *D. salina* may assist in the prevention of a range of conditions, including cardiovascular disease, some cancers and exercise-induced asthma.
- The antioxidants in *D. salina* may provide some protection against exposure to the sun and other sources of radiation.

## DOSAGE RANGE

1–3 g of whole dried *D. salina* powder (which contains around 1–2% beta-carotene) when taken as a supplement.

## ADVERSE REACTIONS

*D. salina* is classified as an edible species of microalgae. While no human toxicology studies have been carried out, there are no reported adverse effects from consumption of the whole microalgae or beta-carotene extract from *D. salina* in human clinical studies. An orange or yellow skin colouration (carotenoderma) may become evident after a few months of consumption but this is harmless and reversible on discontinuation (see *Beta-carotene* monograph).

## SIGNIFICANT INTERACTIONS

No known interactions at this time.

### PREGNANCY USE

While *D. salina* is considered safe, there is insufficient information to guide its use in pregnancy.

### PATIENTS' FAQs

#### What will it do for me?

*D. salina* provides a source of natural beta-carotene and minerals that may promote energy and vitality, enhance skin health and appearance and assist in healthy ageing. As a rich source of beta-carotene, *D. salina* acts to supplement vitamin A levels without the risk of vitamin A toxicity. It may be used to assist in maintaining healthy skin, eyes and immune function, preventing cancer and cardiovascular

disease and reducing oxidative stress. *D. salina* may also provide photoprotection, detoxification of heavy metals and protective effect for patients with exercise-induced asthma.

#### When will it start to work?

Effects may be observable within 1 week but may take up to 3 months to obtain full benefits, while benefits of long-term supplementation on disease prevention may take many years to become evident. *D. salina* should be taken with meals or other dietary fats to increase the bioavailability of carotenoids.

#### Are there any safety issues?

*D. salina* is considered non-toxic. Large doses over long periods of time may produce carotenoderma, which is a harmless and reversible yellow-orange discolouration of the skin.

#### STORAGE

*D. salina* should be stored in airtight containers or capsules away from direct sunlight, as carotenoids will oxidise on exposure to air and light.

## Echinacea

**HISTORICAL NOTE** Echinacea was first used by Native American Sioux Indians centuries ago as a treatment for snakebite, colic, infection and external wounds, among other things. It was introduced into standard medical practice in the United States during the 1800s as a popular anti-infective medication, which was prescribed by eclectic and traditional doctors until the 20th century. Remaining on the national list of official plant drugs in the United States until the 1940s, it was produced by pharmaceutical companies during this period. With the arrival of

antibiotics, echinacea fell out of favour and was no longer considered a 'real' medicine for infection. Its use has re-emerged, probably because we are now in a better position to understand the limitations of antibiotic therapy and because there is growing public interest in self-care. The dozens of clinical trials conducted overseas have also played a role in its renaissance.

## COMMON NAME

Echinacea

## OTHER NAMES

*Echinacea angustifolia* — American coneflower, black sampson, black susans, coneflower, echinaceawurzel, Indian head, kansas snakeroot, purple coneflower, purpursonnenhutkraut, racine d'echinacea, *Rudbeckia angustifolia* L., scurvy root, snakeroot

*E. purpurea* — *Brauneria purpurea* (L.) Britt., combflower, purple coneflower, red sunflower

*Rudbeckia purpurea* L. — *E. pallida*, *Brauneria pallida* (Nutt.) Britt., pale coneflower, *Rudbeckia pallida* Nutt.

## BOTANICAL NAME/FAMILY

*Echinacea* species (family Asteraceae [Compositae])

The name 'echinacea' generally refers to several different plants within the genus — *E. purpurea*, *E. pallida* and *E. angustifolia*.

## PLANT PARTS USED

Root, leaf and aerial parts

## CHEMICAL COMPONENTS

The most important constituents with regard to pharmacological activity are the polysaccharides, caffeic acid derivatives, alkylamides, essential oils and polyacetylenes, although there are other potentially active constituents, as well as a range of vitamins, minerals, fatty acids, resins, glycoproteins and sterols (Pizzomo & Murray 2006). Cynarin, a potential immunosuppressant and CD28 ligand, was also identified in *E. purpurea* (Dong et al 2006). Constituent concentrations vary depending on the species, plant part and growing conditions. With regard to the final chemical composition of an echinacea-containing product, the drying and extraction processes further alter chemical composition. Therefore, the pharmacological effects of an echinacea product depend very much on which constituents are present and their relative ratios. This is outlined further in the following sections.

## Pharmacokinetics

The absorption of *E. purpurea* alkylamides from lozenges is rapid and linear (Guiotto et al 2008).

A clinical study with healthy volunteers showed that, following ingestion of tablets containing ethanolic echinacea extract, alkylamides were detectable in plasma 20 minutes after ingestion, whereas caffeic acid derivatives were not detectable in the plasma

at any time after tablet ingestion (Matthias et al 2005a). A further study by the same authors showed that there was no significant difference in the bio-availability of alkylamides from a liquid and solid oral dosage form of an echinacea product (mixture of *E. purpurea* and *E. angustifolia*), with  $T_{max}$  reached at 20 and 30 minutes, respectively (Matthias et al 2007b). Two other studies reported that, 30–45 minutes following administration of *E. purpurea* products (Echinaforce tincture, tablets, spray) containing milligram amounts of alkylamides, plasma concentrations of alkylamides of about 0.07–0.40 ng/mL were recorded (Woelkart et al 2006, 2008b), and effects on the immune markers were observed 23 hours after oral administration (Woelkart et al 2006).

Furthermore, tetraene alkylamides, present in *E. angustifolia* and *E. purpurea*, are metabolised by CYP450 enzymes (Matthias et al 2005b). In addition, the metabolism of tetraene alkylamides can be significantly decreased by monoene alkylamides that are only found in *E. angustifolia* (Matthias et al 2005b). A recent study found that the human CYP450 enzymes involved in the metabolism of one of the most abundant alkylamides, *N*-isobutyldodeca-2E,4E,8Z,10Z-tetraenamide, are CYP2E1, CYP2C9 and CYP1A2 (Toselli et al 2010).

## MAIN ACTIONS

Due to the wide assortment of chemical constituents found in echinacea, it has varied pharmacological effects.

### Immunomodulator

Experimental results suggest that echinacea functions more as a modulator of the immune response rather than as a straightforward immune stimulant. This is well illustrated by a recent study conducted by Ritchie et al (2011), which showed that the response to treatment with the product Echinaforce was dependent on subjects' baseline constitution. For example, echinacea treatment induced an additional formation of antiviral interferon-gamma, chemotactic molecules (interleukin-8 [IL-8]) or monocyte chemoattractant protein-1 in subjects with a low initial production at baseline (from +18 to +49%). In contrast, subjects with higher levels of these factors at baseline experienced no further increase after treatment (Ritchie et al 2011). Similarly, volunteers reporting higher stress levels or higher susceptibility to cold infections have reacted to echinacea treatment with improved immune responses (Schapowal 2013).

The immunomodulator activity of echinacea has been the subject of countless studies and appears to be the result of multiple mechanisms.

Overall, the fresh-pressed leaf juice of *E. purpurea* and alcoholic extracts of the roots of *E. pallida*, *E. angustifolia* and *E. purpurea* have been shown to act mainly on non-specific cellular immunity (Blumenthal et al 2000). It was reported that no one single constituent is responsible for the herb's immunomodulating action, with the most important elements being polysaccharides, glycoproteins, alkaloids and flavonoids (Ernst 2002). More recent research indicates that the water-soluble compounds (such as polysaccharides) rather than lipophilic constituents are chiefly responsible for the immunostimulatory activity (Pillai et al 2007).

Macrophage activation has been well demonstrated, as has stimulation of phagocytosis (Barrett 2003, Bauer et al 1988, Groom et al 2007, Pugh et al 2008, Zhai et al 2009a). Orally administered root extracts of echinacea have produced stronger effects on phagocytosis than aerial parts, with *E. purpurea* roots producing the greatest effect, followed by that of *E. angustifolia* and *E. pallida* (Pizzorno & Murray 2006).

The activation of polymorphonuclear leucocytes and natural killer (NK) cells and increased numbers of T-cell and B-cell leucocytes have also been reported for echinacea (Groom et al 2007, Zhai et al 2007a).

Echinacea stimulates cytokine (Altamirano-Dimas et al 2007, Brush et al 2006, Dong et al 2006, 2008, Farinacci et al 2009, Sharma et al 2006, Zhai et al 2007a, Zwickley et al 2007) and chemokine production (Wang et al 2006, 2008).

Moreover, various echinacea species stimulate nitric oxide (NO) production in vitro (Classen et al 2006, Sullivan et al 2008).

Contradictory results were obtained for tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ) production, possibly due to the different preparations used producing different effects. In one study, echinacea significantly increased TNF- $\alpha$  production (Senchina et al 2006), whereas no effects on TNF- $\alpha$  were observed for all echinacea species in another study (McCann et al 2007), and in a third study, NF- $\kappa$ B expression and TNF- $\alpha$  levels decreased in non-stimulated macrophages following echinacea treatment (Matthias et al 2007a).

In lipopolysaccharide-stimulated (endotoxin) cells, echinacea inhibited NF- $\kappa$ B, TNF- $\alpha$ , NO and cytokine production, with different alkylamides exerting different effects (Matthias et al 2007a, 2008, Raduner et al 2006, Sasagawa et al 2006, Stevenson et al 2005, Woelkart et al 2006, Zhai et al 2007a). Another study found that the *E. purpurea* root extract (polysaccharide-rich) increased specific surface biomarkers whereas the leaf extract (alkylamide-rich) inhibited their expression. Moreover, IL-6 and TNF- $\alpha$  production was increased due to the root extract, but unchanged following exposure to the leaf extract (Benson et al 2010).

Similarly, a more recent study found that different alkylamides either suppressed or stimulated influenza A-induced secretion of cytokines,

chemokines and prostaglandin  $E_2$  from RAW264.7 macrophage-like cells (Cech et al 2010). Unidentified constituents from echinacea have been shown to stimulate inositol-1,4,5-trisphosphate receptor and phospholipase C mediation of cytosolic  $Ca^{2+}$  levels in non-immune mammalian cells (Wu et al 2010).

### Anti-inflammatory

Studies indicate that alcohol extracts of all three echinacea species (*E. angustifolia*, *E. purpurea* and *E. pallida*) exert significant anti-inflammatory activity (Raso et al 2002, Zhai et al 2009a). The result is due to multiple constituents acting with multiple mechanisms. The alkylamide fraction inhibits inducible nitric oxide synthase (iNOS) and the caffeic acid fraction enhances arginase activity (Zhai et al 2009a). In vivo tests further identify anti-inflammatory effects also for *E. angustifolia* and *E. pallida* when applied topically (Speroni et al 2002, Tragni et al 1985, Tubaro et al 1987).

A recent study reports on the selective induction of pro- and anti-inflammatory cytokines by low-dose *E. purpurea* (Kapai et al 2011). Similarly, anti-inflammatory effects have been identified for the essential oils of *E. purpurea* extract, with proinflammatory cytokines such as IL-2, IL-6 and TNF- $\alpha$  being reduced in the blood of treated mice (Yu et al 2013).

### COX-1/COX-2

Alkylamides from the roots of *E. purpurea* partially inhibit both cyclooxygenase-1 (COX-1) and COX-2 isoenzymes, thus decreasing prostaglandin  $E_2$  levels (Clifford et al 2002, LaLone et al 2007, Raman et al 2008). Several alkylamides isolated from a  $CO_2$  extract of the roots of *E. angustifolia* have been shown to inhibit COX-2-dependent prostaglandin  $E_2$  formation, although COX-2 mRNA and protein expression were not inhibited, but rather increased (Hinz et al 2007). A 2009 study further confirmed that certain alkylamides and ketones present in various *Echinacea* species were the key anti-inflammatory contributors inhibiting prostaglandin  $E_2$  production (LaLone et al 2009).

### Cannabinoid and TRPV1 receptor interaction

The alkamides from echinacea also modulate TNF- $\alpha$  mRNA expression in human monocytes/macrophages via the cannabinoid type 2 (CB2) receptor, thus identifying a possible mode of action for its immunomodulatory activity (Raduner et al 2006, Woelkart & Bauer 2007). Two alkylamides, which bind to the CB2 receptor more strongly than endogenous cannabinoids and activate it, have been classified as a new class of cannabinomimetics (Gertsch et al 2006). It was found that some of the alkylamides in echinacea self-assemble into micelles in aqueous solution, which then determines their binding to the CB2 receptor (Raduner et al 2007). In a subsequent study, Chicca et al (2009) showed that ethanolic *E. purpurea* root and herb extracts and

specific *N*-alkylamides within produce synergistic pharmacological effects on the endocannabinoid system in vitro by simultaneously targeting the CB2 receptor, endocannabinoid transport and degradation. In contrast, ketoalkenes from *E. pallida* did not interact with cannabinoid receptors (Egger et al 2008).

Ethanol extracts from echinacea roots showed potent agonist activity on TRPV1, a mammalian pain receptor. The compounds involved in the TRPV1 receptor activation differ from those involved in the inhibition of prostaglandin E<sub>2</sub> production (Birt et al 2008).

### Antiviral activity

Four different *Echinacea* species (*E. angustifolia*, *E. purpurea*, *E. tennessensis* and *E. pallida*) increase the amount of iNOS protein, but to varying degrees. The results suggest that any potential antiviral activities of *Echinacea* spp. extracts are not likely to be mediated through large inductions of type 1 interferon, but may involve iNOS (Senchina et al 2010). *E. purpurea* extract Echinaforce inhibited the induction of multiple proinflammatory cytokines by respiratory viruses (Sharma et al 2009). The same authors showed in a three-dimensional tissue model of normal human airway epithelium that this specific *E. purpurea* extract, Echinaforce, reversed rhinovirus type 1A (RV1A)-stimulated mucopolysaccharide inclusion in goblet cells, RV1A-induced mucin secretion and the RV1A-stimulated secretion of proinflammatory cytokines (Sharma et al 2010).

### Herpes simplex virus

Extracts of eight taxa of the genus *Echinacea* were found to have antiviral activity against herpes simplex virus type 1 (HSV-1) in vitro when exposed to visible and ultraviolet A light (Binns et al 2002). Antiviral activity was confirmed for *E. purpurea* extracts in 2008, with evidence suggesting that polyphenolic compounds other than the known HIV inhibitor, cichoric acid, may also be involved (Birt et al 2008). A 2010 study found that hydroalcoholic *E. pallida* extracts interfere with free HSV-1 or HSV-2 and pressed juice is able to interact with HSV-1 or HSV-2 inside and outside the cell, as well as to protect cells against viral infection, probably by interfering with virus attachment (Schneider et al 2010). Another study in mice showed that *E. purpurea* polysaccharide reduces the latency rate in HSV-1 infections when supplied prior to infection (Ghaemi et al 2009).

### Antibacterial activity

An in vitro study showed that Echinaforce inhibits the proliferation of *Propionibacterium acnes* and decreases bacterial-induced inflammation (Sharma et al 2011). Antiadhesive activity against *Campylobacter jejuni* was found for two different *Echinacea* species, with *E. purpurea* extract displaying a higher activity than *E. angustifolia*. The extracts used were of the MediHerb brand (Bensch et al 2011). The

standardised extract of *E. purpurea* (Echinaforce) readily inactivated *Streptococcus pyogenes*, *Haemophilus influenzae* and *Legionella pneumophila* and also reversed their proinflammatory responses. *Staphylococcus aureus* (methicillin-resistant and sensitive strains) and *Mycobacterium smegmatis* were less sensitive to the bactericidal effects of *Echinacea*; however, their proinflammatory responses were still completely reversed. In contrast, some other pathogens tested, including *Candida albicans*, were relatively resistant (Sharma et al 2010).

### Cytochromes and P-glycoprotein

Earlier research suggested caution when using echinacea with anticancer and antiretroviral agents (Meijerman et al 2006, van den Bout-van den Beukel et al 2006), due to possible effects on drug-metabolising and transporting enzymes. However, most of the warnings were based on in vitro studies, which now appear to have little or no clinical relevance in vivo (Heinrich et al 2008, Huntimer et al 2006, Izzo 2012, Unger 2010). Moreover, recent research found no pharmacokinetic interactions between echinacea and different antiretrovirals and warfarin (Abdul et al 2010, Hermann & von Richter 2012).

In fact, clinical studies found that echinacea has no clinically significant effect on CYP1A2, CYP2D6, CYP2E1 or CYP3A4 activity (Gurley et al 2004). This was demonstrated for the *E. purpurea* extract Echinaforce (Modarai et al 2011) and 400 mg of powdered dried root of *E. purpurea* taken four times daily for 8 days (Gorski et al 2004). Moreover, studies by Gurley et al found no effects on CYP2D6 in healthy volunteers after echinacea (*E. purpurea*) use for 14 days (Gurley et al 2008a).

To further confirm no clinically significant effects of *E. purpurea* on CYP3A4, two more recent studies using a dose of 500 mg three times daily found no change to the pharmacokinetics of lopinavir-ritonavir (CYP3A4 substrates) in healthy people (Penzak et al 2010) and darunavir-ritonavir in HIV patients (Moltó et al 2011).

In another study investigating echinacea 1275 mg, four times daily (capsules containing a mixture of 600 mg of *E. angustifolia* roots and 675 mg of *E. purpurea* root; standardised to contain 5.75 mg of total alkylamides per tablet) with warfarin in 12 healthy male subjects (single oral dose of 25 mg warfarin or received this dose after 14 days of pre-treatment with echinacea) significantly reduced plasma concentrations of S-warfarin and no change for R-warfarin were reported. Warfarin pharmacodynamics, platelet aggregation and baseline were not significantly affected by echinacea (Abdul et al 2010).

Differences between in vitro and clinical results were also found among studies investigating effects on P-glycoprotein, indicating that the effect on P-glycoprotein is not clinically significant (Hellum & Nilsen 2008). A 14-day clinical trial of 18 healthy volunteers detected no significant alteration to

digoxin pharmacokinetics for *E. purpurea* extract consisting of 195 mg aerial, root and seed parts, and 72 mg *E. angustifolia* root parts which were standardised to contain 2.2 mg isobutylamides per capsule (Gurley et al 2008b).

#### **Clinical note — Echinacea and cannabinoid receptors**

Alkylamides found in echinacea show a structural similarity with anandamide, an endogenous ligand of cannabinoid receptors. CB1 and CB2 receptors belong to G-protein-coupled receptors. CB2 receptors are believed to play an important role in various processes, including metabolic dysregulation, inflammation, pain and bone loss. Compounds such as cannabinoids, which act on these receptors, are becoming more and more popular as they represent new targets for drug discovery. A well-known plant cannabinoid is delta-9-tetrahydrocannabinol, a constituent of *Cannabis sativa*.

## **OTHER ACTIONS**

### **Antioxidant**

Free radical scavenging activity can be attributed to numerous antioxidant constituents found in echinacea, such as vitamin C, beta-carotene, flavonoids, selenium and zinc. One in vitro study reported that the antioxidant activity exerted by echinacea tincture was significantly greater than that observed for *Ginkgo biloba* (Masteikova et al 2007).

### **Anaesthetic**

The alkylamides exert a mild anaesthetic activity, which is typically experienced as a tingling sensation on the tongue (Pizzorno & Murray 2006).

### **Apoptosis**

Apoptosis, or programmed cell death, is a physiological, active cellular suicide process that can be modulated by various stimuli, including hormones, cytokines, growth factors and some chemotherapeutic agents. Research has been undertaken with the three clinically used *Echinacea* spp., several key constituents and different herbal fractions to investigate mechanisms of action, strength of activity and specificity of effect.

The *n*-hexane extracts of all three *Echinacea* spp. exert cytotoxic effects on human pancreatic and colon cancer cells in a concentration- and time-dependent manner, with *E. pallida* being the most active species (Aherne et al 2007). The effects were partially due to apoptosis by significantly increasing caspase-3/7 activity (Chicca et al 2007, 2008). Cytotoxic effects of the *n*-hexane extract of *E. angustifolia* on lung cancer cells have also been reported (Ramirez-Erosa et al 2007). However, in comparison to other herbal medicines such as wild yam and dichora root, echinacea exhibits only weak tumoricidal effects (Mazzio & Soliman 2009).

Isolated hydroxylated polyacetylenes and polyenes (more hydrophilic) from *E. pallida* are less cytotoxic than the more hydrophobic compounds (Pellati et al 2006).

It has been shown that the effects of isolated constituents on cell proliferation vary. In cervical and breast cancer cells treated with doxorubicin and *E. purpurea* extract or isolated echinacea constituents (i.e. cynarin, chicoric acid), the ethyl acetate fraction of echinacea extract and chicoric acid increased breast cancer cell growth and cynarin enhanced the growth of cervical cancer cells. However, cynarin showed antiproliferative effects on breast cancer cells (Huntimer et al 2006).

### **Chemoprevention**

Several experimental studies with mice have found that treatment with echinacea reduces the incidence of tumour development (Brousseau & Miller 2005, Hayashi et al 2001, Miller 2005). Most research has been conducted with *E. purpurea*. In a study with gamma-irradiated mice, *E. purpurea* was able to show radioprotection (use before radiation) as well as radio-recovery effectiveness (Abouelella et al 2007). One study reported that *E. angustifolia* can stimulate mammary epithelial cell differentiation (Starvaggi Cucuzza et al 2008).

An animal study showed that the administration of *E. purpurea* extract to rats with hyperplasia for 4 and 8 weeks gradually and significantly reduced the prostate mass and reversed the degenerative changes in the structure of the prostate gland (Skaudickas et al 2009).

### **Immunological adjuvants**

In vitro studies in human lymphocytes activated with different lectins showed that using *E. purpurea* root extract in addition to individual lectins increased lymphoproliferation, which would suggest adjuvant activity (Chaves et al 2007). In mice, no adjuvant activity was detected for lipophilic, neutral and acidic extracts of echinacea (Gaia Herbs) (Ragupathi et al 2008).

### **Antifungal activity**

Hexane extracts of echinacea have phototoxic antimicrobial activity against fungi (Binns et al 2000). The extracts inhibited growth of yeast strains of *Saccharomyces cerevisiae*, *Candida shehata*, *C. kefyr*, *C. albicans*, *C. steatulytica* and *C. tropicalis*. A recent study reports on antifungal activities of echinacea against *S. cerevisiae* and *Cryptococcus neoformans* by disrupting the fungal cell wall structure (Mir-Rashed et al 2010).

### **Antiparasitic**

Aqueous extracts of echinacea showed activity against gastrointestinal nematodes in goats and pigs (Lans et al 2007). Four preparations of echinacea, with distinct chemical compositions, inhibited the proliferation of *Leishmania donovani*, *Leishmania major* and *Trypanosoma brucei* and at least one extract seems

to reverse the proinflammatory activity of *L. donovani* (Canlas et al 2010).

### Anxiolytic

The anxiolytic potential of five different echinacea preparations (*E. purpurea*: two different root and one herb extract; *E. angustifolia*: two different root extracts) were tested in a rat model. Three of these decreased anxiety but two of them had a very narrow effective dose range. One extract, *E. purpurea* root extract (70% ethanol v/v), decreased anxiety within a wide dose range (3–8 mg/kg) in three different tests of anxiety. These findings suggest for the first time that certain preparations have a considerable anxiolytic potential (Haller et al 2010).

### Hypoglycaemic

Alkylamides and fatty acids isolated from an *n*-hexane extract of the flowers of *E. purpurea* were found to activate peroxisome proliferator-activated receptor gamma without stimulating adipocyte differentiation. This suggests that these compounds have the potential to manage insulin resistance and type 2 diabetes (Christensen et al 2009).

### CLINICAL USE

Clinical trials using echinacea have used various preparations, such as topical applications, homeopathic preparations, injectable forms and oral dose forms, characteristics that should be noted when reviewing the data available. Overall, the majority of clinical studies performed in Europe have involved a commercial product known as Echinacin (Madaus, Germany), which is a hydrophilic product prepared from the stabilised juice of fresh *E. purpurea* tops (aerial parts). However, other preparations have also been tested, such as the fresh plant tincture of the whole plant of *E. purpurea* and several preparations manufactured by an Australian company, Mediherb. Due to the different species, plant parts and extraction processes used, the chemical constituent profiles of the different preparations will vary, which may partly account for the differences in test results.

### Upper respiratory tract infections

Clinical studies investigating the use of various echinacea preparations in the treatment of upper respiratory tract infections (URTIs) have produced inconsistent results due to the use of different extracts and plant parts, *Echinacea* species, populations and study designs, making interpretation difficult. Overall, the most consistently positive results are obtained from preparations containing *E. purpurea* and *E. angustifolia* for reducing symptoms and possibly the duration of infection, when used as soon as symptoms arise. However, supportive evidence has also accumulated for the use of echinacea as a preventive approach.

In 2000, a Cochrane review was published that had assessed the evidence available from 16 clinical trials (eight treatment and eight prevention) involving a total of 3396 subjects (Melchart et al 2000),

and it concluded that some echinacea preparations may be better than placebo, with a majority of studies reporting favourable effects.

Certain facets of quality of life improve with echinacea treatment during an UR TI, according to a 2006 review, suggesting that treatment provides symptom relief and improved wellbeing (Gillespie & Coleman 2006). A more recent Cochrane systematic review (Linde et al 2009) evaluated data from 16 trials (up to October 2007). While reviewers reported that evaluation was difficult because of the heterogeneity of preparations tested and variability of trial approaches, it was concluded that preparations based on the aerial parts of *E. purpurea* might be effective for the early treatment of colds in adults, although results are not completely consistent. Also, beneficial effects of other echinacea preparations (i.e. from *E. angustifolia* and *E. pallida*) may exist, but independently replicated rigorous randomised controlled trials (RCTs) are lacking (Linde et al 2009) and further research is needed (Woelkart et al 2008b).

A review including evidence until August 2009 concluded that there is moderate evidence to support the use of *E. purpurea* for treatment of the common cold (Nahas & Balla 2011). Treatment should be commenced at the first signs of infection (Schoop et al 2006a, Woelkart et al 2008a).

Since then a large placebo-controlled trial ( $n = 719$ ) testing an echinacea preparation made from the roots of *E. purpurea* and *E. angustifolia* (tablets containing the equivalent of 675 mg *E. purpurea* root standardised to 2.1 mg alkamides and 600 mg *E. angustifolia* root standardised to 2.1 mg alkamides: MediHerb brand) failed to find that treatment decreased the severity and duration of the common cold compared to placebo (Barrett et al 2010). Frequency of adverse effects did not differ between the placebo and echinacea group.

Commission E approves the use of *E. purpurea* herb as an immune system support in cases of respiratory and lower urinary tract infection, and *E. pallida* root as supportive treatment in influenza-like infections (Blumenthal et al 2000).

### Prevention

According to a 2009 Cochrane systematic review, the beneficial effects of echinacea preparations for the prevention of UR TIs may also exist, but require further investigation (Linde et al 2009). Since then, two new RCTs have been published confirming *E. purpurea* preparations are effective at reducing the incidence of the common cold (Jawad et al 2012, Tiralongo et al 2012).

An Australian study published by Tiralongo et al (2012) used a standardised echinacea tablet, known as Echinacea Premium, by MediHerb, which contained 112.5 mg *Echinacea purpurea* 6:1 extract (equivalent to 675 mg dry root) and 150 mg *Echinacea angustifolia* 4:1 extract (equivalent to 600 mg dry root), standardised to 4.4 mg alkylamides. The prevention study did not use artificial rhinovirus

inoculation, unlike previous studies, choosing to test the treatment effectiveness in preventing respiratory symptoms in air travellers. The RCT included 175 adults travelling overseas on a long-haul, economy flight for a period of 1–5 weeks. Treatment with the echinacea preparation before and during travel reduced the incidence of respiratory symptoms during travel compared to placebo (Tiralongo et al 2012).

A much larger RCT ( $n = 755$  healthy adults) found that compliant prophylactic use of *E. purpurea* (Echinaforce, produced by Bioforce, Switzerland, containing an alcoholic extract of *E. purpurea*, 95% herb and 5% roots) over a 4-month period reduced the total number of cold episodes, cumulated episode days and painkiller-medicated episodes, inhibited virally confirmed colds and especially prevented enveloped virus infections ( $P < 0.05$ ). Preventive effects increased with therapy compliance and adherence to the protocol (Jawad et al 2012).

Additionally, the treatment was considered well tolerated, with adverse event incidence similar to placebo and no induction of allergic reactions, leucopenia or autoimmune diseases (Schapowal 2013).

Previously, a 2006 meta-analysis by Schoop et al concluded that the odds of experiencing a clinical cold were 55% higher with placebo than with pressed *Echinacea purpurea* juice or hydroethanolic *E. angustifolia* extract following inoculation with rhinovirus. Schoop et al concluded that *E. purpurea* (pressed juice) and *E. angustifolia* (alcoholic extract) show the most promise as preventive treatment, although further investigation is still required to confirm this (Schoop et al 2006b). A 2007 meta-analysis published in *Lancet Infectious Diseases* was also positive and concluded that echinacea products from all species were beneficial in significantly decreasing the incidence (by 58%) and duration (by 1.4 days) of the common cold (Shah et al 2007b).

#### Athletes

Echinacea has been used to prevent exercise-induced immunosuppression (Gleeson et al 2001). Standardised *E. purpurea* extract (Echinaforce Forte) was effective in the prophylaxis, as well as treatment, of athletes in an open-label study ( $n = 80$ ) (Ross 2010, Schoop et al 2006a). It is believed that echinacea attenuates mucosal immune suppression known to occur with intensive exercise and can reduce the duration of URTIs that exercising people incur (Hall et al 2007).

Interestingly, a double-blind study of 24 healthy men (20–28 years of age) showed that oral echinacea supplementation resulted in significant increases in erythropoietin,  $VO_{2max}$  and running economy (Whitehead 2012).

#### Paediatric studies

Four randomised studies published after 2000 were conducted with children and generally produced

disappointing results (Cohen et al 2004, Spasov et al 2004, Taylor et al 2003, Weber et al 2005). A short review by Koenig and Roehr (2006) has also concluded that there is currently no evidence for the efficacy of *E. purpurea* in the treatment of URTI in children (Koenig & Roehr 2006). A 2008 clinical study with 60 children aged 12–60 months suggests that treating cold with *E. purpurea* in otitis-prone young children does not decrease the risk of acute otitis media, but is associated with a borderline increased risk of having at least one episode of acute otitis media during a 6-month follow-up compared to placebo (Wahl et al 2008).

No clear evidence of benefit in children was also reported in the most recent Cochrane reviews (Fashner et al 2012, Linde et al 2009).

#### Clinical note — Common cold symptoms: What is usual?

The pathogenesis of the common cold involves a complex interplay between replicating viruses and the host's inflammatory response (Heikkinen & Jarvinen 2003). The onset of cold symptoms after viral incubation varies considerably and depends on the causative virus. In experimental rhinovirus infections, the onset of symptoms has been reported to occur as soon as 10–12 hours after intranasal inoculation. Generally, the severity of the symptoms increases rapidly, peaks within 2–3 days of infection and decreases soon after. The mean duration of the common cold is 7–10 days, but in a proportion of patients some symptoms can still be present after 3 weeks. Symptoms typically start with a sore throat, which is soon accompanied by nasal stuffiness and discharge, sneezing and cough. The soreness of the throat usually disappears quickly, whereas the initial watery rhinorrhoea becomes thicker and more purulent over time and can be accompanied by fever, most usually in children. Other symptoms associated with the cold syndrome include hoarseness, headache, malaise and lethargy.

#### Acute sore throat

A multicentre, randomised, double-blind, double-dummy-controlled trial ( $n = 154$ ) found that an echinacea/sage preparation is as efficacious and well tolerated as a chlorhexidine/lignocaine spray in the treatment of acute sore throat (Schapowal et al 2009).

#### Wound healing

Several uncontrolled clinical studies support the topical use of echinacea to enhance wound healing. A trial involving 4598 people investigated the effects of a preparation consisting of the juice of the aerial parts of *E. purpurea* on various wounds, burns, skin infections and inflammatory skin conditions (Kinkel et al 1984). Topical application of echinacea produced an 85% overall success rate, and the key

constituent responsible for enhancing wound healing appears to be echinacoside (Speroni et al 2002).

Preclinical research with a mice model provides some support for its role. An alcoholic extract of *E. pallida* reversed stress-delayed wound healing in mice, but had no apparent wound-healing effect for the non-stressed mice when compared to controls (Zhai et al 2009b).

Commission E approves the external use of *E. purpurea* herb for poorly healing wounds and chronic ulcerations (Blumenthal et al 2000).

### Genital herpes (*Condyloma acuminata*)

Human papillomavirus is the most common cause of sexually transmitted disease. It is associated with immunosuppression and shows a marked tendency to recur.

A prospective, double-blind, placebo-controlled, crossover trial conducted over 1 year investigated the effects of an extract of the plant and root of *E. purpurea* (Echinaforce 800 mg twice daily) on the incidence and severity of genital herpes outbreaks in 50 patients (Vonau et al 2001). Treatment was taken for 6 months, then crossed over to the alternative treatment for an additional 6 months. The entry criteria specified a minimum of four recurrences during the previous 12 months or prior to suppressive aciclovir. The study found no statistically significant benefit compared with placebo after 6 months of therapy. It is important to note that, during the study, 15 people dropped out, thereby reducing the sample size, which was considered insufficient by the authors.

### IN COMBINATION

A preventive effect against recurrence was found in a more recent RCT for a herbal combination consisting of echinacea, uncaria, tabebuja, papaya, grapefruit and andrographis (*Andrographis paniculata*). In this study, 261 patients allocated to surgical excision were divided into two groups, with one receiving additional treatment with the herbal combination in a dose of three tablets per day for 1 month postoperatively or no additional treatment after surgery. Over a 6-month follow-up period, the group receiving the herbal combination experienced a significantly reduced incidence of recurrence of anal condylomata (7.2% [10/139] compared to 27.1% [33/122] in the control group which received no additional treatment:  $P < 0.0001$ ) (Mistrangelo et al 2010).

### Reducing chemotherapy side effects

Results from a small, open, prospective study of subjects with advanced gastric cancer suggest that intravenous administration of a polysaccharide fraction isolated from *E. purpurea* may be effective in reducing chemotherapy-induced leucopenia (Melchart et al 2002). Test subjects had advanced gastric cancer and were undergoing palliative chemotherapy with etoposide, leucovorin and 5-fluorouracil. The median number of leucocytes 14–16 days after chemotherapy was 3630/mcL

(range 1470–5770 mcL) in the patients receiving herbal treatment compared with 2370/mcL (870–3950 mcL) in the patients of the historical control group ( $P = 0.015$ ).

### Radiation-associated leucopenia

Equivocal evidence exists for the use of echinacea in radiation-induced leucopenia, according to a small number of randomised studies (Ulbricht & Basch 2005). The product tested was Esberitox, which contains ethanolic extracts of three herbs, including root of echinacea. A study investigated the radioprotective properties of *E. purpurea* tablets (two 275 mg echinacea tablets twice daily) in a group of radiation workers who were identified as carrying dicentric chromosomes in their lymphocytes. After the 2-week treatment, lymphocyte chromosome aberration frequency dropped significantly, and the number of apoptotic cells increased, indicating that echinacea treatment may be beneficial for the prevention of adverse health effects in workers exposed to ionising radiation (Joksić et al 2009).

### Halitosis

A study with healthy volunteers suggests that a palatal adhesive tablet containing echinacea may serve as an effective means of treatment for patients complaining of oral malodour, because it resulted in a significant reduction in both oral malodour scores and volatile sulfide compound levels. The reduction in volatile sulfide compound levels was significantly higher than with zinc and chlorhexidine (Sterer et al 2008).

### Recurrent candidiasis

The herb is used to treat recurrent candidiasis, chiefly because of its antifungal and immunostimulant properties. Controlled studies are unavailable to determine effectiveness in this condition.

### OTHER USES

Echinacea has also been used to treat urinary tract infections, allergies, acne and abscesses, and as adjunctive therapy in cancer (Mills & Bone 2000). Based on the herb's antiviral activity against HSV-1 in vitro, it is also used in the treatment of herpes infections. In practice, it is prescribed with other herbs to treat common infections and to prevent infections generally.

A recent study reported on preliminary results suggesting that Polinacea could be used to improve the immune response to influenza vaccine (Di Piero et al 2012). The extract is made from the roots of *E. angustifolia* standardised to the complex polysaccharide IDN5405, the phenylethanoid echinacoside and substantial lack of alkamide. This follows a previous study showing that this preparation modulates bovine peripheral blood mononuclear cell proliferation (Wu et al 2009).

It may have potential as a topical cream for improving skin hydration and reducing wrinkles,

according to a small study with 10 healthy people aged 25–40 years; however it showed low storage stability (Yotsawimonwat et al 2010).

## DOSAGE RANGE

### General guide

- Dried herb: 3 g/day of either *E. angustifolia* or *E. purpurea*.
- Liquid extract (1:2): 3–6 mL/day of either *E. angustifolia* or *E. purpurea*.

This dose may be increased to 10–20 mL/day in acute conditions.

Treatment is usually started at the first sign of URTI and continued for 7–14 days.

### Specific guide

- *E. angustifolia* dried root: 1–3 g/day.
- *E. purpurea* dried root: 1.5–4.5 g/day.
- *E. purpurea* dried aerial parts: 2.5–6.0 g/day.
- *E. purpurea* expressed juice of fresh plant: 6–9 mL/day.

It appears that the cold-pressed juice and ethanolic extract of the aerial parts of *E. purpurea* and the hydroethanolic extracts from the roots of *E. angustifolia* are the most studied preparation for URTIs.

## Doses according to clinical trials

### URTI: Treatment

- 10.2 g of dried echinacea root during the first 24 hours and 5.1 g during each of the next 4 days. One tablet contained: 675 mg *E. purpurea* root and 600 mg *E. angustifolia* root standardised to 2.1 mg alkalimides (MediHerb brand, produced by Integria Healthcare).
- 4000 mg of extract/day taken as 0.9 mL five times a day, Echinaforce, produced by Bioforce, Switzerland (alcoholic extract of *E. purpurea*, 95% herb and 5% roots, 5 mg/100 g, standardised to contain 5 mg/100 g of dodecatetraenoic acid isobutylamide)

### Prevention

- 3825 mg dry root equivalent/day, taken as one tablet three times a day for 6 weeks. One tablet contained: 675 mg *E. purpurea* root and 600 mg *E. angustifolia* root standardised to 2.1 mg alkalimides (MediHerb brand, produced by Integria Healthcare).
- 2400 mg of extract/day taken as 0.9 mL three times a day for 1 month, Echinaforce, produced by Bioforce, Switzerland (alcoholic extract of *E. purpurea*, 95% herb and 5% roots, 5 mg/100 g, standardised to contain 5 mg/100 g of dodecatetraenoic acid isobutylamide).
- Two tablets per day, over 8 weeks; each 750-mg tablet contained 1200 mg of tincture mass of Echinaforce, which corresponded to 18.6 mg dry mass of *E. purpurea* (drug extract ratio of the 95% herb = 1:12; ratio of the 5% root = 1:11).

## Protection from radiation

- Two 275 mg *E. purpurea* tablets twice daily for 2 weeks (brand not specified).

## Genital herpes

- Echinaforce 800 mg twice daily for 1 year.

## ADVERSE REACTIONS

Echinacea is well tolerated. A recent analysis of systematic reviews noted only minor adverse effects for *Echinacea* spp. (Posadzki 2013). Short-term use of echinacea is associated with a good safety profile, with a slight risk of transient, reversible and self-limiting gastrointestinal symptoms and rashes (Huntley et al 2005). However, cases of allergic reactions have been reported, resulting in pruritus, urticaria, angio-oedema and anaphylaxis (Mullins 1998, Mullins & Heddle 2002), especially in people with known plant allergies (Tiralongo et al 2012). Hypereosinophilia has been reported, and various authors suggest that the allergic reaction observed is an IgE-mediated hypersensitivity reaction (Maskatia & Baker 2010, Mullins & Heddle 2002).

Overall, echinacea is safe for asthmatics and only in rare instances has been associated with allergic reactions or disease exacerbation (Huntley et al 2005).

It is unclear whether children are more prone to rashes with *E. purpurea* than adults. One study found that rash occurred in 7.1% of children using echinacea compared with 2.7% taking placebo (Taylor et al 2003), whereas a more recent study failed to identify allergic responses or adverse reactions in children with echinacea use (Saunders et al 2007).

There is no clear evidence from basic science or human studies to show that echinacea causes liver toxicity (Ulbricht & Basch 2005). Echinacea (8000 mg/day) taken over 28 days resulted in an increase in serum erythropoietin levels at days 7, 14 and 21, but did not significantly alter red blood cell, haemoglobin and haematocrit levels (Whitehead et al 2007). A single 350-mg dose of *E. purpurea* had no effect on electrocardiographic and blood pressure measurements (Shah et al 2007a).

One clinical study has reported that 1 g *E. purpurea* administered over 10 days altered the gastrointestinal microflora by significantly increasing total aerobic bacteria and bacteria belonging to the *Bacteroides* genus, but not significantly changing the number of enteric bacteria, enterococci, lactobacilli, bifidobacteria or total anaerobic bacteria (Hill et al 2006). Moreover, a review reported several ocular adverse effects due to *E. purpurea* (Santaella & Fraunfelder 2007). A recent review states that echinacea contributes to dry eye (Askeroglu et al 2013). One case report exists where it is believed that an ethanolic extract of *E. pallida*, taken 10–20 days before, may have induced or exacerbated severe thrombotic thrombocytopenic purpura in a healthy 32-year-old man (Liatsos et al 2006).

## SIGNIFICANT INTERACTIONS

### Cyclophosphamide

Echinacea appears to increase the immunostimulatory effect of low-dose cyclophosphamide, which may be detrimental in autoimmune disease where low doses are used (Stargrove et al 2008) — the clinical significance of this observation is unknown — avoid until safety can be assured.

### Immunosuppression agents (e.g. cyclosporine)

Theoretically, there may be an antagonistic pharmacodynamic interaction with immunosuppressive medication, but the clinical relevance is unclear. Exercise caution when using immunosuppressive agents and echinacea concurrently.

### Myelosuppressive chemotherapeutic agents

Use of echinacea between treatment cycles may theoretically improve white cell counts, reduce dose-limiting toxicities on myelopoiesis and improve patient's quality of life — potentially beneficial interaction under professional supervision.

### Etoposide

One recent case study of a 61-year-old man undergoing chemoradiation with cisplatin and etoposide reports on a probable interaction with echinacea resulting in profound thrombocytopenia requiring platelet transfusion. The authors postulated an interaction via the CYP3A4 enzyme, with echinacea being an inhibitor of CYP3A4 in vitro and etoposide being a substrate of CYP3A4 (Bossauer & Odle 2012). However clinical research casts doubt on this given that various echinacea extracts had no effect on CYP3A4 in human studies (see section on [cytochromes and P-glycoprotein](#), above).

### Duration of use

Based on evidence that parenterally administered echinacea reversibly depresses immune parameters, Commission E has recommended that echinacea should not be used for more than 8 weeks. However, in a study in which it was taken orally for up to 6 months, no changes in immune parameters were detected (Vonau et al 2001). As such, no conclusive evidence demonstrates that long-term use is detrimental.

### PREGNANCY USE

Oral use of echinacea has generally been considered safe in pregnancy when used in recommended doses (Mills & Bone 2005). This was substantiated by preliminary results from a prospective study of 206 women who had inadvertently taken echinacea during their pregnancy; the study found that gestational use was not associated with an increased risk for major malformations (Gallo et al 2000). Moreover, a review concluded that echinacea is non-teratogenic when used during pregnancy, but that caution should prevail when using echinacea during lactation until further high-quality human studies can determine its safety (Perri et al 2006).

Studies in animal models have reported that echinacea preparations derived from *E. purpurea* produce unwanted effects in pregnant animals, such as interference with embryonal angiogenesis (Barcz et al 2007), alteration of maternal haemopoiesis, fetal growth and a reduction in number of viable fetuses (Chow et al 2006). Due to the high rate of false positives obtained in such animal studies and problems with extrapolating data to humans from these models, the clinical significance of these findings remains unknown.

### CONTRAINDICATIONS AND PRECAUTIONS

Contraindicated in people with allergies to the Asteraceae (Compositae) family of plants (e.g. chamomile, ragweed).

Commission E warns against using echinacea in cases of autoimmune disorders, such as multiple sclerosis, systemic lupus erythematosus and rheumatoid arthritis, as well as tuberculosis or leucocytosis (Blumenthal et al 2000). A recent review identifies echinacea as one of the herbs with the largest number of documented contraindications, adding multiple sclerosis, tuberculosis and HIV infection to the above list. However, most references used in this review to support this claim were older than 2004 and were not critically evaluated (Tsai et al 2012). As highlighted by Lee and Werth (2004), most contraindications are based on theoretical considerations and case reports with a questionable causal relationship; however, this warning does not appear to be warranted. For example, Boullata and Nace (2000) recommended

the avoidance of echinacea use in patients with autoimmune disease, but this recommendation was only seen as the 'extrapolation from experimental observations of echinacea's effects on the immune system' by other authors (Logan & Ahmed 2003).

Moreover, no adverse effects were reported when echinacea was consumed by mice afflicted with autoimmune (type 1) diabetes for up to 18 weeks. Instead, a consistent, long-lasting immunostimulation of only NK cells was observed, thus warranting further research (Delorme & Miller 2005). In addition, recent human studies reported safe and effective systemic echinacea treatment of low-grade autoimmune idiopathic uveitis, resulting in longer steroid-free treatment periods for patients on echinacea treatment (Neri et al 2006).

In practice, echinacea has been successfully used by herbalists in autoimmune disease without mishap (Mills & Bone 2005).

**Practice points/Patient counselling**

- Different types of echinacea have demonstrated immunomodulating, anti-inflammatory, anti-fungal, antiviral and antioxidant activity.
- Overall, clinical studies support the use of echinacea in URTIs, such as bacterial sinusitis, common cold, influenza-like viral infections and streptococcal throat. Current evidence supports its use as acute treatment in URTIs, with some evidence supporting its use as prophylactic treatment.
- Several uncontrolled clinical studies support the topical use of echinacea to enhance wound healing.
- Echinacea is also used to treat urinary tract infections, allergies, acne and abscesses, as adjunctive therapy in cancer, herpesvirus infections and candidiasis.
- Although controversy still exists over which part of the plant and which particular plant has the strongest pharmacological activity, it appears that the cold-pressed juice and ethanolic extracts of the *E. purpurea* plant and *E. angustifolia* root are the most-studied preparations for URTIs.

**! PATIENTS' FAQs****What will this herb do for me?**

Echinacea stimulates immune function and also has antifungal (candida), antiviral (herpes) and anti-inflammatory activity. Human studies support its use as an acute treatment and preventive medicine for URTIs in adults. It may also be useful as an adjunct to reduce chemotherapy and radiation-associated side effects. Topically it seems to be useful for chronic wounds and sore throats.

**When will it start to work?**

As an acute treatment for URTI, echinacea should be started when the first signs and symptoms of infection appear.

**Are there any safety issues?**

Echinacea is well tolerated, although allergic reactions are possible in rare cases. Patients being treated for autoimmune diseases should be cautious due to echinacea's immune-stimulating effects. Interactions with some immunosuppressant medicines may occur.

## Elder

**HISTORICAL NOTE** The elder tree has enjoyed much popularity throughout the ages. Ancient Egyptians used elderflowers to heal burns and improve their complexion. Throughout England elder was termed ‘the medicine chest of the country people’, and Native Americans used elder for coughs, colds, infections and skin conditions. Elderflowers are a favorite ingredient in herb teas, cordials and some wines.

### COMMON NAME

Elder

### OTHER NAMES

Black elder, common elder

### BOTANICAL NAME/FAMILY

*Sambucus nigra*/Caprifoliaceae

### PLANT PART USED

Flower or ripe berry

### CHEMICAL COMPONENTS

#### Flowers

Flavonoids, primarily quercetin, isoquercetin, rutin and astragaline (Dawidowicz et al 2006, Wach et al 2007), as well as alpha-linolenic acid and linoleic acid and the predominant flavanone in grapefruit, naringenin, has been reported to be present in elderflowers (Christensen et al 2010). Elderflowers also contain essential oils.

#### Berries

Anthocyanins are abundant in the berries, including cyanidin 3-sambubioside-5-glucoside, cyanidin 3,5-diglucoside, cyanidin 3-sambubioside, cyanidin 3-glucoside and cyanidin 3-rutinoside. Cyanidin 3-sambubioside is the most abundant anthocyanin and accounts for more than 50% of all anthocyanins found in the berries (Veberic et al 2009, Murkovic et al 2000). The berries also contain flavonoids, including quercetin, quercetin 3-rutinoside and quercetin 3-glucoside, organic acids and sugars (Veberic et al 2009). The unripe berries contain cyanogenic glycosides (Dellagrega et al 2003).

### MAIN ACTIONS

There is more research evaluating the actions of elderberries than elderflowers; however, most research has been conducted in vitro or with animal models with relatively few human clinical trials available.

#### Antioxidant

Elderflowers contain flavonoids such as quercetin, isoquercetin and rutin which all possess potent antioxidant properties (Dawidowicz et al 2006). The berries also contain these flavonoids and additionally have appreciable amounts of anthocyanins, chiefly cyanidin 3-sambubioside and cyanidin 3-glucoside (Veberic et al 2009, Murkovic et al 2000).

The effects of dietary cyanidin-3-O-glucoside (2 g/kg) and a concentrate of elderberry (2 g/kg) on the plasma and tissue concentrations of tocopherol and cholesterol were investigated for a period of 4 weeks in vivo (Frank et al 2002). Cyanidin-3-O-glucoside increased the levels of vitamin E in the liver and lungs and appeared to have a sparing effect. Cholesterol levels were not affected, but both cyanidin-3-O-glucoside and elderberry reduced the amount of saturated fatty acid in the liver. Higher temperatures (100 degrees C) during aqueous extraction appear to yield a higher flavonoid content (Dawidowicz et al 2006).

#### Antiviral/Antimicrobial

In vitro studies have shown that a proprietary product known as Sambucol, whose chief ingredient is elderberry extract (1.9 g per 5 mL) is effective against ten strains of influenza virus (Zakay-Rones et al 1995). Other ingredients in the product include raspberry extract, sucrose, citric acid and honey.

Interestingly, recent research suggests that the in vitro anti-influenza activity of concentration elderberry juice is relatively weak, while the in vivo activity is relatively strong (Kinoshita et al 2012).

Research investigating the activity of several flavonoids from the elderberry extract (5,7,3', 4'-tetra-O-methylquercetin and 5,7-dihydroxy-4-oxo-2-(3,4,5-trihydroxyphenyl)chroman-3-yl-3,4,5-trihydroxycyclohexanecarboxylate), as well as the synthetic analogue dihydromyricetin have demonstrated an ability to bind to H1N1 virions, thus blocking the ability of the viruses to infect host cells (Roschek et al 2009).

These combined findings warrant further investigation to determine whether the effects of oral elderberry extracts have a role as a treatment in pandemic influenza infections (Kong 2009).

'Rubini' (BerryPharma AG), a standardised elderberry extract, was investigated for its antimicrobial and antiviral activity in the treatment of respiratory tract infections (e.g. pneumonia). This standardised elderberry liquid extract displayed an inhibitory effect on the propagation of human pathogenic influenza viruses. It also showed antimicrobial activity against both Gram-positive bacteria of *Streptococcus pyogenes* group C and G, streptococci and the Gram-negative bacterium *Branhamella catarrhalis* in liquid cultures (Krawitz et al 2011).

### Immunostimulating

The standardised black elderberry product Sambucol has been shown to increase the production of certain inflammatory cytokines (IL-1 beta, TNF-alpha, IL-6, IL-8) in human monocytes (Barak et al 2001). It is proposed that this may be one of the mechanisms via which elderberry improves immune system activity. Another study confirmed these results and, in addition, showed that elderberry also increases the anti-inflammatory cytokine IL-10 (Barak et al 2002). An in vitro study using a lectin isolated from elderflower (*Sambucus nigra* agglutinin) found the extract increased the release of IL-4 from basophils (Haas et al 1999). In vivo evidence confirms that concentrated elderberry juice suppresses viral replication and stimulates the immune response (Kinoshita et al 2012).

### Chemo-preventative

Elderberry extract exhibited a dose-dependent inhibitory effect on the growth of human colorectal adenocarcinoma HT29 cells in vitro (Jing et al 2008).

### Anti-inflammatory

An extract of elderflower was found to reduce inflammatory mediators in monocytes, macrophages and neutrophils incubated with whole cells of the periodontal pathogens *Porphyromonas gingivalis* and *Actinobacillus actinomycetemcomitans* (Harokopakis et al 2006). The extract appeared to inhibit the activation of nuclear factor kappa B and phosphatidylinositol 3-kinase. Human trials are required to determine

whether the effect occurs clinically and the potential of elderflower extract as a treatment for reducing inflammation in periodontitis.

### Diuretic

Elderflower has traditionally been used as a diuretic agent. An in vivo study found that the extract possessed diuretic properties comparable to the reference product hydrochlorothiazide (Beaux et al 1999). The extract also increased sodium excretion. However, *Sambucus nigra* L. has no impact on urinary pH and therefore does not affect the solubility of stone-inducing ions (Walz & Chrubasik 2008).

### Antidiabetic

An aqueous extract of elderflowers has been shown to increase insulin secretion and enhance muscle glucose uptake (70%), glucose oxidation (50%) and glycogenesis (70%) in pancreatic beta cells in vitro (Gray et al 2000). Extracts of elderflowers have been found to activate human PPAR (peroxisome proliferator-activated receptor) gamma and to stimulate insulin-dependent glucose uptake, suggesting a potential role in the prevention and/or treatment of insulin resistance (Christensen et al 2010). The insulinotropic effects of elder were slightly stronger with a hot preparation. An aqueous extract of elder failed to increase glucose diffusion in another in vitro study (Gallagher et al 2003). The authors theorise that the anti-diabetic effects of elder may not be related to intestinal absorption.

Preliminary in vivo evidence suggests that the natural polyphenols extracted from elder berries may positively influence bone mineral density in diabetic rats (Badescu et al 2012).

### Cardioprotective

It has been proposed that *Sambucus nigra* polyphenols have cardioprotective effects that may be useful in practice. These cardioprotective effects are believed to be due to antioxidant, hypolipidaemic and hypocholesterolaemic properties of the polyphenols (Ciocoiu et al 2009). In vivo evidence suggests elderberry has the potential to improve endothelial function (Morosanu et al 2011). Polyphenols extracted from elderberries have been shown to lower oxidative stress in rats with hypertension, resulting in a biostatistically significant ( $P < 0.05$ ) blood pressure drop between the control group (who received no polyphenols) and the intervention group (Ciocoiu et al 2012).

Whether these in vivo observations have clinical relevance in humans remains uncertain, based on current clinical research. For example, a placebo-controlled RCT of 52 healthy postmenopausal women found treatment with 500 mg/day anthocyanins as cyanidin glycosides (from elderberry) taken for 12 weeks (2 capsules twice daily) did not significantly alter biomarkers of CVD risk (inflammatory biomarkers, platelet reactivity, lipids and glucose) (Curtis et al 2009). Similarly, another placebo-controlled

RCT of 34 healthy volunteers failed to find any evidence of lipid-lowering activity with oral capsules of freeze-dried elderberry juice (400 mg containing 10% anthocyanins) when taken three times daily for 2 weeks (Murkovic et al 2004).

### OTHER ACTIONS

Elderflower preparations are traditionally believed to have expectorant, decongestant and diaphoretic activity.

### CLINICAL USE

Most human research has been conducted exploring the use of elderberry preparations for treating infections. Some studies have investigated commercial elder preparations that also contain ingredients such as echinacea, vitamin C and zinc.

#### Influenza

Three clinical trials investigating elderberry oral mixture (Sambucol) or oral lozenges demonstrate that it reduces symptom severity more rapidly than placebo and may shorten the duration of infection.

In regards to clinical use, the elderberry extract Sambucol (contains 1.9 g of elderberry extract per 5 mL; other ingredients include raspberry extract, sucrose, citric acid and honey) was evaluated in a multi-centre, randomised, placebo-controlled clinical trial to investigate its efficacy in decreasing the severity and duration of influenza A and B infections (Zakay-Rones et al 2004). Sixty patients aged between 18 and 54 years were enrolled in the study when they had three or more symptoms of influenza (fever, malaise, nasal discharge, etc). Patients were given 15 mL four times daily with meals for 4 days. The first dose was given within 48 hours of the onset of symptoms. The global evaluation scores for the elderberry group using visual analogue scales showed a significant improvement after an average of 3.1 days ( $\pm 1.3$ ) as compared to 7.1 ( $\pm 2.5$ ) days for the placebo group ( $P < 0.001$ ).

The same extract was investigated in a placebo-controlled study of 27 children and adults during an outbreak of influenza B Panama (Zakay-Rones et al 1995). Children were given 2 tablespoons of mixture for 3 days, while adults received 4 tablespoons for the same duration. Patients were followed for 6 days and their symptoms were monitored. A significant improvement in symptoms was seen in 93.3% of people in the treatment group within 2 days whereas it was not until after 6 days that 91.7% of the patients in the placebo group were feeling better ( $P < 0.001$ ).

A randomized, double-blind clinical trial involving 64 participants (aged 16–60 years) evaluated the efficacy of a standardised, proprietary elderberry extract in reducing influenza symptoms ( $n = 32$ ) compared to placebo ( $n = 32$ ) (Kong 2009). The elderberry extract was administered in the form of slowly dissolving lozenges taken 4 times daily for 2 days. Both the proprietary elderberry extract and placebo lozenges were supplied by HerbalScience

Singapore Pte. Ltd. After 24 hours, the group receiving active treatment showed significant improvements in most of the symptoms, whereas the placebo group showed no such improvements. By 48 hours, 9 patients (28%) in the active treatment group were void of all symptoms, and 19 patients (60%) showed relief from some symptoms. In comparison, no patient in the placebo group achieved complete recovery, and only 5 patients (16%) showed improvement in one or two symptoms at the same time point.

#### Hyperlipidaemia—not effective

Negative results have been obtained to date showing no significant lipid-lowering activity in humans with the tested preparations.

One randomised, double-blind, placebo-controlled study investigated the effect of elderberry juice on serum cholesterol and triglyceride levels (Murkovic et al 2004). The study began with 34 healthy volunteers who took capsules containing either spray-dried elderberry juice (400 mg containing 10% anthocyanins) or placebo three times a day for two weeks. A subgroup of 14 participants continued for another week to further evaluate the resistance of LDL-cholesterol to copper-induced oxidation. In the next phase, six subjects took a single dose of elderberry juice 50 mL together with a fat-laden breakfast to test the short-term effects of elderberry on serum lipid levels.

Results from the main study found that a small but not statistically significant change was noted in cholesterol concentrations in the elderberry group (from 199 to 190 mg/dL) compared to the placebo group (from 192 to 196 mg/dL). Additionally, elder did not improve LDL-cholesterol oxidation and failed to significantly reduce postprandial triglyceride concentrations after a high-fat meal.

More recently, a randomised, placebo-controlled trial of 52 healthy postmenopausal women found treatment with 500 mg/day anthocyanins as cyanidin glycosides (from elderberry) was ineffective when taken for 12 weeks (2 capsules twice daily). Treatment did not alter biomarkers of CVD risk (inflammatory biomarkers, platelet reactivity, lipids and glucose) (Curtis et al 2009).

#### Chronic constipation—in combination

No studies were located that evaluated the effects of elder preparations on constipation however, one study did produce supportive evidence when it was used as part of a herbal combination treatment.

A phytotherapeutic combination containing *Sambucus nigra* L., *Pimpinella anisum* L., *Foeniculum vulgare* Miller, and *Cassia angustifolia* was assessed for efficacy in 20 subjects with chronic constipation. This randomised, crossover, placebo-controlled, single-blind study revealed that active herbal treatment produced a laxative effect and was a safe treatment option for the treatment of constipation (Picon et al 2010). The contribution of elder to producing this effect is unknown.

### Other uses

Elder preparations have also been used traditionally to treat colds, influenza, scarlet fever, bronchitis, sinusitis, hayfever, wounds and skin disorders. They have also been used as diaphoretic agents to increase sweating during temperatures or fevers. It is believed that the action is greatly improved by the use of a hot infusion. German Commission E approves the use of elderflowers as a diaphoretic and expectorant treatment (Blumenthal et al 1998).

## DOSAGE RANGE

### General guide

#### Flowers

- Tea: 10–15 g flowers/day.
- Liquid extract: 2–6 mL of 1:2 extract/day.

#### Berries

- Elderberry syrup: usually contains 30–38% elderberry; dose at 15 mL, 3 times daily (*Sambucus nigra* (elderberry) 2005).
- Powdered extracts: often available in 500 mg capsules, dose 2–3 times daily (*Sambucus nigra* (elderberry) 2005).

### According to clinical studies

#### Influenza

- 15 mL of the elderberry syrup (Sambucol) taken 4 times daily.
- 1 slow-release lozenge, four times daily, for 2 days. Each lozenge must contain 175 mg of elderberry extract.

## ADVERSE REACTIONS

Elderberries have been generally well tolerated in clinical trials (Zakay-Rones et al 1995, 2004). Although there are no clinical studies using elderflowers, it is generally thought that they are most likely to also be very safe. In large doses elder may produce nausea, diarrhoea and polyuria (Mills & Bone 2005).

## SIGNIFICANT INTERACTIONS

'Sambucus Force', a commercially manufactured capsulated formulation containing *E. purpurea* and *S. nigra*, has been shown in vitro to be a relatively weak inhibitor of CYP3A4 (Schroder-Aasen et al 2012). Whether this is clinically relevant remains to be tested.

### Diuretic drugs

Elderflower has diuretic activity. Increased diuresis is possible with concomitant use — observe (Beaux et al 1999).

### Hypoglycaemic drugs

Elderflower has demonstrated hypoglycaemic effects in vitro; the clinical significance of this observation remains unknown, and further research is required (Gray et al 2000, Gallagher et al 2003).

## ❓ CONTRAINDICATIONS AND PRECAUTIONS

A small number of people in the general population may experience allergy to elderflowers as shown by skin prick and RAST tests (Forster-Waldl et al 2003). Avoid in sensitive patients.

Never consume unripe or uncooked berries. They contain cyanogenic glycosides and can be dangerous.

## 👤 PREGNANCY USE

Elder is likely to be safe when consumed in dietary amounts; however, safety is not known when used in larger quantities.

## Practice points/Patient counselling

- Elder is a popular herbal medicine and both the fruit and the berry are used medicinally.
- Elderflower exhibits antiviral, anti-inflammatory, antioxidant, antibacterial, antiproliferative, diaphoretic, diuretic and anti-diabetic properties. The berry also possesses antioxidant and antiviral properties.
- Commission E approves the use of elderflowers as a diaphoretic and to increase bronchial secretion.
- Elderflower has been used traditionally to treat colds, influenza, scarlet fever, bronchitis, sinusitis, hay fever and skin disorders.
- Three clinical trials investigating elderberry oral mixture (Sambucol) or oral lozenges demonstrate that it reduces symptom severity more rapidly than placebo and may shorten the duration of infection.
- The unripe and uncooked berries should never be consumed as they contain cyanide.

## ❗ PATIENTS' FAQs

### What will this herb do for me?

Elderberry preparations appear to reduce the severity and duration of flu symptoms, according to clinical trials. They may also be useful in the treatment of colds, sinusitis and bronchitis; however, less research has been conducted to date to confirm this.

### When will it start to work?

Clinical trials of elderberry in influenza have shown that symptom relief may be experienced within 24–48 hours and that the duration of illness may be reduced by up to 3 days. Elder, when taken as a hot infusion, appears to work immediately as a diaphoretic.

### Are there any safety issues?

Elderflowers and berries (when cooked) appear to be very safe. No serious adverse events have been reported with the proprietary elderberry extract (Sambucol) in trials with adults and children suggesting it may be suitable for children and elderly

influenza patients, who can develop complications more readily (Kong 2009). The unripe and uncooked berries however should never be consumed as they contain cyanide.

# Eucalyptus

**HISTORICAL NOTE** Indigenous Australians traditionally used eucalyptus to treat wounds, fungal infections, fevers and respiratory infections, accounting for its name ‘fevertree’ (Chevallier 2001). European settlers also recognised the medicinal qualities of eucalyptus and surgeon Consider is credited with producing the first essential oil sample in 1788. Bosisto investigated oils from several Australian plants and in 1854 eventually produced essential oils, including Eucalyptus, commercially in association with Müller, a pharmacist. Bosisto and Müller concentrated on oils rich in 1,8-cineole, which includes *Eucalyptus* species. In the late 1800s, articles about its medicinal use appeared in medical journals such as *The Lancet*, focusing on its potential use in scarlet fever and diphtheria.

## COMMON NAME

Eucalyptus

## OTHER NAMES

The term ‘Eucalyptus’ encompasses a large genus of more than 900 species and subspecies of trees and

shrubs native to Australia, but many species are cultivated in other parts of the world.

### OTHER NAMES

*Aetheroleum Eucalypti*, cineole, *Oleum Eucalypti*, *Essence of eucalyptus rectifiae*

Common names include Australian fevertree leaf, blue gum, eucalyptol, fevertree, gum tree, red gum, stringy bark tree.

### BOTANICAL NAME/FAMILY

*Eucalyptus* species (family Myrtaceae)

The species most commonly used in healthcare are:

- *Eucalyptus globulus* (blue gum)
- *Eucalyptus citriodora* (lemon scented gum)
- *Eucalyptus dives* (broad leaf peppermint)
- *Eucalyptus polybractea*
- *Eucalyptus olida*
- *Eucalyptus staigeriana*
- *Eucalyptus sideroxylon*

### PLANT PARTS USED

The essential oil is primarily extracted by steam distillation from fresh twigs and leaves. Once the oil is extracted it is analysed to determine the chemical composition using gas chromatography and mass spectrograph analysis. Modern eucalyptus essential oils are primarily extracted from *E. polybractea*, *E. dives*, *E. leucoxylon*, *E. sideroxylon*, *E. citriodora* and *E. radiata* in Australia, but other species are used in other countries (Gilles et al 2010, Lassak & McCarthy 2001).

### CHEMICAL COMPONENTS

The major chemical constituents of many eucalyptus species are oxides and hydroterpenes, primarily 1,8-cineole, which is the most significant constituent and ranges from 54–95% depending on the species. The 1,8-cineole component is particularly high in *E. globulus* and *E. radiata*. However, the chemical make-up of essential oils extracted from the same species depends on the parts of the plant used; for example oil extracted from the fruit of *E. globulus* contains ~31% aromadendrene in addition to cineole and other constituents (Mulyaningsih et al 2011). The dominant constituents in *E. dives* are piperitone,  $\alpha$ -phellandrene, p-cymene and terpin-4-ol. *E. staigeriana* contains 1,8-cineole, neral, geranial,  $\alpha$ -phellandrene and methyl geranate. In contrast, *E. olida* contains one major constituent, (E)-methyl cinnamate, although over 20 constituents are present in the oil (Gilles et al 2010).

Eucalyptus oils also contain citronellal, camphene, fenchone, limonene,  $\alpha$ -phellandrene, geranial, methyl geranate, (E)-methyl cinnamate and pinene depending on the species (Clarke 2002, Gilles et al 2010, Mulyaningsih et al 2011).

The exact chemical composition of an essential oil depends on the particular species from which it is extracted and to some extent the extraction process and, as indicated, the part of the plant used;

most eucalyptus species contain over 20 chemical constituents. Small amounts of alpha-pinene (2.6%), alpha-cymene (2.7%), aromadendrene, ciminaldehyde, globulol and pinocarveol and *d*-limonene, alpha-phellandrene, camphene and alpha-terpinene are often present (Bisset 1994, Bruneton 1995, Serafino et al 2008).

Other essential oils high in 1,8-cineole include *Rosmarinus officinalis* ct. cineole, *Laurus nobilis*, *Cinnamomum camphora* ct. cineole and *Melaleuca cajuputi*.

### MAIN ACTIONS

The main reported actions are expectorant, antitussive (Misawa & Kizawa 1990), nasal decongestant (Burrows 1983, FDA 1994), analgesic (Gobel 1995), antimicrobial (Gilles et al 2010, Raho 2012), antioxidant (Shahwar et al 2012) and anti-inflammatory and antispasmodic properties have been reported in animal and human studies.

### Antitussive

Antitussive effects were compared with codeine in guinea pigs in which cough was mechanically stimulated. Essential oil 5% in normal saline was administered by inhalation and had a significant antitussive effect relative to codeine ( $P < 0.05$ ) (Misawa & Kizawa 1990). The antitussive effects of 1,8-cineole were demonstrated in humans in 1980 in a single-blind crossover study in healthy volunteers using a commercially available chest rub where eucalyptus was the active ingredient in the blend (Packman & London 1980). It appears that 1,8-cineole interacts with the M8 (TRPM8) receptor potential channel, the cool-sensitive thermoreceptor primarily affected by menthol, which produces a cooling sensation (Behrendt et al 2004). However, the antitussive effect may also be due to an effect on pulmonary C-fibres, which also contain TRPM8 receptors. Likewise, topically applied vapour rubs (containing camphor, menthol and eucalyptus oil) applied on two consecutive days might be effective in improving nocturnal cough, congestion and sleep in children with coughs due to upper respiratory tract infections (URTI) (Paul 2012).

### Nasal decongestant

Two clinical studies have demonstrated that inhalation of eucalyptus oil reduces nasal congestion (Burrows 1983, FDA 1994). Likewise, Cohen and Dressler (1982) showed statistically significant differences in patients with acute coryza inhaling a volatile mixture of menthol 56% and eucalyptus oil 9% for 20 minutes compared to a control group on 14 of the 22 indices of respiratory function, measured from baseline to 60 minutes after inhalation. In contrast, Burrows et al (1983) showed no decongestant effect of inhaling camphor, eucalyptus or menthol for 5-minute periods via a face mask ( $n = 31$ ), although cold receptors in the nose were stimulated, creating a sensation of increased airflow and improved comfort.

Oral doses or inhaling eucalyptus oil is an effective treatment for purulent and non-purulent respiratory infections such as bronchitis, asthma and chronic obstructive pulmonary airways disease (COPD), possibly due to eucalyptus' broad spectrum antimicrobial action (Sadlon & Lamson 2010).

### Antimicrobial

Previous studies indicate eucalyptus has antimicrobial activity in vitro against *Pseudomonas aeruginosa*, *Bacillus subtilis*, *Enterococcus faecalis* and *Escherichia coli* (Kurrerath & Mundulaldo 1954), herpes simplex (Schnitzler et al 2001) and oral pathogens (Takarada et al 2004). A clinical observational study involving 30 patients with head and neck cancer and necrotic malodorous ulcers demonstrated improved quality of life and social interaction with the addition of a twice-daily cleansing of the ulcers with an essential oil mix whose main component was eucalyptus (Warnke et al 2006). In addition, the researchers reported evidence of re-epithelialisation and anti-inflammatory effects. Raho and Benali (2012) showed antimicrobial activity of *E. globulus* oil obtained from the leaves against *Escherichia coli* (Gram negative) and *Staphylococcus aureus* (Gram positive) in an in vitro assay. Gilles et al (2010) reported on varying degrees of antimicrobial activity of oils from *E. staigeriana*, *E. dives* and *E. olida*: *E. staigeriana* had the highest activity in general. Gram-positive bacteria were more sensitive to the essential oils than Gram-negative organisms. *Staphylococcus aureus* was the most sensitive organism and *Pseudomonas aeruginosa* the most resistant organism. The authors stated the antimicrobial activity of the three essential oils, especially *E. staigeriana* and *E. dives*, 'compared favourably with that of the standard antibiotics tested', but did not describe the comparison process or list the 'standard antibiotics' in the method. From the results these appear to be chloramphenicol and nystatin. The clinical utility of these findings requires further study.

Ceremelli et al (2008) evaluated the antimicrobial activity of *E. globulus* against isolates of a range of bacteria such as *Streptococcus pyrogenes*, *S. pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae* and *Klebsiella pneumoniae* and two viruses, adenovirus and a mumps virus strain. *Haemophilus influenzae* and *S. pneumoniae* were the most susceptible bacteria and there was a mild inhibitory effect on the mumps virus. As indicated earlier, oil extracted from the fruit of *E. globulus* is effective against methicillin-resistant *Staphylococcus aureus* (Mulyaningsih et al 2011).

### Anti-inflammatory

Eucalyptus inhibits prostaglandin synthesis in vitro (Wagner 1986) at a concentration of 37 micromol/L. Anti-inflammatory and antinociceptive effects have been demonstrated in animal models (Ulbricht & Basch 2005). Alternatively, a study in which 1,8-cineole was injected into the rat hind-paw demonstrated that eucalyptus induced oedema, most likely

due to the release of mast cell mediators (Santos & Rao 1997). The clinical implications of this finding for topically-applied eucalyptus oil require further investigation. Anti-inflammatory activity of *E. radiata* has been demonstrated in patients with dry and weeping dermatitis, most probably due to inhibition of inflammatory markers such as TNF-alpha, COX enzymes, 5-lipoxygenase and other leukotrienes, and it could be an alternative to topical steroid medicines (Hadj-Minglou & Bolcato 2005, Santos & Rao 2000). Juergens et al (2003) demonstrated 1,8-cineole maintained lung function four times better than controls in a double blind clinical trial of patients ( $n = 32$ ) with severe steroid-dependent bronchial asthma. Patients were randomly assigned to 1,8-cineole 200 mg three times daily for 3 weeks or placebo. Steroid doses were reduced by 2.5 mg every 3 weeks. Twelve of the 16 receiving 1,8-cineole remained stable despite reduced steroid doses.

### Analgesic

Analgesic properties are attributed to the monoterpenoid components of eucalyptus oil. The monoterpenoid profile differs among eucalypt species and may account for variations in therapeutic effect. *E. globulus* has a high 1,8-cineole content (60–90%) (Juergens et al 1998, Shahwar et al 2012, Wei & Shibamoto 2010). Silva et al (2003) investigated the analgesic and anti-inflammatory effects of *E. tereticornis*, *E. citriodora* and *E. globulus* in rats. The results showed central and peripheral analgesic effects of the three oils. Santos and Rao (2000) also demonstrated 1,8-cineole had anti-inflammatory properties and reduced granuloma in rat studies.

### OTHER ACTIONS

Eucalyptus oil is metabolised in the liver; however, evidence is contradictory as to whether it induces the cytochrome P450 enzyme system. One study conducted with an animal model demonstrated a slight increase in CYP4A expression (Ngo et al 2003), whereas 1,8-cineole has demonstrated CYP450 induction in vitro and in animal studies (Ulbricht & Basch 2005). *E. globulus* induces a cell-mediated immune response, and morphological and functional activation in human macrophages stimulates the phagocytic response (Serafino et al 2008). Some eucalyptus species, such as *E. sideroxylon*, have antioxidant properties, but the clinical application is unknown. Some essential oils have chemopreventive properties, thus inducing enzymes to detoxify the carcinogen (Wei & Shibamoto 2010). In addition, they have chemotherapeutic properties by inhibiting tumour proliferation and enhancing tumour death. The inhibitory actions may be due to dietary isoprenoids, especially monoterpenes, in essential oils (Wei & Shibamoto 2010).

Umezu (2012) compared the effects of 20 essential oils, including eucalyptus, with conventional medicines that act on the central nervous system (CNS) to determine whether the essential oils had

stimulant, depressive or neither of these effects in mice. They found that essential oils from eucalyptus and rose reduced the avoidance rate (number of avoidance responses/number of avoidance trials) without affecting the response rate, which suggests that these essential oils may have some effect on the CNS.

## CLINICAL USE

Eucalyptus oil has been investigated in numerous forms; however, there is a lack of controlled, clinical studies.

It is mainly used in topical preparations or as an inhalant and not generally used internally.

### Respiratory conditions

As indicated in other sections, eucalyptus oil is used as symptomatic treatment in obstructive respiratory conditions such as bronchitis, asthma, the common cold and other conditions associated with catarrh of the upper respiratory tract. Although it is used internally and externally in Europe for these indications, in Australia the oil is generally used externally in vaporisers, chest rubs and nasal inhalations.

Nasal decongestant properties were assessed in 31 healthy volunteers using inhalations of 10 mL of essential oil for 5 minutes. There was no effect on nasal resistance to air flow, but there was a stimulant effect on the cold receptors in the nose and the majority of subjects reported being able to breathe more easily (FDA 1994). A single-blind, parallel clinical trial ( $n = 234$ ) was conducted to assess whether vaporised essential oil reduced nasal congestion compared with steam. The essential oil was significantly more effective ( $P < 0.02$ ), but only in the first hour after inhalation. Other researchers found no significant differences in nasal decongestion compared with placebo (Burrows 1983). There was no significant difference between placebo and topically applied *E. piperita* to the forehead and temples to treat headache in a randomised, double crossover trial ( $n = 32$ ); however, cognitive performance and muscle and mental relaxation were greater in the essential oil group (Gobel 1995).

Eucalyptus oil has mucolytic, bronchodilating and anti-inflammatory properties largely due to 1,8-cineole and is known to reduce exacerbations of COPD (Sadlon & Lamson 2010, Worth & Dethlesen 2012). A double-blind placebo trial involving 247 people with a confirmed diagnosis of asthma were randomly assigned to 200 mg cineole or placebo three times per day as concomitant therapy for 6 months (Worth & Dethlesen 2012). The cineole group showed statistically significant improvements in forced expiratory volume and asthma symptoms and quality of life using the Asthma Quality of Life Questionnaire.

### Aromatherapy

Eucalyptus, as it is traditionally used in aromatherapy, has not been systematically investigated under

clinical trial conditions. Therefore, most evidence is derived from traditional sources.

Aromatherapists use eucalyptus for its mentally uplifting and stimulating effects and to aid concentration. It is also used in massage and vaporisers to relieve respiratory symptoms, treat minor skin infections and acne and relieve headache and muscular aches and pain. Usually eucalyptus oil is included in a blend of 3–5 essential oils for a massage, but may be used alone for an inhalation. One study investigating the effects of topical application of eucalyptus oil to the forehead and temples found it was an ineffective treatment for headache (Gobel 1995).

### OTHER USES

Eucalyptus oil is often included in OTC and other medicines in various formulations such as rubs, mouthwashes, 'cold and 'flu' preparations, cleansing products, inhalers, soaps and insect repellents in which the 1,8-cineole content is standardised to 80–90%. Bosisto's Eucalyptus Oil is commonly sold in supermarkets and has an Aust R label (10908). It is not used in aromatherapy and is dispensed in a ribbed poison bottle with a childproof cap.

### Dust mite removal

Eucalyptus oil can be formulated with a kitchen detergent concentrate to form an inexpensive acaricidal wash that reduces the number of live mites found in blankets during normal machine washing (Tovey & McDonald 1997). When compared with detergent concentrate alone, a 30-minute pre-wash soak of woollen blankets with the eucalyptus oil/detergent formula reduced the number of live mites that could be recovered by 97%. This eliminates the need for very hot water and may maintain low allergen levels in bedding for longer than normal laundering alone because mites are adversely affected by low concentrations of eucalyptus oil vapour, which lingers for 2–3 days. In this study, the dish-washing liquid detergent concentrate (Kit, L&K, Rexona, Sydney, Australia) was used to form an emulsion in water because the essential oil is not soluble in water.

### Cleaning agent

Washing in diluted eucalyptus oil is also used as a method of removing stains from fabric; however, it does leave a faint characteristic odour for 2–3 days despite rinsing and drying, and some people may find this irritating.

### Malodorous necrotic ulcers

These ulcers are a major concern for cancer patients and can lead to social isolation and reduced QOL because current treatments inadequately reduce the foul smell to acceptable levels. A paper published in 2006 reported that rinsing the ulcers twice a day with an antibacterial essential oil mixture (mainly eucalyptus oil) resulted in complete disappearance of odour by day 3 or 4 in all patients ( $n = 30$ ) (Warnke et al 2006). The eucalyptus was used in

combination with a standard course of antibiotics. A number of beneficial secondary findings were anti-inflammatory activity, promotion of healing and complete re-epithelialisation and emotional relief on resolution of the condition.

### DOSE RANGE

Dose recommendations vary, but generally low doses are used. Internal formulations may take longer to show an effect than conventional medicines.

- Inhalation: 12 drops in 150 mL of boiling water or 5 drops in a nebuliser, which delivers approximately 35 mg (unpubl. data: Harris & Harris—Aromatic Medicine: The Interfaces of Absorption, seminar course notes, Melbourne, 2003). High doses are not recommended because they can irritate the eyes and mucous membranes and may trigger an asthma-like attack.
- Mouth wash: 20 mL (0.91 mg/mL) solution gargled twice daily.
- Massage: traditionally aromatherapists use essential oils as 3.5–5% in a carrier substance but doses between 5 and 20% are used for adults and much lower doses for children and older people.
- Ointments, creams, gels and poultices: 5–10% in a carrier substance such as beeswax.
- Internal use: 0.3–0.6 mL/day essential oil 1–4 times daily; capsules 100–200 mg; lozenges 0.2–15.0 mg dissolved slowly in the mouth every 30–60 minutes.

Most Australian aromatherapists do not currently administer essential oils via the internal route (oral, vaginal and rectal), but they are administered via these routes in other countries, especially France. The safety risk is great with internal use.

### TOXICITY

Toxicity is influenced by the purity of the essential oil, the administration mode and the knowledge and competence of the individuals using the oil. Toxicity symptoms occur rapidly, but may be delayed for hours and include altered consciousness state, drowsiness and unconsciousness, which are dose-dependent. Symptoms reported in other studies include epigastric burning, nausea, vomiting, dizziness, muscular weakness, delirium and convulsions, especially with oral ingestion.

The acute oral LD<sub>50</sub> dose of 1,8-cineole in rats is 2.48 g/kg and the dermal LD<sub>50</sub> dose in rabbits is > 5 g/kg.

Fatal poisoning has occurred in children after accidental ingestion of whole or diluted eucalyptus oil in amounts ranging from 2 to 10 mL. Tibballs (1995) reported 109 children who were admitted to hospital for eucalyptus oil poisoning in an 11-year period; 27 had been accidentally poisoned when an adult administered the oil orally by mistake and most of the remaining 82 children had ingested the oil from a vaporiser. Another review of 41 cases of eucalyptus oil poisoning (Webb & Pitt 1993) indicated that 80% were asymptomatic. There was no

### Practice points/Patient counselling

- It is essential to buy eucalyptus essential oils from reputable sources and to ensure the products have appropriate labels that contain enough information to use the oils safely. That is, the product should comply with safety and manufacturing and labelling requirements.
- Eucalyptus essential oils are steam-distilled from a number of *Eucalyptus* species, and have different chemical compositions depending on the species. Many contain a large proportion of 1,8-cineole, which appears to be responsible for the action on the respiratory system.
- Eucalyptus is primarily used in aromatherapy as an inhalation to relieve nasal congestion and in massage to relieve muscular aches and pain, as well as in ointments, gels and compresses, and via a vaporiser for mental stimulation and to aid concentration.
- Eucalyptus leaf extract is an approved food additive in Australia and is used in lozenges, lollies, teas, tinctures and conventional medicines.
- When used topically in an appropriate manner and appropriate doses, eucalyptus oil is considered to be safe; however, several cautions should be considered when determining the risk of adverse reactions and toxicity. People using eucalyptus essential oil should be monitored for allergies and the oil should not be applied to the face of children. Eucalyptus should not be used internally unless it is diluted and used in the recommended doses and dose intervals on the advice of appropriately qualified practitioners.
- Signs of poisoning usually occur rapidly and include confusion, irritability, respiratory distress, hypotension, nausea and vomiting. If poisoning is suspected medical care should be sought urgently. Do not induce vomiting. Use oral charcoal and monitor consciousness.
- Several medicine-essential oil interactions are theoretically possible; however, their clinical significance is unknown.

relationship between the amount of oil ingested and the presence and severity of symptoms. A recent case reports shows dermal application of eucalyptus oil can induce seizures. A healthy 4-year-old girl was treated with eucalyptus for head lice. Her symptoms included vomiting, ataxia, lethargy and tonic-clonic seizure, which resolved spontaneously when the skin was washed (Waldman 2011). Oral ingestion of eucalyptus is known to induce neurological symptoms and seizures. Waldman's case report suggests dermal application might also induce seizures in susceptible individuals.

Another case study demonstrated severe poisoning following a low oral dose of eucalyptus in a

58-year-old chemist suffering from acute delusions who drank 4–5 drops of undiluted eucalyptus oil. He developed complications, including compromised respiratory and cardiac function and hypertension, which resolved after treatment (Waldman et al 2011). This case history highlights the importance of storing essential oils and vaporisers out of reach of children and cognitively impaired adults.

The Victorian Poisons Information Centre (see Appendix 3) recommends that all people who ingest  $\geq 1$  mL of eucalyptus oil be assessed in an emergency department. The centre attributes the toxicity to the 1,8-cineole, terpene and  $\alpha$ -phellandrene content and indicates that, although hydrocyanic acid is only present in small amounts, it may be responsible for most of the toxicity.

### ADVERSE REACTIONS

Eucalyptus oil is generally safe when used externally in an appropriate manner.

A number of adverse reactions are reported for topical application, including systemic toxicity in a 6-year-old girl, and urticaria, contact dermatitis and skin irritation in other cases (Darben 1988). Likewise, there is a low risk of skin sensitivity to *E. staigeriana* because of the citral content in geranial acetate (Tisserand & Balacs 1995). However, when considering the risks of topical application of eucalyptus oil the state of the skin must be considered as well as the individual's susceptibility to atopic conditions such as eczema and asthma.

Allergic reactions to lozenges have also been reported anecdotally.

Inhalations may irritate the eyes and mucous membranes.

### SIGNIFICANT INTERACTIONS

Due to the lack of clinical evidence, interactions are theoretical and speculative.

#### CNS depressants

Oral ingestion of eucalyptus has been associated with CNS depression, therefore additive effects are theoretically possible — use with caution.

#### Medicines metabolised by CYP 450

Some evidence suggests CYP induction is possible; however, it is not known which CYP enzymes are affected, thus making recommendations difficult. Interactions are unlikely when used topically or inhaled, but could theoretically occur when used internally (Springhouse Corporation 2001).

#### Hypoglycaemic agents

If used in combination with oral glucose-lowering conventional or complementary medicines by people with diabetes, doses of eucalyptus might contribute to hypoglycaemia. Blood glucose levels should be monitored to detect hypoglycaemia (Springhouse Corporation 2001).

### CONTRAINDICATIONS AND PRECAUTIONS

Essential oils are not recommended in the first 3 months of life because the barrier function of the skin is not fully developed. In addition, inhaling menthol can induce transient apnoea in premature infants due to its effects on the TRPM8 receptor (Javorka et al 1980); thus, essential oils containing 1,8-cineole should not be applied on or near the face of babies and small children. *E. globulus* may cause skin allergy in susceptible individuals such as people prone to asthma and allergies, and those who had a previous reaction to eucalyptus. Skin testing might be indicated in these people.

Eucalyptus oil should not be administered internally to children or people with inflammatory gastrointestinal tract disease or impaired liver function, or during pregnancy.

Eucalyptus oil should not be applied to the face, especially of infants and young children because of the risk of bronchospasm and irritation.

The oil should be stored out of the reach of children and confused people. This precaution includes eucalyptus essential oil in vaporisers, which should also be placed out of reach. Poisoning has occurred following essential oil ingestion from vaporisers.

Oily carrier fluids should not be used for nasal sprays because they inhibit protective nasal ciliary movement and could cause lipid pneumonia.

The essential oil is highly flammable and represents a fire risk when used in candle vaporisers.

### PREGNANCY USE

No studies have been undertaken. The essential oil is not teratogenic in animal studies, but doses of 500 mg/kg cross the placenta in large enough amounts to stimulate hepatic activity in rodents (Jori & Briatico 1973). Aromatherapists do not recommend using eucalyptus essential oil during pregnancy, especially in the first trimester.

### PATIENTS' FAQs

#### What will this essential oil do for me?

Eucalyptus essential oil can be used in a vaporiser or on tissues to help clear the nose and make breathing easier if you have an upper respiratory tract infection (URTI). It can also increase mental alertness. In a massage blend eucalyptus can help relieve muscular and arthritic pain.

Eucalyptus oil can be added to the washing machine to help kill dust mites in human clothes and animal bedding. Dust mites are responsible for many respiratory conditions such as asthma.

**When will it start to work?**

Inhaled eucalyptus oil usually acts quickly and provides symptomatic relief quickly. Oral doses and massage blends usually take longer to have an effect.

**Are there any safety issues?**

Ingested eucalyptus oil has caused poisoning especially in children and therefore any source of the oil, including from vaporisers, should be placed out of reach of children and confused people.

Eucalyptus can irritate the eyes and mucous membranes. It should be kept away from the face, especially of infants and children.

Ingested eucalyptus oil could affect the action of some medicines such as antidepressants, sedatives and anaesthetic agents. It increases absorption of nicotine.

# Fenugreek

F

**HISTORICAL NOTE** Fenugreek's seeds and leaves are used as food, and as traditional medicine throughout the world. It is indigenous to Western Asia and Southern Europe and now mainly cultivated in India, Pakistan, France, Argentina and North African countries. In ancient Egypt it was used as an aphrodisiac and, together with honey, for the treatment of rickets, diabetes, dyspepsia, rheumatism, anaemia and constipation. It has also been described in early Greek and Latin pharmacopoeias for hyperglycaemia and was used by Yemenite Jews for type 2 diabetes (Yeh et al 2003). In India, China and the Middle East, it is still widely used as a therapeutic agent and as an ingredient in traditional Indian chutney and spice blends and in Egyptian confectionery (Basu & Srichamroen 2010). In the United States, it has been used therapeutically since the 19th century for postmenopausal vaginal dryness and dysmenorrhoea (Ulbricht & Basch 2005), and commercially is a principal flavouring ingredient of simulated maple syrup, flavouring agent of tobacco and of hydrolysed vegetable protein powder (Basu & Srichamroen 2010). It is a herb still used today as part of traditional herbal treatment for type 2 diabetes in Tunisia and Palestine (Ali-Shtayeh et al 2012, Othman et al 2013).

## COMMON NAME

Fenugreek

## OTHER NAMES

Trigonella seeds, bird's foot, Greek hay, hu lu ba, methi, trigonella

## BOTANICAL NAME/FAMILY

*Trigonella foenum-graecum* (family Leguminosae)

## PLANT PARTS USED

Dried mature seed. Leaves are used less commonly.

## CHEMICAL COMPONENTS

The main chemical constituents are fibre, tannic acid, fixed and volatile oils and a bitter extractive, steroidal saponins, flavonoids, polysaccharides, alkaloids, trigonelline, trigocoumarin, trigomethyl coumarin, mucilage (up to 30%), seven essential amino acids and vitamins A, C, D, B<sub>1</sub>, B<sub>2</sub> and B<sub>3</sub> (Bin-Hafeez et al 2003, Fisher & Painter 1996, Shang et al 1998, Zia et al 2001). Leaves contain 25% protein and 25.9% starch and are a rich source of calcium, iron and beta-carotene. The seeds contain 6–10% lipids (mostly unsaturated), 44–59% carbohydrates (mostly galactomannans) and 20–30% protein (rich in arginine, alanine and glycine and low in lysine and methionine) (Basu & Srichamroen 2010).

## MAIN ACTIONS

### Hypoglycaemic and antidiabetic

The hypoglycaemic effect of fenugreek seeds has been demonstrated in numerous studies involving experimentally-induced diabetes (both type 1 and type 2) in rats, dogs, mice and rabbits as well as diabetic humans (Aларcon-Aguilara et al 1998, Eidi et al 2007, Madar et al 1988, Mohammad et al 2006, Raju et al 2001, Ribes et al 1984, 1986, Riyad et al 1988, Sharma et al 1990, Vats et al

2002), and the effect has been described as slow but sustained (Puri et al 2002). Interestingly, however, no reduction in fasting or postprandial blood sugar levels was observed in a placebo-controlled study in non-diabetic people who used a dose of 5 g/day over 3 months (Bordia et al 1997).

It is recognised that there is a synergistic effect from a range of compounds, resulting in both glucose absorption inhibition and the promotion of pancreatic function to effect lower blood glucose and enhance other metabolic indicators (Basu & Srichamroen 2010). The mechanism for the hypoglycaemic effect of fenugreek has been explored in many in vivo trials. The viscous fibre, galactomannan, reduces intestinal absorption of glucose and thus postprandial blood glucose (Kaur et al 2011, Srichamroen et al 2009). Fenugreek also has an insulinomimetic effect and may increase the sensitivity of tissues to available insulin (Puri et al 2002), and enhance utilisation of glucose (Al Habori et al 2001). Extracts of fenugreek stimulated insulin secretion of INS-1 cells in vitro (Kaur et al 2011). Biguanides (metformin) are the widely used pharmaceutical treatment for type 2 diabetes. Significant levels of biguanide-related compounds were found in analyses of fenugreek seeds (Perla & Jayanty 2013). Another mouse study revealed that an extract of fenugreek opposed the development of diabetes in mice fed a high-fat diet and had an antidiabetic effect in mice with established diabetes (Hamza et al 2012).

### Antiulcerogenic activity

Both an aqueous extract and a gel fraction isolated from the seeds demonstrated significant ulcer-protective effects in vivo (Pandian et al 2002). The seed fractions given orally to test animals provided dose-dependent gastric protection against the effects of ethanol, which was as potent as that of omeprazole. Furthermore, histological studies found that the soluble gel fraction was significantly more

protective than omeprazole. Preliminary research suggests that the polysaccharide composition and/or flavonoid components of the mucilaginous gel are responsible for the gastroprotective and antisecretory activities of the seeds.

### Hypocholesterolaemic effect

Significant cholesterol-lowering activity has been demonstrated in numerous animal studies and human studies with diabetic volunteers (Belguith-Hadriche et al 2013, Boban et al 2008, Gupta et al 2001, Petit et al 1995, Rao et al 1996, Sharma et al 1990, Sowmya & Rajyalakshmi 1999, Stark & Madar 1993).

One mechanism of action, although unclear, appears to be the fibre and steroidal saponins interacting with bile salts in the digestive tract (Stark & Madar 1993). In one study, an unusual amino acid, 4-hydroxyisoleucine 5, was isolated and tested in dyslipidaemic hamsters and was found to significantly decrease plasma triglyceride levels by 33%, total cholesterol by 22% and free fatty acids by 14%, accompanied by an increase in high-density lipoprotein (HDL) cholesterol:total cholesterol ratio by 39% (Narender et al 2006). A thermostable extract of fenugreek seeds (TEFS) upregulated low-density lipoprotein receptors, resulting in enhanced low-density lipoprotein (LDL) uptake in vitro. Studies of fat-supplemented mice showed that TEFS decreased serum triglycerides, LDL and body weight in a time-dependent manner, indicating inhibition of fat accumulation and upregulation of LDL receptors (Vijayakumar et al 2010). Another in vivo study showed that ethyl acetate extracts of fenugreek seeds had significant hypocholesterolaemic and antioxidant effects in cholesterol-fed rats when other extracts did not. There was speculation that this was due to the flavonoid content of the extract (Belguith-Hadriche et al 2013).

### Immunostimulant activity

Enhanced humoral immunity, significant increases in macrophage activity and a stimulatory effect on lymphoproliferation have been demonstrated in vivo (Bin-Hafeez et al 2003). Stimulatory effects were observed at 100 mg/kg and in some cases at 250 mg/kg.

### Anti-inflammatory and antipyretic activity

Potent anti-inflammatory activity was demonstrated in an animal model for both single-dose and chronic-dose applications of a dried-leaf decoction of fenugreek (Ahmadiani et al 2001). The effectiveness of the 1000 mg/kg dose of the extract was relatively equal to 300 mg/kg sodium salicylate for single dosing; however, chronic administration was more effective than sodium salicylate. Additionally, the fenugreek decoction exhibited stronger antipyretic activity than that of sodium salicylate. These findings have been supported in an in vivo study of a water-soluble fraction of fenugreek seed that was shown to have significant analgesic and anti-inflammatory actions (Vyas et al 2008).

### Antinociceptive effects

Two studies in animal models have identified antinociceptive activity for fenugreek (Ahmadiani et al 2001, Javan et al 1997). This seems to be mediated through central and peripheral mechanisms. According to Javan et al (1997), the antinociceptive effects of 2000 mg/kg of the extract were more potent than those of 300 mg/kg sodium salicylate. One animal study concluded that the anti-inflammatory effects of fenugreek reduced pain in peripheral neuropathy (Morani et al 2012).

### Effect on thyroid hormones

Administration of fenugreek seed extract for 15 days to both mice and rats significantly decreased serum triiodothyronine ( $T_3$ ), suggesting that thyroxine ( $T_4$ )-to- $T_3$  conversion is inhibited and leads to increases in  $T_4$  levels (Panda et al 1999).

### Stimulates digestion

Traditionally, fenugreek is used to improve digestion. In vivo studies have identified that it enhances the activities of pancreatic and intestinal lipases, and sucrase and maltase, thereby providing support for this traditional use (Platel & Srinivasan 1996, 2000).

### Effect on neurotransmitters

A range of constituents extracted from fenugreek seeds exhibited potential anticholinesterase activity and therefore should be explored for potential benefits in the treatment of memory disorders (Satheesh Kumar et al 2010, Sharififar et al 2012). An amino acid constituent of fenugreek, 4-hydroxyisoleucine, exhibited antidepressant-like effects by enhancing brain serotonin turnover in preclinical studies (Gaur et al 2012).

### OTHER ACTIONS

Fenugreek has been studied for a wide range of actions. Positive findings for other properties of fenugreek have been found in vitro and in vivo, including antioxidant, antihypertensive, hepatoprotective, chemoprotective and renoprotective actions (Amin et al 2005, Annida & Stanely Mainz Prince 2005, Balaraman et al 2006, Bhatia et al 2006, Dixit et al 2005, 2008, Liu et al 2012, Shetty & Salimath 2009). The polyphenolic compounds of fenugreek seeds confer antioxidant and hepatoprotective properties comparable to silymarin in trials on rats (Kaviarasan & Anuradha 2007, Kaviarasan et al 2004, 2006, 2008). Analysis of fenugreek ethyl acetate extract showed it to be a good source of flavonoids and flavonoid glycosides, possibly responsible for the majority of its antioxidant properties (Kenny et al 2013). The fenugreek mucilage, in rat studies, demonstrated potential beneficial effect on induced arthritis in rats (Sindhu et al 2012).

Antineoplastic activity has been observed for fenugreek in the Ehrlich ascites carcinoma model in mice (Sur et al 2001). Protodioscin, purified from fenugreek, has also exhibited antineoplastic activity on human leukaemia cell lines in vitro (Hibasami et al 2003). Fenugreek extract induces apoptosis in

vitro to breast, pancreatic and prostate cancer cell lines, but not normal cells (Sebastian & Thampan 2007, Shabbeer et al 2009).

Ethanol extract (50%) seemed to possess profound antiplasmodial activity in vitro (Palaniswamy et al 2010), but no in vivo trials have yet been undertaken. Although fenugreek contains coumarin constituents, a placebo-controlled study found that it does not affect platelet aggregation, fibrinolytic activity or fibrinogen (Bordia et al 1997).

Traditionally, it is thought to promote lactation in nursing mothers and act as a general tonic; however there is conflicting scientific evidence to support its efficacy. The mechanism as a galactagogue is also unclear. Fenugreek is thought to exert oestrogenic activity through its phyto-oestrogen and diosgenin content (Mortel & Mehta 2013).

## CLINICAL USE

Fenugreek is both a food and medicine that has demonstrated significant pharmacological effects beyond its nutrient value. It is one of the more validated herbal medicines for blood glucose lowering and has multiple mechanisms of relevance to the diabetic patient.

### Dyspepsia and loss of appetite

Although controlled studies are unavailable, the increased activities of pancreatic and intestinal lipases seen in animal studies provide a theoretical basis for its use in dyspepsia.

Commission E approved the internal use of fenugreek seed for loss of appetite (Blumenthal et al 2000).

### Elevated lipid levels

Several clinical studies conducted in people with and without diabetes have identified significant lipid-lowering activity with different fenugreek preparations, such as defatted fenugreek, germinated seed and hydroalcoholic extracts (Bordia et al 1997, Gupta et al 2001, Sharma et al 1990, Sowmya & Rajyalakshmi 1999). As can be expected, the dose used and type of preparation tested have an influence on the results.

An open study using a daily dose of 18 g germinated fenugreek seed in healthy volunteers demonstrated significant reductions in total cholesterol and LDL cholesterol levels. A placebo-controlled study found no effect after 3 months with a lower dose of 5 g seed daily (Bordia et al 1997, Sowmya & Rajyalakshmi 1999), suggesting that higher intakes may be required for lipid-lowering activity to become significant.

### Diabetes

Fenugreek is a popular natural treatment used to aid blood sugar regulation in diabetes in numerous cultures, particularly Asia. A meta-analysis of various herbal medicines affecting HbA<sub>1c</sub> levels concluded that fenugreek supplements are effective in controlling glycaemic levels in people with type 2 diabetes (Suksomboon et al 2011).

This was further confirmed in a 2014 meta-analysis which reviewed results from 10 clinical trials ( $n = 278$ ). The meta-analysis concluded that ingestion of fenugreek seeds (1–100 g/day; median 25 g) for at least 1 week significantly changed fasting blood glucose by  $-0.96$  mmol/L (95% confidence interval [CI]  $-1.52$ ,  $-0.40$ ;  $I^2 = 80\%$ ; 10 trials), 2-h post-load glucose by  $-2.19$  mmol/L (95% CI  $-3.19$ ,  $-1.19$ ;  $I^2 = 71\%$ ; seven trials) and HbA<sub>1c</sub> by  $-0.85\%$  (95% CI  $-1.49\%$ ,  $-0.22\%$ ;  $I^2 = 0\%$ ; three trials) compared with control interventions (Neelakantan et al 2014). Significant effects on fasting and 2-h glucose levels were only found for studies that administered medium or high doses of fenugreek seed powder ( $\geq 5$  g) to people with diabetes and not in overweight people without established diabetes. The effect on fasting blood glucose appears to be dose-dependent, as no effects were seen for low doses ( $< 5$  g/day) and greater effects were seen with higher doses.

The mean age of study participants in the 10 clinical studies reviewed by Neelakantan et al (2014) ranged from 22.0 to 54.4 years (median: 43.1 years) and most trials included participants with type 2 diabetes treated with diet or oral antidiabetic medication. A variety of different fenugreek preparations have been studied, including powdered fenugreek seeds, debitterised powdered fenugreek seeds (25–50 g twice daily) or hydroalcoholic seed extract (1 g/day) either in the form of capsules or as an ingredient of unleavened bread. These were provided in equal doses 2–3 times daily.

The effect is quite quick, as demonstrated in a study of people with type 2 diabetes ( $n = 166$ ), which showed that 2-h post prandial plasma glucose levels were positively affected by fenugreek seed consumption (Bawadi et al 2009).

Fenugreek is also being incorporated into other foods as a means of improving glycaemic control. Bread baked with 5% fenugreek significantly reduced insulin levels in a pilot double-blind study of 8 diet-controlled diabetic subjects (Losso et al 2009).

Trigonelline, a major alkaloid component of fenugreek, is one of the key constituents responsible for the effects seen in diabetes and has been shown to affect beta-cell regeneration, insulin secretion, activities of various enzymes related to glucose metabolism, reactive oxygen species, axonal extension and neuron excitability (Zhou et al 2012).

### With sulfonylureas

The efficacy and safety of fenugreek in the treatment of patients with type 2 diabetes mellitus were investigated in 69 patients whose blood glucose levels were not well controlled by oral sulfonylureas (Lu et al 2008). This 12-week trial demonstrated that combined treatment of fenugreek with sulfonylureas improved glycaemic control, further reduced blood glucose levels and ameliorated clinical symptoms in the treatment of type 2 diabetes. Fenugreek treatment was also found to be safe.

### Lipid lowering in diabetes

Studies investigating the effects of fenugreek seed and seed powder have demonstrated significant lipid-lowering activity in this population. Oral doses of 25 g fenugreek seed powder taken twice daily significantly reduced serum total cholesterol, triacylglyceride and LDL cholesterol in hypercholesterolaemic type 2 diabetic patients. Results were recorded at 3 weeks and 6 weeks (Moosa et al 2006). A placebo-controlled study using a lower dose of 2.5 g unaltered fenugreek seed twice daily over 3 months found that this was ineffective in type 1 diabetes but did have a lipid-lowering effect in patients with diabetes and coronary artery disease (Bordia et al 1997). In this population, total cholesterol and triglyceride levels were significantly reduced.

Studies with defatted fenugreek seed (100 g/day) in patients with type 1 diabetes also identified significant reductions in total cholesterol, LDL and very-low-density lipoprotein cholesterol and triglyceride levels, but no changes to HDL cholesterol under randomised conditions (Sharma et al 1990).

Ethanollic extracts of fenugreek have also demonstrated good results. A 2001 double-blind, placebo-controlled study found that a dose of 1 g ethanollic extract of fenugreek was able to significantly decrease serum triglyceride levels and increase HDL cholesterol in mild to moderate type 2 diabetes mellitus (Gupta et al 2001). Previously, similar results were obtained with an ethanollic extract of defatted fenugreek seeds *in vivo*, which produced an 18–26% reduction in plasma cholesterol level (Stark & Madar 1993).

### IN COMBINATION

A combination powdered mixture of three traditional Indian medicinal plants — fenugreek seeds, bitter gourd and jamun seeds — in raw and cooked form produced benefits in a study of 60 non-insulin-dependent people with diabetes. Daily supplementation of 1 g of this mixture for a 1.5-month period and then a further increase to 2 g for another 1.5 months significantly reduced the fasting and postprandial glucose levels in this population. A significant decrease in oral hypoglycaemic drug requirements was observed and, for some subjects, cessation of drug therapy could be achieved after the 3-month feeding trial (Kochhar & Nagi 2005).

### Promoting lactation

Although fenugreek has been used traditionally for centuries as a galactagogue, to increase milk production and improve lactation, and is the most commonly used herbal galactagogue in published literature, there is only one valid clinical trial supporting its use. A double-blind randomised controlled trial involving 66 mother–infant pairs demonstrated that three cups of fenugreek herb tea per day were able to enhance breast milk production (measured on day 3 post-birth) and facilitate infant birth weight regain in the early postnatal days

in exclusively breast-fed infants compared to placebo (Turkyilmaz et al 2011). In contrast, another placebo-controlled study of mothers of premature newborns suggested that fenugreek had no effect on prolactin levels or on volume of breast milk (Rowe et al 2013).

While little scientific research has been conducted to truly explore the effects of fenugreek in lactation, contemporary lactation consultants in the United States and Europe, midwives, herbalists and the general public continue to use it to increase milk supply when milk supply is low, with few side effects for mother or baby. Fenugreek is often mixed with other herbs such as blessed thistle (*Carduus marianum*) and taken up to 3 g a day (Humphrey & Romm 2010).

Due to the safety of fenugreek, a trial is worthwhile considering before any pharmaceutical options are used (Forinash et al 2012).

### Externally — to reduce local inflammation

Although controlled studies are not available, evidence of anti-inflammatory and antinociceptive activity provides a theoretical basis for this indication.

Commission E approves the external use of fenugreek as a poultice for local inflammation (Blumenthal et al 2000).

### OTHER USES

In Ayurvedic and Unani systems of medicine, fenugreek is used to treat fever, epilepsy, paralysis, gout, dropsy, chronic cough and piles. In Morocco, fenugreek is used as a preventive treatment against the development of kidney stones. There are some tests in experimental models which provide support for this use (Laroubi et al 2007).

In Ayurveda the seeds are reported to have nutritive properties and to stimulate digestive processes, and have been used to treat a range of gastrointestinal disorders. It is also used as a general tonic, mixed with milk and sugar, to promote lactation and to lower lipid and glucose levels.

### Parkinson's disease

A double-blind study of 50 people with Parkinson's disease (diagnosis of over 6 months), showed that a fenugreek standardised extract (IBHB) reduced deterioration as measured by the Unified Parkinson's Disease Rating Scale. All participants were stabilised and taking L-dopa therapy together with IBHB 300 mg twice daily. IBHB had an excellent safety and tolerability profile and offers a novel use for fenugreek as integrative treatment with Parkinson's sufferers (Nathan et al 2013).

### DOSAGE RANGE

#### Internal use

According to clinical studies

- General dose range: liquid extract (1:2): 2–6 mL/day.

- Diabetes: 50–100 g seed daily taken in divided doses with meals, or >1 g/day ethanolic seed extract.
- Lipid-lowering activity: according to the above studies, 18.0 g germinated fenugreek or 100 g defatted seeds daily taken in divided doses with meals.

#### External use

- As a poultice: 50 g powdered seed in 0.5–1 L hot water applied topically to affected area.

#### TOXICITY

Safety studies indicate that fenugreek is extremely safe. When consumed as 20% of the diet, it did not produce toxic effects in animal tests.

#### ADVERSE REACTIONS

One clinical study found that a dose of 50 g taken twice daily produced mild gastrointestinal symptoms, such as diarrhoea and flatulence, which subsided after 3–4 days. Allergic reactions have been reported, more usually as a consequence of cross-reactivity in patients with peanut allergy. Primary fenugreek allergy is rare (Faeste et al 2009). The Norwegian Food Allergy Register identified two legumes, lupine and fenugreek, as ‘new’ allergens in processed foods. Mandatory labeling of lupine, but not fenugreek, has since been established (Namork et al 2011). A ‘maple-syrup’ odour can appear after fenugreek ingestion. Rats fed a diet of 30% fenugreek seeds exhibited antifertility effects to the point of toxicity (Kassem et al 2006). Doses of 500 and 1000 mg/kg/day aqueous extracts of fenugreek resulted in increase in fetal death rates, decreased litter sizes, reduction in fetal body weight and increased incidence of morphological abnormalities (Khalki et al 2010). Proportional doses in humans would be near-impossible to administer.

#### Practice points/Patient counselling

- Fenugreek seeds and leaves are used as a functional food and as an ingredient in traditional medicine systems.
- Clinical studies have identified significant hypoglycaemic and potential for lipid-lowering activity.
- In animal studies, fenugreek has been shown to exert immunostimulant, anti-inflammatory and antinociceptive activity, stimulate digestive enzyme production and provide significant antiulcerogenic effects.
- In practice, it is used to manage blood sugar levels in patients with diabetes, to lower cholesterol levels, to provide symptom relief in dyspepsia and to promote lactation.
- Externally it is made into a poultice with hot water and used as an anti-inflammatory application.

#### SIGNIFICANT INTERACTIONS

Where controlled studies are not available, interactions are speculative and based on evidence of pharmacological activity and case reports.

#### Hypoglycaemic agents

Additive effects are theoretically possible in diabetes and drug dose reductions may be required in some patients — monitor serum glucose levels closely — potentially beneficial interaction.

#### Iron

Frequent use of fenugreek can inhibit iron absorption — separate doses by 2 h.

#### Warfarin

A placebo-controlled study found that fenugreek does not affect platelet aggregation, fibrinolytic activity or fibrinogen (Bordia et al 1997) so it should be considered safe.

#### CONTRAINDICATIONS AND PRECAUTIONS

Fenugreek is contraindicated in people with allergy to the herb, which has been observed in several case reports (Patil et al 1997), or those with allergy to chickpeas, because of possible cross-reactivity (Ulbricht & Basch 2005). Monitor patients with thyrotoxicosis when using this herb at doses above usual dietary intake.

#### PREGNANCY USE

When taken in usual dietary amounts, fenugreek is likely to be safe; however, the safety of larger doses has not been scientifically evaluated.

#### PATIENTS' FAQs

##### What will this herb do for me?

Fenugreek lowers blood sugar levels in patients with diabetes, reduce cholesterol levels and stimulate digestion. It may also protect the gastrointestinal tract from ulcers, stimulate immune function and provide anti-inflammatory and antipyretic effects. Traditionally, it has also been used to promote lactation.

##### When will it start to work?

Studies suggest that blood sugar effects can be seen within 10 days in type 1 diabetes, whereas lipid-lowering effects can take up to 3 months to establish. Traditionally, digestive effects are thought to occur soon after ingestion of the seeds.

##### Are there any safety issues?

Used as a food, fenugreek appears extremely safe but may interact with blood-thinning medicines. When used in high doses as a medicine, it may cause flatulence, diarrhoea and mild stomach discomfort. Allergies to fenugreek are possible. When

used with diabetic medicine, it may increase sugar-lowering activity and safety should be monitored.

## Feverfew

**HISTORICAL NOTE** Feverfew has been used traditionally to treat migraine (Shrivastava et al 2006). Feverfew has been used for centuries as a febrifuge, with the common plant name being derived from the Latin term ‘febrifugia’ which means to ‘drive out fevers’ (Knight 1995). Feverfew has been used for centuries in Europe to treat headaches, arthritis, coughs and colds, atonic dyspepsia, worm infestation and menstrual disorders, and used as an emmenagogue and anthelmintic agent. In the 1970s it was ‘rediscovered’ by the medical establishment and subjected to clinical studies, which produced encouraging results that suggested feverfew was an effective prophylactic medicine for migraine headache. The ancient Greeks called it parthenolide because legend has it that it was used to save the life of a worker who had fallen from the Parthenon during its construction (Setty & Sigal 2005).

### Clinical note — Natural variations in parthenolide content

The amount of parthenolide present in commercial preparations of feverfew leaves varies significantly, with some exhibiting levels as high as 1.7% dry weight and others as low as 0.01% to non-detectable (Cutlan et al 2000). The study by Cutlan et al measured the parthenolide content in plants produced from seeds taken from over 30 different sources and germinated under identical

conditions. According to this study, feverfew collected from the wild and distributed by botanical gardens or US Department of Agriculture seed banks yielded plants with the highest mean parthenolide value, and plants with yellow leaves also had significantly higher parthenolide levels than those with green leaves.

**OTHER NAMES**

Altamisa, bachelor's button, camomilegrande, featherfew, featherfoil, chrysanthemum parthenium, mutterkraut, matrem, midsummer daisy, tanacetum parthenii herba/folium

**BOTANICAL NAME/FAMILY**

*Tanacetum parthenium* (family [Asteraceae]  
Compositae)

**PLANT PART USED**

Leaf

**CHEMICAL COMPONENTS**

The leaves and flowering tops contain many monoterpenes and sesquiterpenes as well as sesquiterpene lactones (chrysanthemolide, chrysanthemonin, 10-epi-canin, magnoliolide and parthenolide), reynosin, santamarin, tanaparhins and other compounds. Until recently, the sesquiterpene lactone parthenolide was thought to be the major biologically active constituent. However, in vitro and in vivo research suggests that others are also present (Brown et al 1997, Pugh & Sambo 1988). A study from the early 1990s (Heptinstall et al 1992) found that feverfew grown in the United Kingdom contained a high level of parthenolide in leaves, flowering tops and seeds but had lower levels in stalks and roots. The level of parthenolide in powdered-leaf material fell during storage. Melatonin has been detected in leaf samples of feverfew (1.37–2.45 mcg/g) and in a commercially available product (0.57 mcg/g) (Murch et al 1997).

**MAIN ACTIONS****Anti-inflammatory and analgesic**

Parthenolide has been shown to have multiple effects on target cells, ranging from phosphorylation to transcriptional inhibition activities (Mathema et al 2012). Several in vivo studies have identified anti-inflammatory and antinociceptive activity for feverfew extracts and parthenolide. When feverfew extracts were orally administered, or pure parthenolide was injected intraperitoneally, significant dose-dependent, anti-inflammatory and antinociceptive effects were observed in animal models (Jain & Kulkarni 1999). Similarly, when feverfew extracts and parthenolide from *Tanacetum vulgare* were administered orally in a rat model, gastric ulcer index was significantly reduced (Tournier et al 1999).

The mechanisms responsible for these effects are not well elucidated. Jain and Kulkarni (1999) demonstrated that the antinociceptive effect was not mediated through the opiate pathway and was not associated with sedation. With regard to the anti-inflammatory effect, several mechanisms appear to be responsible.

In vitro studies have found evidence of cyclooxygenase (COX) and lipooxygenase (LOX) inhibition (Capasso 1986, Pugh & Sambo 1988, Sumner

et al 1992), while other tests reveal no effect on COX (Collier et al 1980, Makheja & Bailey 1982). Preincubation of intact rat and human leucocytes for 10 minutes with crude chloroform extracts of fresh feverfew leaves caused a dose-dependent and potent inhibition of their capacity to generate COX and LOX pathways (Sumner et al 1992).

Inhibition of phospholipase A<sub>2</sub> has also been suggested (Heptinstall 1988, Sumner et al 1992). Direct binding and inhibition of I-kappa B kinase beta, an important subunit involved in cytokine-mediated signalling, has been demonstrated for parthenolide in in vitro studies (Kwok et al 2001). Parthenolide also inhibits nitric oxide production, an important regulator and inducer of various inflammatory states (Wong & Menendez 1999). More recently, results from an in vivo study confirm that parthenolide inhibits proinflammatory cytokine responses, although the authors propose that proinflammatory mediators, including chemokines (MIP-2), plasma enzyme mediators (complement, kinin and clotting systems) and lipid mediators (COX, prostaglandins, platelet-activating factor), are also likely to be involved (Smolinski & Pestka 2003). Parthenolide acts as inhibitor of inflammasomes. Inflammasomes engage and activate caspase-1, which in turn processes the inactive pro-IL-18 and pro-IL-1 $\beta$  into their corresponding active forms of proinflammatory cytokines, IL-18 and IL-1 $\beta$ , respectively (Mathema et al 2012). In an in vitro study, synovial fibroblasts were cultured with and without feverfew extract and subsequently stimulated with interleukin-1 (IL-1), interferon (IFN) and tumour necrosis factor (TNF) to induce expression of intercellular adhesion molecule-1 (ICAM-1). The most potent inhibition of ICAM-1 was seen in cultures stimulated with IL-1 and TNF (46–95% suppression) and less so in cultures stimulated with IFN-gamma (17–39% suppression). One of the major proinflammatory functions of ICAM-1 in vivo is as a cellular ligand for T cells. Feverfew inhibition of ICAM-1 was associated with a decrease in functional T-cell adhesion. Feverfew inhibition of IL-1-induced ICAM-1 was dose-dependent (Piela-Smith & Liu 2001).

Parthenolide suppresses inflammation by inhibiting activity of NF- $\kappa$ B (Mathema et al 2012). The majority of NF- $\kappa$ B activities are related to TNF-alpha and oxidative stress.

In vitro testing has identified that parthenolide-induced reduction in IL-6 secretion is dose-dependent: 29% by 200 nm ( $P < 0.001$ ); 45% by 1 mcm ( $P < 0.001$ ); 98% by 5 mcm ( $P < 0.001$ ). At the highest concentration tested, at 5 mcm, it reduced the secretion of TNF-alpha by 54% ( $P < 0.001$ ) (Magni et al 2012). These combined actions, inhibiting proinflammatory agents and reducing microglial activation, provide a theoretical rationale behind the proposed clinical effects of feverfew in reducing the frequency and severity of acute migraine attacks.

The essential oil constituent of feverfew, chrysanthenyl acetate, inhibits prostaglandin synthetase

in vitro and also seems to possess analgesic properties (Pugh & Sambo 1988).

### Antispasmodic

The results from several in vitro studies generally indicate that feverfew decreases vascular smooth-muscle spasm (Barsby et al 1992, 1993a, 1993b, Collier et al 1980).

### Inhibits serotonin release and binding

Parthenolide and several other sesquiterpene lactone constituents inhibit serotonin release but do not bind to 5-HT<sub>1</sub> receptors, according to in vivo data (Groenewegen & Heptinstall 1990, Marles et al 1992, Weber et al 1997a). Some tests with 5-HT<sub>2A</sub> receptors show that parthenolide is a low-affinity antagonist (Weber et al 1997b), whereas other tests found no effect on 5-HT<sub>2A</sub> or 5-HT<sub>2B</sub> receptors. Feverfew extract potently and directly blocked 5-HT<sub>2A</sub> and 5-HT<sub>2B</sub> receptors and neuronally released 5-HT, suggesting that feverfew powder or extracts are more effective than isolated parthenolide (Mittra et al 2000).

### Anticancer activity

In the last decade, there has been increasing investigation into the parthenolide constituent from feverfew as an anticancer agent. It displays multiple mechanisms, such as its selectivity to biological and/or epigenetic targets, tumours and cancer stem cells (Ghantous et al 2013), which make it an attractive candidate for further cancer research.

Parthenolide has been shown to withdraw cells from cell cycle or to promote cell differentiation, and finally to induce programmed cell death (Pajak et al 2008). It has an ability to induce apoptosis in a variety of cancer lines, has chemosensitising properties and is non-toxic to normal cells. The potent anticancer activity of parthenolide is in part due to its ability to inhibit transcription factor NF- $\kappa$ B, thereby reducing survival potential in a number of cancer cells (Anderson & Bejcek 2008, Pajak et al 2008, Zunino et al 2007). The effect is specific to tumour cells. Parthenolide-induced generation of reactive oxygen species (ROS) in cancer cells has also been shown to play a role in promoting apoptotic cell death. Interestingly, experiments in animal models indicate that, in non-cancerous cells, parthenolide acts as an antioxidant molecule by increasing levels of intracellular glutathione, resulting in a decrease in ROS. In contrast, an increase in ROS generation in response to parthenolide appears to increase apoptotic cell death in cancer cells. Recently, parthenolide was found to induce apoptosis in cancer cells, through mitochondrial dysfunction. Through this mechanism, it was shown to significantly inhibit tumour growth and angiogenesis in a xenograft model, exhibiting anticancer activity in human colorectal cancer in vitro and in vivo (Kim SL et al 2012). This proapoptotic action is suggested to occur through the activation of p53 and the increased production of ROS (Mathema et al 2012).

Signal transducer and activator of transcription (STAT) proteins are transcriptional factors responding to extracellular ligands that mediate diverse biological functions, such as cell proliferation, differentiation and apoptosis. Parthenolide shows strong NF- $\kappa$ B and STAT inhibition-mediated transcriptional suppression of proapoptotic genes. Parthenolide induced ROS exclusively in tumour cells. Parthenolide was found to have the unique ability to induce sensitisation to extrinsic as well as intrinsic apoptosis signalling in cancer cells. The proapoptotic activity is not observed in normal cells (Mathema et al 2012). A comparison of parthenolide treatment with that of the standard chemotherapy drug cytosine arabinoside (Ara-C) found it was much more specific to leukaemia cells (Guzman et al 2005), whereas Ara-C killed both leukaemia cells and normal cells to an equivalent extent; parthenolide showed significantly less toxicity to normal haematopoietic cells from bone marrow and cord blood.

Parthenolide is cytotoxic to several breast cancer cell lines, one human cervical cancer cell line (SiHa), prostate tumour-initiating cells isolated from prostate cancer cell lines, as well as primary prostate tumour-initiating cells, glioblastoma cells and pre-B acute lymphoblastic leukaemia lines (Anderson & Bejcek 2008, Kawasaki et al 2009, Wu et al 2006, Zunino et al 2007).

An in vitro and in vivo study of parthenolide in breast cancer found that parthenolide has significant in vivo chemosensitising properties in the metastatic breast cancer setting (Sweeney et al 2005). Parthenolide was effective either alone or in combination with docetaxel in reducing colony formation, inducing apoptosis and reducing the expression of prometastatic genes IL-8 and the antiapoptotic gene GADD45beta in vitro. In an adjuvant setting, animals treated with parthenolide and docetaxel combination showed significantly enhanced survival compared with untreated animals or animals treated with either drug. The enhanced survival in the combination arm was associated with reduced lung metastases. In addition, nuclear NF- $\kappa$ B levels were lower in residual tumours and lung metastasis of animals treated with parthenolide, docetaxel or both.

Studies are being conducted with a series of aminoparthenolide analogues, which have been synthesised by a conjugate addition of several primary and secondary amines to the alpha-methylene-gamma-butyrolactone function of the sesquiterpene lactone, parthenolide (Nasim & Crooks 2008).

Metastatic melanoma is a highly life-threatening disease. Parthenolide has been found to inhibit the proliferation of various cancer cells, mainly by inducing apoptosis (Lesiak et al 2010). In this in vitro study, parthenolide reduced the number of viable adherent cells in melanoma cultures. Half maximal inhibitory concentration values were around 4  $\mu$ mol/L. Cell death accompanied by mitochondrial membrane depolarisation and caspase-3 activation was observed as the result of

parthenolide application (Lesiak et al 2010). In breast cancer cell lines, parthenolide reduced the number of viable MCF-7 and MDA-MB-231 cells, with half maximal inhibitory concentration values between 6 and 9  $\mu\text{mol/L}$  (Wyřbska et al 2013).

In colorectal cancer cell line COLO205, parthenolide depletes intracellular thiols and increases ROS and cytosolic calcium levels, resulting in cellular stress, which consequently leads to cell apoptosis. Similar effects of parthenolide mediate mitochondrial damage and cell death in human gastric cancer cell line SGC7901, suggesting that parthenolide-induced ROS-mediated apoptosis may be common to many types of cancer cells (Mathema et al 2012).

Parthenolide has been found to selectively affect gene regulation or activity and consequently controls of target cells (Mathema et al 2012).

## OTHER ACTIONS

### Platelet aggregation inhibition

Evidence is contradictory as to whether feverfew inhibits platelet aggregation. Several *in vitro* studies and animal models have observed inhibition of platelet aggregation (Heptinstall et al 1988, Jain & Kulkarni 1999, Makheja & Bailey 1982). However, no significant effects were seen in a clinical study of 10 patients receiving feverfew (Biggs et al 1982). Feverfew was found to inhibit secretory activity in platelets. Release of serotonin from platelets induced by various aggregating agents (adenosine diphosphate, adrenaline, arachidonic acid, collagen and U46619) was inhibited. Platelet aggregation was consistently inhibited. It is interesting to note that parthenolide stimulated functional platelet production from human megakaryocyte cell lines as well as from primary mouse and human megakaryocytes *in vitro*. Parthenolide enhanced platelet production via inhibition of NF- $\kappa$ B signalling in megakaryocytes. Parthenolide significantly reduced the basal NF- $\kappa$ B activity at 6 h. This effect was found to be independent of the parthenolide-induced oxidative stress response. Additionally, parthenolide treatment of human peripheral blood platelets attenuated activation of stimulated platelets (Sahler et al 2011).

### Mast cell stabilisation

Tests with rat mast cells indicate that feverfew extract inhibits histamine release, but the mechanism of action is different from cromoglycate and quercetin (Hayes & Foreman 1987). *In vivo* tests confirm that parthenolide significantly inhibits IgE antigen-induced mast cell degranulation in a dose-dependent manner (Miyata et al 2008). The formation of microtubules is well known to be crucial for IgE antigen-induced degranulation in mast cells, and parthenolide exhibits tubulin/microtubule-interfering activity. The mast cell stabilisation effect is rapid *in vivo*, as an immediate-type allergic response was induced in test animals and strongly inhibited by parthenolide administration.

### Hepatoprotective effects

Parthenolide exhibits potent antifibrotic activity both *in vitro* and *in vivo*. The apoptotic and antifibrotic effects of parthenolide have been investigated for its apoptotic effects in test tube studies on hepatic stellate cells and for antifibrotic action on hepatic fibrosis in an *in vivo* rat model (Kim IH et al 2012). Parthenolide inhibited cell growth and induced apoptotic cell death in a dose-dependent manner in hepatic stellate cells. Parthenolide (at 2 and 4 mg/kg) significantly reduced hepatic fibrosis in thioacetamide-treated rats and decreased expression of transforming growth factor-beta-1.

### Bone regulation effects

Parthenolide shows potential in bone-destructive disorders associated with osteoclast-mediated bone resorption (Kim SL et al 2012).

Osteoclasts, which are bone-resorbing multinucleated giant cells differentiated from haematopoietic stem cells upon stimulation by two essential cytokines, receptor activator of NF- $\kappa$ B ligand (RANKL) and macrophage colony-stimulating factor (M-CSF), play a central role in bone-destructive disorders. RANKL promotes osteoclast formation from osteoclast precursors while M-CSF supports proliferation and survival of precursor cells during osteoclast differentiation. In a mouse model, parthenolide suppressed RANKL-mediated osteoclast differentiation in bone marrow macrophages. In addition, parthenolide inhibited mRNA expression of osteoclast-associated receptor, tartrate-resistant acid phosphatase, dendritic cell-specific transmembrane protein and cathepsin K by RANKL, suggesting that parthenolide inhibits the bone-resorbing activity of mature osteoclasts. Parthenolide inhibits differentiation and bone-resolving activity of osteoclast by RANKL.

## CLINICAL USE

### Migraine headache

Currently available research investigating the use of feverfew for migraine prophylaxis is promising, especially with the dried feverfew leaf formulations, whereas ethanolic extracts have produced inconsistent results.

Ideally, more research into the most effective formulation and dosage regimen is required to provide more consistent results. In particular, further work is needed to determine which other constituents, beside parthenolide, are important for producing the desired clinical effect, whether by pharmacodynamic or pharmacokinetic interaction with parthenolide or as stand-alone active constituents (Saranitzky et al 2009).

Traditionally, feverfew has been used in the treatment and prevention of headaches. Its growing popularity in the United Kingdom, in the 1970s and 1980s, prompted researchers to investigate its usefulness under controlled trial conditions. The first double-blind study investigating feverfew in

**Clinical note — Migraine**

Migraine is a common episodic familial headache disorder characterised by a combination of headache and neurological, gastrointestinal and autonomic symptoms. It has a 1-year prevalence of approximately 18% in women, 6% in men and 4% in children before puberty (Silberstein 2004). Several underlying mechanisms are considered responsible for the onset of migraine.

One of the genes linked to migraine is associated with dysfunction in P-type neuronal calcium channels, which mediate 5-HT and excitatory neurotransmitter release. This dysfunction can impair release of 5-HT and predispose patients to migraine attacks or impair their self-aborting mechanism (Silberstein 2004). Additionally, nitric oxide may be involved in the initiation and maintenance of migraine headache (Ferrari 1998). Migraine aura is now thought to be caused by neuronal dysfunction, not ischaemia, and headache begins while cortical blood flow is reduced.

In clinical practice, the three goals of migraine-preventive therapy are to reduce attack frequency, severity and duration, improve responsiveness to treatment of acute attacks, improve function and reduce disability. Ultimately, choice of treatment should be based on efficacy, adverse effects and coexisting conditions, with a full therapeutic trial taking 2–6 months.

migraine prophylaxis was published in 1985 and involved 17 patients who had been chewing fresh feverfew leaves on a daily basis (Johnson et al 1985). Therapeutic effect was maintained when capsules containing freeze-dried feverfew powder were continued, whereas those allocated placebo capsules experienced a significant increase in the frequency and severity of headache, nausea and vomiting during the early months of withdrawal.

Since then, numerous clinical studies have been conducted to determine the role of feverfew in the prevention of migraine headache.

In 2000, Ernst and Pittler published a systematic review of six randomised, placebo-controlled, double-blind trials of feverfew as a prophylactic treatment and concluded that the evidence favours feverfew as an effective preventive treatment against migraine headache, and is generally well tolerated. One of the studies in the systematic review noted a 24% reduction in the number of attacks during feverfew treatment but found no significant alteration in the duration of individual attacks. There was a non-significant tendency ( $P = 0.06$ ) towards milder headaches with feverfew and a significant reduction ( $P < 0.02$ ) in nausea and vomiting accompanying the attacks (Murphy et al 1988).

A Cochrane systematic review of five placebo-controlled, randomised, double-blind trials ( $n = 343$ ) concluded that there was insufficient evidence to

determine whether feverfew was superior to placebo in reducing migraine frequency or incidence, severity of nausea or severity of migraines (Pittler & Ernst 2004). A closer look at the studies reveals that results were mixed, methodological quality varied and various dosage regimens, administration forms and extracts were used. One study used three different dosing regimens for a CO<sub>2</sub> extract, two studies used an alcoholic and CO<sub>2</sub> extract, three studies used dried feverfew leaves for 8–24 weeks and one study used an alcoholic extract for 8 weeks. Interpretation of test results is made even more difficult when one considers the naturally occurring chemical variations among the preparations.

The authors have offered several explanations for the inconsistent clinical findings and point out that previous negative studies used extracts standardised for parthenolide concentration; however, it is possible that other compounds found in whole-leaf preparations may also be important for pharmacological activity. In vivo studies support this view (Mitra et al 2000). Others have also suggested that the alcoholic extracts may not contain the same amount of adjunctive compounds necessary for action or, conversely, the alcoholic extract may contain greater concentrations of compounds which reduce the action of parthenolide (Saranitzky et al 2009). It is also possible that the negative results obtained by some studies may be due to underdosing.

Since then, positive results were obtained for a CO<sub>2</sub> extract of feverfew (with enriched parthenolide) in a randomised, double-blind, placebo-controlled, multicentre study of 170 patients with frequent migraine headache (Diener et al 2005). Active treatment with feverfew (MIG-99) at a dose of 6.25 mg, three times daily, significantly reduced the frequency of migraine headache episodes, the number of migraine headache days and migraine duration over a 16-week period. More specifically, migraine frequency decreased from 4.8 to 2.9 attacks per month in the MIG-99 group and to 3.5 attacks for placebo ( $P = 0.046$ ). The prophylactic effect was most pronounced in the first 2 months and then appeared to stabilise. The treatment was very well tolerated. Participants included in this study needed to have experienced migraine headaches for at least 1 year, have an average of 4–6 migraine attacks in the month before commencing treatment and a duration of attack between 4 and 72 hours. All prophylactic migraine treatment was ceased at least 4 weeks prior to study commencement.

**IN COMBINATION**

A number of trials have tested feverfew in combination with other herbs and nutritional supplements. Shrivastava et al (2006) tested a combination of feverfew (600 mg/day) and willow bark (600 mg/day), known as Mig-RL, in a 12-week prospective study for the prophylaxis of migraine and the combination was shown to significantly reduce attack frequency and severity. The combination was selected because previous *in vitro*

studies identified that feverfew and willow bark inhibit binding to 5-HT<sub>2A/2C</sub> receptors and the combination of willow bark with feverfew further inhibited 5-HT<sub>1D</sub> receptors, whereas feverfew on its own did not. Combination herbal treatment significantly reduced migraine attack frequency by 57.2% at 6 weeks ( $P < 0.029$ ) and by 61.7% at 12 weeks ( $P < 0.025$ ) in nine of 10 patients, with 70% of patients having a reduction of at least 50%. Attack intensity was reduced by 38.7% at 6 weeks ( $P < 0.005$ ) and by 62.6% at 12 weeks ( $P < 0.004$ ) in all of the 10 patients, with 70% of patients having a reduction of at least 50%. Attack duration decreased by 67.2% at 6 weeks ( $P < 0.001$ ) and by 76.2% at 12 weeks ( $P < 0.001$ ) in all of the 10 patients. Two patients were excluded for reasons unrelated to treatment. Self-assessed general health, physical performance, memory and anxiety also improved by the end of the study. The treatment was well tolerated and no adverse events occurred (Shrivastava et al 2006).

The combination of feverfew with ginger (GelStat Migraine) in a sublingually administered fluid was evaluated as an acute treatment in an open-label study involving 29 patients with 1-year history of migraine meeting International Headache Society diagnostic criteria of 2–8 migraines per month and  $\leq 15$  headache days per month, with or without aura. People ingested the test substance during the early mild headache phase of an oncoming migraine. Herbal treatment was found to totally relieve pain in 48% of people within 2 hours and a further 34% reported pain had remained mild and not worsened. Of the group, 59% were satisfied with their response to GelStat Migraine therapy (Cady et al 2005). Of note, the product is marketed as a homeopathic product and contains extremely small amounts of both herbs.

In 2011, a randomised, multicentre study of 60 patients found that 2 hours after acute treatment with sublingual feverfew/ginger, 32% of subjects receiving active medication and 16% of subjects receiving placebo were pain-free ( $P = 0.02$ ). At 2 hours, 63% of subjects receiving feverfew/ginger found pain relief (pain-free or mild headache) vs 39% for placebo ( $P = 0.002$ ) and pain severity was significantly less with the feverfew/ginger combination (Cady et al 2011). All subjects in this study had  $< 15$  headache days per month and were not experiencing medication overuse headache.

Feverfew (100 mg) combined with riboflavin (400 mg) and magnesium (300 mg) was compared to stand-alone riboflavin (25 mg) treatment in a randomised, double-blind study of migraine sufferers (Maizels et al 2004). Both treatments showed a significant reduction in number of migraines, migraine days and migraine index in the 3-month trial, which was greater than responses for placebo in other trials of migraine prophylaxis. When treatment responses were compared, no significant differences were seen between the groups, indicating that feverfew at this low dose is ineffective.

Women patients ( $n = 22$ ) with headache who were treated with acupuncture for 10 weeks showed significant improvements in symptoms, migraine disability assessment score (MIDAS; quantifies headache-related disability over a 3-month period) and overall health-related quality of life (Ferro et al 2012). When feverfew

(150 mg/day taken at bedtime) was combined with acupuncture ( $n = 23$ ), the results were better than in patients who received acupuncture ( $n = 22$ ) or feverfew alone ( $n = 23$ ). There was a substantial mean reduction from baseline in the visual analogue scale (rated from 0 [pain-free] to 10 [unbearable pain]) outcome measure in both treatment groups. However, the combination of acupuncture and feverfew was statistically significantly more effective than acupuncture or feverfew alone in reducing the mean of score of pain on the visual analogue scale.

### Arthritic conditions

Although traditionally used as a treatment for inflammatory joint conditions, the results of a randomised, double-blind study involving 41 patients with symptoms of rheumatoid arthritis found no difference between chopped dried feverfew (70–86 mg) or placebo after 6 weeks' treatment (Patrick et al 1989).

## OTHER USES

### Dermatology

Feverfew may protect the skin from the numerous external aggressions encountered daily by the skin as well as reduce the damage to oxidatively challenged skin (Martin et al 2008). Parthenolide-free feverfew extract is being investigated in various dermatological conditions. It has been found to protect the skin against inflammation and ultraviolet (UV)-induced damage (Finkey et al 2005). When the parthenolide-free feverfew extract was topically applied, it significantly reduced loss of cell viability, increase in proinflammatory mediator release and induction of DNA damage induced by solar-simulated UV radiation in a human epidermal model. It also exhibited potent antioxidant activity in vitro and has been shown to dismutate superoxide, thereby protecting cells from the pro-oxidant depletion of endogenous skin antioxidants.

In the next phase of testing, a clinical study was conducted with an emollient containing the parthenolide-free feverfew extract, which confirmed that treatment significantly reduced the erythema effects of acute UVB exposure by up to 60% compared to placebo. Assessment was done by a blinded clinical grader and a chroma meter. These results suggest that topical application of parthenolide-depleted feverfew extract (PD-feverfew) can protect skin from UV-induced damage and from oxidative damage and help to repair damaged DNA.

In another study, PD-feverfew extract was found to possess free radical scavenging activity against a wide range of ROS and with greater activity than vitamin C (Martin et al 2008). In vitro, PD-feverfew attenuated the formation of UV-induced hydrogen peroxide and reduced proinflammatory cytokine release. It also restored cigarette smoke-mediated depletion of cellular thiols. In vivo, topical PD-feverfew reduced UV-induced epidermal hyperplasia, DNA damage and apoptosis. This

suggests that feverfew has the ability to scavenge free radicals, preserve endogenous antioxidant levels, reduce DNA damage and induce DNA repair enzymes, which can help repair damaged DNA.

### Oncology

Parthenolide has demonstrated potent antitumour activity in a variety of experimental models (in vitro and in vivo), and its mechanisms of action are becoming better elucidated. The positive results obtained in these preliminary studies indicate that it may have potential in the treatment of cancer; however, no clinical studies have been published to date to determine its efficacy in humans.

### DOSAGE RANGE

- Dried leaf: 50–200 mg daily.
- Fresh plant tincture (1:1): 0.7–2.0 mL/day.
- Dried plant tincture (1:5): 1–3 mL/day.
- Prevention of migraine headaches (based on clinical studies): 125–600 mg/day of powder, standardised to contain a minimum parthenolide content of 0.2%, or 400 mcg, which should be taken for at least 4 months. It is still controversial as to whether ethanolic standardised extracts are best for migraine prophylaxis or not.
- According to a large 2005 randomised controlled trial: a commercial CO<sub>2</sub> extract of *Tanacetum parthenium* (MIG-99) 6.25 mg taken three times daily

### TOXICITY

Unknown, although no major safety issues have been identified (Ernst & Pittler 2000).

### ADVERSE REACTIONS

According to a Cochrane systematic review of five studies (Pittler & Ernst 2004), feverfew is well tolerated and adverse events are generally mild and reversible. Symptoms were most frequently reported by long-term users and were predominantly mouth ulceration and gastrointestinal symptoms. Contact dermatitis, mouth soreness and lip swelling have also been reported when leaves are chewed. People allergic to the Asteraceae (Compositae) family of plant, or feverfew in particular, should avoid feverfew products that contain parthenolide, as it is this component which is thought to be the main inducer of the allergic response (Sharma & Sethuraman 2007).

### SIGNIFICANT INTERACTIONS

Controlled studies are not available; therefore, interactions are based on evidence of activity and are largely theoretical and speculative.

### Anticoagulants

Theoretically, feverfew may increase bruising and bleeding; however, although feverfew inhibits platelet aggregation in vitro and in vivo, no effects were seen in a clinical study (Biggs et al 1982) — observe patients taking this combination.

### ? CONTRAINDICATIONS AND PRECAUTIONS

Hypersensitivity to plants in the daisy (Asteraceae/Compositae) family (e.g. chamomile, ragweed).

### ! PREGNANCY USE

Feverfew is contraindicated in pregnancy. An in vitro and in vivo preliminary screen using a rat model suggested that feverfew consumption may have detrimental effects in pregnancy, a finding which needs to be more fully explored in larger studies (Yao et al 2006). Feverfew-treated animals had reduced litter sizes, a greater proportion of smaller fetuses than the control group and increased pre-implantation loss, indicating maternal and embryonic effects. However, it should be noted that the doses used were 59 times the accepted human dose, and therefore the clinical relevance of the findings are unclear. A full reproductive toxicity study is warranted to determine whether the observed effects are clinically significant.

### Practice points/Patient counselling

- Currently available research investigating the use of feverfew for migraine prophylaxis is promising, especially with the dried feverfew-leaf formulations, whereas ethanolic extracts have produced inconsistent results.
- A study with a commercial CO<sub>2</sub> extract of *Tanacetum parthenium* (MIG-99) showed it reduced the frequency, severity and duration of migraine headache in chronic sufferers.
- Tincture or solid-dose preparations may be better tolerated than chewing the fresh leaves, which have been associated with mouth ulcers and lip swelling in some individuals.
- Traditionally, feverfew has also been used to treat coughs and colds, fevers, atonic dyspepsia, worm infestation, menstrual disorders, nervous debility, joint pain and headaches.
- Parthenolide-free feverfew shows promise as a dermatological and UV-protective agent when used topically.
- Many preliminary studies with parthenolide confirm that it has potent antitumour activity; however, it has not yet been tested in humans.
- Use is contraindicated in pregnancy until safety can be better established.

### ! PATIENTS' FAQs

#### What will this herb do for me?

Evidence suggests that feverfew may reduce the frequency and severity of migraine headaches when dried-leaf preparations are used, whereas results with ethanolic extracts are inconsistent. Topical

application with parthenolide-free feverfew cream shows promise as a dermatological preparation to reduce redness after sun exposure and help heal damaged skin.

#### **When will it start to work?**

Of those studies producing positive results, it appears that benefits in migraine occur within 2 months of use; however, in practice, some patients experience benefits within the first 4 weeks.

#### **Are there any safety issues?**

Feverfew should not be used in pregnancy or by people with Asteraceae (Compositae) allergy.

## Fish oils

### BACKGROUND AND RELEVANT PHARMACOKINETICS

One of the two human essential fatty acids (EFAs) EFAs is alpha-linolenic acid (ALA or 18:3 $\omega$ -3), which, due to the position of its first double bond, is classified as an omega-3 ( $\omega$ -3) EFA. Although mammals have the ability to introduce double bonds into most positions of the fatty-acid chain in fat metabolism, therefore producing various unsaturated metabolites, they lack the capacity to insert double bonds at the  $\omega$ -3 and  $\omega$ -6 positions. Consequently, linoleic acid (LA) and ALA, which already have the double bond at the  $\omega$ -3 or  $\omega$ -6 position, respectively, are considered essential and must be consumed in the diet. When the EFAs are consumed in this precursor state they follow a pathway of further elongation and desaturation via the action of delta-6- and delta-5-desaturase until they form the 'active' fatty acids: eicosapentaenoic acid (20:5 $\omega$ -3) (EPA) and docosahexaenoic acid (DHA) (22:6 $\omega$ -3), also referred to as the  $\omega$ -3 long-chain polyunsaturated fats ( $\omega$ -3 LCPUFAs).

Fish oils, also known as marine oils, are rapidly absorbed from the gastrointestinal tract and compete with arachidonic acid (AA) for incorporation into phospholipids, particularly of platelets, erythrocytes, neutrophils, monocytes and liver cells (Simopoulos 1999). When stimulated, the cell membranes release polyunsaturated fatty acids (PUFAs), which are then converted into 20-carbon eicosanoids, which have profound and extensive physiological effects. The most active of these metabolites are prostaglandins, prostacyclins and thromboxanes, which affect blood chemistry, muscle contraction, immune function and inflammation. Dietary fats not used in this way are stored in adipose tissue and ultimately oxidised to produce energy. The fatty-acid cell membrane profile of different tissues will have varying ratios of EPA and DHA, but generally DHA is considered the major component of phospholipids in the retina, brain, male reproductive tissue and myocardium (Groff & Gropper 2004).

Supplements based on fish liver oils, such as cod and halibut, contain EPA and DHA together with high levels of vitamins A and D. As such, they have additional actions and safety issues besides those found with traditional marine lipid supplements. This review will focus on the research surrounding those fish oils that are not liver extractions.

### CHEMICAL COMPONENTS

Dietary fish contains a number of nutrients important for health, such as several B vitamins, vitamin E, calcium, magnesium and potassium, and are an excellent source of protein with a low saturated fat content. Importantly, they also contain the two PUFAs: EPA and DHA. EPA has 20 carbon atoms and five double bonds, and DHA has 22 carbon atoms and six double bonds. Both are derived from ALA and are considered conditionally essential. The EPA and DHA found in whole fish are predominantly esterified in the *sn*-2 position of triacylglycerols and glycerophospholipids; however, when found in supplements, most commonly exist as ethyl esters (Visioli et al 2003). This minor chemical distinction may explain the speculated superior bio-availability of these fats when derived from the diet as opposed to supplements.

### FOOD SOURCES

Most dietary EPA and DHA are consumed in the form of fish or seafood. Deep-sea cold-water fish, such as salmon, mackerel, halibut and herring, provide the most concentrated sources. Current Australian estimates of intake indicate inadequate consumption according to World Health Organization (WHO) standards (Meyer et al 2003).

### DEFICIENCY SIGNS AND SYMPTOMS

Based on epidemiological studies, low levels of  $\omega$ -3 LCPUFAs are associated with:

- fetal alcohol syndrome (DHA) (Horrocks & Yeo 1999)
- attention-deficit hyperactivity disorder (ADHD) (DHA) (Horrocks & Yeo 1999)

- learning deficits (DHA) (Horrocks & Yeo 1999)
- cystic fibrosis (DHA) (Horrocks & Yeo 1999)
- phenylketonuria (DHA) (Horrocks & Yeo 1999)
- cardiovascular disease (CVD), including an increased risk of sudden death due to heart disease (Siscovick et al 2003)
- inflammatory disorders
- rheumatoid arthritis (RA) (Navarro et al 2000)
- unipolar depression (DHA) (Horrocks & Yeo 1999)
- senile dementia.

In addition to these symptoms, lack of dietary EFAs has been implicated in the development or aggravation of numerous diseases such as breast cancer, prostate cancer, RA, asthma, pre-eclampsia, depression and schizophrenia (Yehuda et al 2005).

**Clinical note — Are ALA-rich oils a worthy substitute for fish oils?**

Both EPA and DHA are derived from ALA, so food sources containing ALA are seen as indirect dietary sources. ALA is commonly found in non-hydrogenated canola oil, linseed oil, soybean oil, flaxseed, pumpkin and walnuts. Studies investigating the effects of ALA supplementation have not consistently produced the same positive results as for fish oils, most likely due to inefficient conversion of ALA into EPA and DHA. This is reportedly poor in healthy individuals, with only 5–10% of ALA converted to EPA and 2–5% of ALA converted to DHA (Davis & Kris-Etherton 2003). Consequently, the few foods that contain both EPA and DHA in their preformed state offer a significant advantage over other sources. The most concentrated dietary source of both EPA and DHA is deepsea oily fish (See Flaxseed monograph for further information.)
